Mr. Prescott—I would say the higher the specific resistance and the lower the temperature coefficient the better adapted the wire is for use in rheostats. The wire can be handled, as it is not too brittle. All the wire that I have has come from the Coe Brass Company, who made it according to specifications.

Capt. Michaelis—I cannot contribute anything to the knowledge on the subject in the way of any investigation in respect to

Digitized by Google

the special matter under discussion. But I would like to call the attention of the Institute to something that has struck me in this discussion, namely, the interdependence of investigations on different lines; and I want to call the attention of the Institute, for the purpose of getting some information, to something that may have a bearing on this matter. You know the question of winding guns has been a very important one in the last ten or fifteen years, and the subject of the winding tension of wire has a very important part to play in the amount of pressure brought to bear upon the core. Now it appears to me that in winding these coils that point should be taken into consideration, for no matter how small a winding tension you have, when you consider the very small cross-section that your wire has, even if you have but an ounce or a pound or whatever your winding tension is—when you increase that directly with the area of the cross-section of your wire, you will find, when you come to square inches that you have a most enormous winding tension to deal with. Now in a wire wound gun, which is after all nothing but a large bobbin, we have to take into consideration the resulting pressure due to successive layers. Of course we generally put a tube in the gun, and the initial pressure on that tube is calculated; but that pressure increases, of course, constantly with the number of windings on it. In this investigation of the amount of pressure, of course we use the ordinary formula in regard to a cylinder subjected to a uniform fluid pressure where the pressure produced at any point, if I recollect right, is equal to the thrust divided by the radius. Now say you have wound the coil to a certain radius, your successive wires that are brought around it will exert, entirely as a result of the winding tension, a definite amount of pressure on the layers that you have already there. In other words, suppose you have wound your bobbin one-half, you can consider that half wound bobbin as a new core, and it will be subjected to a very high pressure, merely as a result of the winding tension of the wire, and I would like to ask some of the learned gentlemen who have given this matter consideration whether the effect of that winding tension in producing pressure, and of course consequently changing the mechanical condition of the wire, has been considered in these investigations.

The President—Prof. Anthony might give us some information on this.

Prof. Anthony—There has been a good deal said in regard to the difference in different batches of german silver, and in regard to difference in temperature co-efficient. We know that the temperature co-efficient would vary considerably in different batches. If the wires I was describing were made from different batches of german silver I should expect the results to be as I found them, in fact very much more variant than I found them. But if reliable makers manufacture standard instruments, such as this is, from different batches of german silver, it is a very reprehensible practice. I supposed that care would be taken to select wires which had been drawn from the same batch of metal. I do not believe that with all the care taken in the mixing of german silver that you could get two batches that would give the same result for the temperature co-efficient, and for that reason I should suppose that in making such an instrument as this that it would be necessary to take the german silver from the same batch, and not from two batches supposed to be exactly alike. The point I wanted to make was that as coarse wires and fine wires drawn out of the same batch may not have the same temperature co-efficient because difference in annealing and tempering would make a difference in the temperature co-efficient, and that must be guarded against, as well as difference in composition due to accidental variations of the wire, and possibly also in the annealing process, since a fine wire would have to be annealed several times over, while a coarse wire would not have to be annealed at all. In the process of annealing change of position might occur from partial oxidation of one of the metals to a greater extent than the other. So my suggestion was that it would be important in making fine instruments of this sort, not only to use german silver from the same batch, but to take the wire all of the same lot, of the same size, that had been drawn at the same time, and subjected to the same pressure throughout from the time the metal was melted until it was finally wound up in wire and covered and wound up on the coil, and then to use several of those wires in multiple arc for the low resistances.

Mr. Mailloux—I would submit that in the winding of fine wires the tension is usually made as slight as is consistent with the proper guidance of the wire in winding. I do not think that the tension would figure in small coils, though I think it might have some influence in large wires.

Mr. Hamilton—I might say in respect to what Capt. Michaelis says, that a report was published in the *Philosophical Magazine* three or four years ago, where the writer had taken quite a number of different wires and taken his resistances both before and after they were wound, and the differences were quite considerable. I have recognized, though, for a long time, this point of temperature co-efficient for the wire, and a number of years ago, in ordering wires for coils, I specified that the wires should be of the same quality all the way through, so I should be sure of the temperature co-efficient. I also think that the suggestion of Prof. Anthony that the wires should be drawn of the same size is a very good one and winding wires that are liable to have heavy currents in multiple arc.

Prof. Thomson—It occurs to me that this point might be touched—whether in winding a large wire there is not more mechanical energy expended and a hardening or change of the molecules of the large wire, since it is wound on the same diameter as the smaller wire in making the coil. We will assume that we have a wire of a certain diameter, and compare it with a wire of much smaller diameter. Now in going around a certain arc the metal on the half of the wire towards the center will be compressed while that on the exterior will be expanded, and the amount of compression and expansion, with a certain radius of winding, will be of course much greater in a coarse coil than in a coil of fine wire. This may have some influence perhaps on the point under discussion.

Mr. Mailloux—With regard to the remarks made by Mr. Hamilton about the resistance of wire before winding and after winding, I think that it is due precisely to the point mentioned by Prof. Thomson. I have myself noticed (although I have not the resources of a physical laboratory at my command) that a wire that has been wound and unwound several times has a difference in resistance, especially if it is in large lengths, and I thought at first that I was mistaken; but with very careful measurement I found that there was a slight difference between the two and I cannot find it to be due to any other cause except some molecular disturbance in the wire.

Prof. Thomson—Take a metal band and bend it on the edge, and then bend it on the flat, and it seems to me by that means we would arrive at the fact or not of there being a change of resistance produced by bending flat wise and on edge.

The President—The next paper which we shall take up will be that by Mr. Dugald C. Jackson, of Cornell University, on The Relation Between the Cross-Section of the Iron in Armature and Field of the Gramme Dynamo.

Mr. Jackson then read his paper. (See page 221.)

DISCUSSION.

The President—The paper is now before you for discussion. It seems to me that Mr. Jackson has thrown down two or three gauntlets that some of you would be in a position to pick up. Mr. Wheeler has done some very important work in this direction.

Mr. Wheeler—All I can say in discussing the subject, is that the paper deserves the most unlimited praise. I will admit frankly that I did not expect it would, but having heard it I cannot say too much in favor of it. I think the paper is nearly perfection. I shall have to study over some of the points. I have arrived at some of the conclusions which are expressed on that sheet of paper (curves, see page 222), not exactly by different processes of reasoning, but by different tests; for instance, using a prony brake pulled up tight to the pulley, and a scale to show the pull. The pull or torque in the dynamo is the equivalent of the electromotive force; in fact, in the early stages of dynamo work, some gentlemen whom I know made their electromotive force calculations entirely by the pull.

That second curve on the sheet of paper is extremely interesting and extremely valuable. I understand, without having had enough time to digest thoroughly the important points stated, that that curve represents the effect of making changes in the cross-section of the armature; that is to say, as you go to the right hand in the curve the short perpendicular line represents increases in the section of the armature core, compared with the field, and the distance up and down represents (to speak very practically) the benefit derived. The result of the work of my friends and of myself has been that we have pitched our machine at exactly the point where the crease is in that paper. There is no line drawn there, but it is exactly at that point—just above that large letter B; and after carefully studying the subject, and weighing the considerations, the effect of increasing and decreasing that would—or, if we should get a little away from that, would not—be as good. The curves above these are very valuable, and I have listened to the whole paper with a great deal of interest.

Prof. Thomson—The subject of dynamo designing is undoubtedly one of very great importance, and I have some few remarks to offer thereon, as I have designed a large number of dynamos of various types, and experimented with a considerably greater number.

I think that the first thing we should settle, in dealing with this subject, is the type—what is the machine to do. If you are to run arc lights your design must be entirely distinct and different from that which you use in running incandescent lights. The reason of that may not, at first, be so obvious; but if we consider the nature of an arc light we will see it. An electric arc may be running so steadily—I speak now, of course, of the long, quiet arc; what may be called the perfectly developed arc, not a hissing arc—(that is, a semi-incandescent light, and partakes somewhat of the nature of an incandescent load for the machine)—but a long, well-developed arc, with the crater fully exposed, burning quietly, possesses peculiar properties. If it is at a certain condition—10 amperes and 45 volts—and you

Digitized by Google

increase the current a little, you may convert that arc into a hissing arc abruptly, with a great fall in its resistance. Now what will be the effect, if you have a machine that is worked at its normal current, on the curve of that machine? You will find that the machine is not stable. The current will not stop at 10 amperes, if at this point the current of the field magnets is represented at 10 amperes in a series dynamo—the current will continue rising until a point is reached on the curve where the electromotive force of the machine either drops or does not increase by the addition of current in its field magnet, or exciting circuit. The consequence is that the successful arc lighting machines depart entirely from such terms as you find here. They go up to a certain point when the normal current is reached. There on the bend, and a little beyond it, the line dips, showing that an increased current drops the electromotive force, and that is the condition of stability in running arc lights. The arc may be burning quietly. That will represent the wide open arc. And this set of actions begins. You design your machine, we will say, with a large amount of iron in your armature and a large amount in your field; you save all the power you can; you make what may be called a very excellent type of an efficient machine, and then you put on a circuit of arc lamps. You have calculated the excitation, &c. You expect to work the arc lights steadily. You find, on closing the circuit, that the carbons go apart; a tremendous roar of current comes through, the arcs draw wide open, suddenly the machine ceases to develop current—down they come, and the same operation is repeated continuously. The reason of that is, that you have adjusted your arc lamps to run on 10 amperes, while your machine is not adjusted to furnish 10 amperes and be stable under those conditions. The current is not stable until the field magnets have reached a certain degree of saturation—unless your arc lamp mechanism is extremely sensitive. Even in those conditions—I speak, of course, of the series machines—while the current in the field continues to increase it causes a fall of resistance in the arc, a further increase of current, accompanied by a further increase of electromotive force of these currents and to such an extent, that quickly as the arc lamp mechanism can act it cannot get ahead of the increase of current. It is always behind time in drawing the arcs apart. It does not act instantaneously, while its effects on the current are always headed off. Finally there is a rupture of the whole circuit, down comes the carbon, and we start again. That is a phenomenon we have met with frequently, and it comes always with an increased amount of iron beyond a certain proportion in the machine. We call it oscillating, surging, or boiling up and dropping down—rough terms that we have used for the purpose of indicating the condition. It may be interesting to remark, in this connection, that we tried at one time compounding the machine and endeavoring to work it with a large amount of iron away below saturation, using a derived circuit winding to drop the curve at the proper point. Even in that case there was the same difficulty of surging or oscillation. Now when we come to the design and construction of dynamos for incandescent lighting, or for motive power purposes, or for the electric motor, then we have, of course, an entirely different state of conditions. Our resistance on the external circuit is not subject to this sudden drop of resistance, but it demands more and more electromotive force to increase the current through, and we have a dead resistance somewhat similar to this in use on a wire resistance. In that case you can work anywhere you please. On this line (indicating) you can work at about this point; and it may be that an explanation of some of the results Mr. Jackson has pointed out would be found in the fact that most dynamo builders prefer to work pretty low down on the curve. They do not like to buy their magnetism dearly. They would rather put in quantities of iron and diminish the copper in the field magnets, and get their magnetism at a rather low degree of saturation, and you will notice at this point that there is not a very great difference. Your differences begin to accumulate as you get up on the curve. But in motor work, we find by actual work that we get very good results in constructing motors by putting in a rather larger amount of iron than has been customary in the armature. We have made the permeability of the armature very much lower than the ordinary practice of dynamo design has called for, and it is a question whether the movement in the direction of increasing the mechanical conductivity of the armature iron is not even with dynamos a proper move. The limitation of increasing the iron sections will be found in that plan between two conditions working against us, and the condition of increased output as shown by these curves working for us; that is, if we use the armature iron in larger sections we may make it so that the changes of current increase the heat; that is, the Foucault currents may trouble us; and if we make it of larger section, also, we increase the length of wire which is to go around it—one turn of wire required to cover the increased section—and those influences may be said to be working against us; so that there will be a point somewhere on this curve at which we will find the maximum conditions. In motor work our design, of course, is to pass as much as possible of the magnetism we develop through the armature, and the armature itself assists us in doing that. There seems to be no reason why we should not use a comparatively large section of armature iron in a motor. We develop a field magnetism which we do not wish to have conducted out into the air, and therefore we give it the best path possible through the armature. The motor would seem to be made of the best design when we have given a very ample section in the armature for the passage of the lines of force.

Mr. Mailloux—I would like to ask Mr. Jackson whether his statement is that 75 per cent. sectional area is what he considers the best proportion. In my practice whenever I have used the Gramme ring, I have always used a sectional area at least equal to the sectional area of the limb. I did that, not because I apprehended that I needed such a large amount, but because I realized that only a portion of that sectional area can be utilized—employed usefully in conveying lines of force. Some years ago, I discussed that question through the press and called attention to what struck me then as a new way of looking at the subject, and it is this—that as the lines of force make the ring their path in passing from one pole to another, it is quite evident that the tendency of lines of force like other things in nature, is to take the path of least resistance, the shortest path, and consequently to crowd each other. Now, it is quite plain to my mind that there must be a condition of lines of force on the periphery of the ring on the outer surface different from what there is inside, and consequently this must mean an increased resistance of penetration. In other words, the co-efficient of permeability must become lower, no matter what the resistance of the iron is, at the point where the lines of force enter into the core, as well as where they emerge from it, so that we might have a core of very great section, and if the magnetic density, so to speak, is very great on the outer surface, then the resistance to further penetration will be so far reduced that only a portion of the sectional area will be useful in conveying lines of force. I was led to look at this from the fact that a great many builders of Gramme rings have departed from the old method of constructing the core by fine wire wound into a solid annulus, and instead have used laminated rings of more or less thickness and separated from each other at a certain distance. Now I have noticed that although they get much less weight of metal in a given area of section in an armature than would be the case if they used fine wire yet they seem to obtain very nearly as good results. And it has always been a question in my mind whether the use of laminated rings, leaving a space between, did not afford better opportunities for the lines of force to seek new paths—to enter by the side of each lamina—instead of being forced to enter at the periphery. I know that there is a great deal of diversity of opinion among physicists as to the possibility of a piece of iron being saturated at one part and not magnetized at another part. I remember at the electric conference the statement made by Prof. Silvanus Thompson was harshly criticised when he said the central part of a core might not be magnetized though the outside might be saturated. I do not know on which side of the fence to stand, but I am willing to be educated on that subject. I have been told by a maker of dynamos that taking cores of very large sectional area he could take out the central part of them without interfering at all with the nature of his characteristic curves. Those are significant points, and some information on them would be very acceptable.

The President—We have two minutes to the lunch hour. If that time is not to be occupied by discussion we will adjourn immediately, and I think as we have so much business before us it would be well to take but an hour. Adjournment till 2 o'clock

AFTERNOON SESSION.

The meeting was called to order at 2 P. M. by President Martin.

The secretary read the list of officers elected at the annual meeting.

The President—The first matter on the regular order of business is the paper that will be contributed by Prof. Elihu Thomson; but before we reach that, I understand that a very important report will be presented, and we will take that up first. Mr. Phelps, as chairman of the committee appointed last night to report at this meeting, will now present his report from the committee on permanent quarters.

Mr. G. M. Phelps, Jr., read the following report:—

REPORT OF THE COMMITTEE ON PERMANENT QUARTERS.

To the American Institute of Electrical Engineers.

GENTLEMEN:

Your committee appointed to consider and report upon a plan for securing permanent quarters and to estimate the cost of same, offer the following report:

It should be stated first that the subject before the committee has been discussed at considerable length during the past week by several officers and members of the Institute active in its work; and that the committee avail themselves of much of the suggestion thus brought out, as well as of information elicited by preliminary enquiries on the part of several members as to cost, ways and means.

As a result of enquiry, and consideration of the needs and

Digitized by Google

possible resources of the Institute, your committee recommend that immediate steps be taken towards securing permanent quarters; and it is their judgment that, in view of considerations presented below, the Institute will be justified in moving to purchase a house in this city, in an eligible location, and of sufficient capacity to provide all accommodations that will be required for many years. A dwelling house, in a respectable neighborhood, not remote from Union or Madison square, somewhat similar to that in which we now assemble, through the kind courtesy of the Society of Civil Engineers, could be easily adapted to our purposes.

The committee have made enquiries as to the cost of such a house, and have been assured that a dwelling house, 24 or 25 feet wide, and of three or four stories, can be purchased for $30,000 or less. Three such houses were found upon the list of a single prominent real estate firm.

How shall sufficient money be raised to purchase and maintain such a house?

The committee recommend that a fund of not less than $10,000, be raised by subscription. They have reason to believe that from $3,000 to $5,000 can be obtained from subscriptions of members of the Institute, and that the balance of the $10,000 proposed can, by proper effort, be secured by subscriptions on the part of gentlemen whose fortunes and business have been connected with the development of electric arts.

It is recommended that all subscriptions be made contingent upon the raising of the sum named, viz., $10,000.

With such a sum in hand, it is the opinion of the committee, that at the Institute would be justified in selecting and purchasing a house. The remainder of the purchase money could be raised on bond or bonds and mortgage, at a low rate of interest, probably not greater than four per cent.

In respect to the maintenance of a house, it is quite obvious that a large increase will be required in the present revenue of the Institute. This would, in the opinion of the committee, be partly supplied by the increase of membership that would follow the provision of permanent quarters, with increased facilities and privileges. A still larger increase could be provided by increasing the rate of annual dues for resident members, in return for which they would have privileges similar to those of a club.

The fixed charges may be approximately and safely estimated (excluding personal services, custodian, etc.):

Interest four per cent. on $20,000	$ 800
Taxes, insurance and repairs	1,200
	$2,000

Further charges would depend upon the nature of the accommodation and facilities provided. It seems safe to say that $1,000 could be made to cover such house expenses as would be required for the first year.

The committee by no means recommend limiting the amount proposed to be raised by subscription to $10,000, but consider that it will be within the bounds of prudence to purchase a house when that shall have been reached. They recommend that efforts to secure subscriptions be pressed diligently, and confidently believe that a very large portion, if not the whole, of the sum named ($30,000) can be obtained.

The committee deem the advantages of having permanent quarters of our own, so obvious as to require no enumeration on their part, and believe that a concerted effort on the part of the members of the Institute will surely lead to success.

They trust that such action will be initiated at this meeting as will result in the provision of a suitable house, properly fitted for the occupancy of the Institute, at the resumption of its monthly meetings next November.

To that end they advise the passage of a resolution authorizing and directing the council to proceed to obtain subscriptions, perfect plans, and report at a special meeting of the Institute, to be called not later than July 1st, next.

Signed,

GEORGE M. PHELPS, JR., *Chairman*,
T. COMMERFORD MARTIN,
GEORGE A. HAMILTON.

NEW YORK, May 18th, 1887.

Mr. Phelps—The thousand dollars mentioned in the report as probable cost of care of house, with the two thousand dollars fixed charges, represent an expenditure of three thousand dollars a year, and it is thought that as we shall begin modestly we may find it desirable, and it would probably be feasible, to derive some revenue from the house. For example, the basement story might be rented for some business purpose that would not be disagreeable in its nature—possibly for a restaurant of a good class, which would be rather an advantage; and it has also been suggested that the third story of such a building could be fitted up for dormitories, neatly and comfortably furnished, and that it would be used largely by out of town members and their friends at a reasonable charge. It is proper to say, further, that a considerable number of members have signified their willingness to subscribe within their ability, towards raising the proposed fund. In view of the interest that has been expressed at various times within the last three years since the formation of this Institute, and the very manifest advantages of having a place of our own where we can be independent and where we can have abundant accommodations, where we will have room for the starting of a laboratory and for a historical collection, and other similar purposes, and the additional standing and prestige that the society will have as soon as it has a habitation of its own, the committee very earnestly recommend the prompt and cordial support of the Institute, in making an earnest effort to carry the movement through.

Mr. Shelbourne—I move that the report be accepted.

The motion was seconded by Mr. Wheeler, and carried.

The President—Having adopted that report, gentlemen, the next thing in order is to have a resolution presented in the shape suggested by the report. I should be very glad to have that resolution put in formal shape immediately.

I understand the report to suggest that the work be entrusted to the council, and that the council summon to its aid all the mind, enthusiasm and weight in the profession to put this undertaking through.

Mr. Fowler—I would like to say that at a recent meeting of the Electric Club this same idea was broached of securing quarters, and I think it would be a good idea for our committee to confer with the members of the Electric Club and see if we could amalgamate in some way, so that instead of running two small sized establishments we could get together and make one large one. We have a good many members in common.

The President—I think that Mr. Fowler's remarks have our hearty sympathy. We move as a national body. This morning the matter was brought up of amalgamation with the New York Electrical Society, which has an electrical record and which desires, in some way, to affiliate with us. I think if we put ourselves on record to-day as willing to undertake this work we shall receive the immediate assistance of both bodies, and we shall have a home in New York of which all three bodies may be proud. The time has now arrived for us to bring the subject to action. I do not think that we can do better than to accept a resolution which I believe Mr. Phelps is now about to offer.

Mr. Wheeler—I think it would be well to get our house movement well under way before considering projects of associating other societies with us.

Mr. Phelps offered the following resolution:

Resolved: That in view of the report of the committee on permanent quarters, the council be directed to take up the subject and to proceed at once to solicit subscriptions, perfect plans, and to report at a special meeting of the Institute to be called not later than July 1st. He said:

The matter is presented in this form so that during the next six weeks, or thereabouts, the subject may be fully considered by the council; it can use its own methods and appoint a committee or otherwise. Final action ought very properly to be taken by the Institute as a body, and at any time not later than July 1st, we can no doubt secure sufficient attendance to take proper action.

Capt. Michaelis—In rising to second the motion, I would simply like to say that aside from the strong grounds already presented in favor of this project, it may be considered in another light, and that is from an ethnological standpoint. Man is a gregarious animal; there is no question about that, and I think that the further we advance in civilization and the older we get, we find there is a tendency to come together; in other words we are clubbable. In all the older countries you find that every man, whatever may be his profession or standing, belongs to some club. That is notably the case in England, and it has got to be so in our country. I am told that here in New York there is not a club in the city whose membership is not full to its constitutional limit, and in some cases hundreds of men are waiting for admission. That principle applies to us. We have got here something that induces us to seek companionship and to come together, and having a house of our own in a measure fulfils that innate desire that we have to become club men and meet. Professional men, and men who are not professional have their Saturday evenings and Wednesday nights to meet here and meet there. There is always this tendency to come together and chat and read papers and do some other things that are not at all disagreeable, and I think that we would find a ready response to anything of the kind, provided that the financial part can be arranged. I do not think that at this early stage of the movement, consolidation with any other body need enter the matter at all. I think Mr. Phelps's resolution meets the point. As I understand it, the idea is to give the council the authority of the Institute, to act in its name, and do what it may deem best to further the object before us. The effect of this resolution will be that the Institute as a body commits itself to the idea that there shall be permanent quarters acquired in whatever way may be deemed best, and I cordially second the resolution.

Mr. Mailloux commended the purpose of the resolution, and trusted its execution would foster and further develop the work of the Institute in its true line, the encouragement of scientific research and study in relation to practical electrical work.

While appreciating very much the social element, he would

Digitized by Google

dislike very much to see the scientific feature of the Institute, which is its foundation, suffer from the introduction of too great a dilution on the social side of it.

Mr. R. W. Pope—If we want a house I feel we can have it, and I think that before this meeting is over we will be sure of starting to get it, and if we make the same progress in three months that we have made in three days, we will have a house to move into next fall.

The President—The question has been called for; I think it is time now to present it. (The president read Mr. Phelps's resolution.)

Mr. R. W. Pope—I have one word to say, and that is, that the committee should go right ahead without waiting for the council.

The President—I shall immediately invite the co-operation of the members in the work.

Mr. Phelps—I was about to say, Mr. Chairman, that everybody concerned will immediately proceed with this work, and the council may come together whenever it chooses, to take any action that may be deemed necessary at any time. I do not think that the fact that the council does not meet regularly until a month from now need cause any delay.

The President—Those in favor of the resolution now before the meeting, will express their sentiments by saying aye.

The resolution was carried unanimously.

The President—That resolution is before you and I presume it means something. I have been surprised myself to find the unanimity and enthusiasm of the members on the subject. They all seem determined, every one to whom I have spoken and every one to whom the members of the council have spoken, to secure permanent quarters, and that being the case there would seem to be no reason for delaying to take energetic steps in that direction. We have the support of leading members of other societies of whose presence we are proud. We have here Mr. Pendleton of the New York Society. Shall this resolution fall to the ground to-day, or shall its purpose be carried out?

Mr. W. J. Johnston—Mr. President and Gentlemen: I think that we should go right on with that resolution now. We are all working together for the same object; we do it perhaps in different ways; one invents and another introduces apparatus, and another chronicles what they are doing. There is no question I think in the mind of anybody who understands the subject, that this Institute ought to have permanent quarters. It seems to me as if it would give it a standing that it has not now either in its own country or abroad. I think that it ought to mean something if you put the fact of your being a member of this institution to your name. I am very much pleased with these quarters of the civil engineers, I do not see why we should not have just as good. There is nothing that would give me more pleasure than to help along a thing of this kind, and I take great pleasure in heading the list with $500.

Mr. Frank L. Pope—Mr. Johnston talks business. I take great pleasure in adding to that, on behalf of the firm that I represent, the sum of $250 to start with.

Mr. Phelps—I took the liberty two days ago when several gentlemen were talking this matter over, and trying to be prepared to do something substantial to-day, of communicating with our very good friend and associate, Mr. J. Frank Morrison, of Baltimore, addressing him a letter stating that we were thinking of doing something of this kind, and that we would be glad to receive a telegram from him the following day, to let us know what we might put him down for. His telegram in reply reads "$200 to start with."

Mr. Wheeler—I have had but since 10 o'clock last night to see what I could do, but I will contribute $100 from our company. We will give more, but I have not had time to talk it over with my associates. I will give that amount, however, on my own responsibility.

Mr. Phelps—I can tender on the part of my father, $100, and on my own part $100.

The President—The president is not a moneyed man, but he has the interest of the Institute of Electrical Engineers at heart, and wishes to put his name down for $100, with liberty to increase

Mr. R. W. Pope, Secretary—The treasurer has been heard from. I intended to speak with the gentleman with whom I am associated, Mr. Hotchkiss, representing A. G. Day, who, as you all know, has been making insulated wire for twenty-five years, and I presume when the proper time comes he will do at least what I do, and I feel an intense interest in this as a kind of stimulus to the work of the secretary. The secretary has to do a good deal of work, and it is rather hard sledding when he is not supported, and in order to help the thing along I want to put myself abreast of the president and treasurer, at least, and you can put me down for $100.

Mr. Wetzler—Mr. President, I would like to contribute my mite of $100.

The President—It seems to me, gentlemen, that we are getting a pretty good expression of feeling on this subject. We evidently mean business. I might say that I have information from my good friend, Mr. Clarence Stump, that he wishes to be counted in to the extent of $100.

Mr. Phelps—That seems to make about $1,650 so far.

The President—In ten minutes.

Mr. Phelps—We said, I think, in our report, that we thought the association itself would raise somewhere from three to five thousand dollars, so we seem to have got half way to the minimum now.

The President—There are some members, perhaps, who may not feel at present that they can contribute to such an extent. It seems to me that we shall easily reach the limit that Mr. Phelps appears to have fixed.

Mr. Frank L. Pope—I think, Mr. President, that we may feel that the more money we raise in the society the greater amount we can get outside. People always are more willing to help those who show a disposition to help themselves. I think we shall have very little trouble in raising the rest of it.

Prof. Anthony—I have been waiting for the hundred dollar men to get through. College professors, perhaps, cannot be expected to go so far as men who are working commercially, but I will be glad to put in $50.

The President—I think that college professors are the poorest paid class of men in this country, considering what they do to promote our best interests, and I regard that as a noble contribution, and one which will be appreciated by the Institute to the full.

Capt Michaelis—I am an army officer, and cannot do quite as well as a college professor, but I received a note from eight little Michaelises and they each said they would give two dollars and a half towards this movement.

The President—The business of the afternoon is to take up first some very interesting phenomena, which will be brought to our notice by Prof. Elihu Thomson, on alternating currents. We all listen to the professor with the utmost interest and pleasure whenever he has an opportunity to address us.

Prof. Thomson then read a paper on "Novel Phenomena of Alternating Currents." (See page 211.)

DISCUSSION.

The President—I think we have reason to be proud of our distinguished member, and of the interest he takes in us when he presents so valuable a paper at our meeting. It is now open for discussion.

Mr. Mailloux—There is one very interesting feature brought out by Prof. Thomson. I think it is the phenomenon which he illustrated by means of his first figure, noting the repulsion and the attraction that takes place when the current is reversed in an ordinary electro-magnet. I could not help thinking, at the time, of some experiments made some years ago by Professors Elphinstone and Vincent, and about which I once took it into my head to write something. The effect was brought out by Messrs. Elphinstone and Vincent of the magnetic circuit that we now so well know and use in dynamo-electric machines. I was very much struck by the statement of Faraday in his experimental researches, where he speaks of lines of force expanding during the action of the beginning of the passage of current through a circuit, and of their collapse when the current is discontinued or decreased, and I remember making a note in this article (which you will find somewhere in the London *Electrician*, several years back) of experiments or observations made by me to show that that phenomenon was observable in an ordinary electro-magnet. I have been able, by means of a delicately suspended needle, or by a very thin piece of iron wire near to the pole, so that it might place itself in the lines of force and follow the oscillations of the lines of force, to trace a positive motion in the lines of force which would be exactly correspondent to that just referred to by Prof. Thomson; in a word, when the electro-magnet is in the process of magnetization, when the current is passing through it, there is an expansion of the lines of force starting apparently from the yoke, and the effect of the motion of these lines of force re-acting on the disc would be such exactly as would produce repulsion in accordance with Lenz's law. On the contrary, there is a collapsing process of the lines of force in the process of demagnetization, and the action would be again such as to produce attraction or the dragging of the disc with it. Now, with regard to the difference of repulsive and attractive effect, there is another fact which I think Prof. Thomson has not taken into consideration, and which, to some extent, increases the difference of repulsive effect. If we assume for a moment that the process of expansion and collapse of lines of force is true, and I have no reason to doubt that it is, then we will readily see that as our current is put on we are dealing with quantities—first, the resistance of the medium to the stress that is produced by the current; and second, the amount of energy, or the rate at which we supply energy, to overcome that elasticity. I might also add, of course, a third quantity, which is reaction, produced by self-induction of surrounding metal; but when the collapse takes place we have the pent up energy that has been stored by the process of contraction. I might explain this by taking a piece of rubber and stretching it. The rapidity with which it is stretched depends upon the rate at which energy is applied to it, and on the elasticity; but when I let go it falls back by virtue of its own

Digitized by Google

elasticity, and nothing else. In the case of the secondary coil, we can deal with this self-induction, but there are experiments which have been made, I think, by Prof. Von Beets, which show very clearly that the impulse of collapse is much more rapid than the impulse of rise. Consequently, there would be a difference of current in the inductive circuits, which would tend, if we follow them carefully by means of the curves produced by Prof. Thomson, to emphasize that difference of action in favor of the repulsive process.

I would like to hear the views of other gentlemen who are well informed on these subjects.

Mr. Prescott—Prof. Thomson has so clearly and beautifully described the experiments he has made that he has left hardly anything to be asked. I would say that I am particularly interested in the application to measuring instruments, and I would like to know whether in the application he has discovered, the repulsion is inversely proportional to the square of the distance of the plates, and if so whether he has preferred to make his instruments to measure that distance directly, or based on the distance directly, or whether he has preferred to counterweight or in some way counteract the movement so as to keep it always constant.

He has paid so much attention to this question of alternating currents that I should like to ask him also whether he has ever made any experiments to determine, for instance, whether a secondary battery in the circuit of an alternating current machine would cut off a portion of the electromotive-force in one direction which was counter and equal to that of the battery itself, in which case an ordinary current instrument would measure the current if connected around the poles of the battery.

Prof. Thomson—In regard to the measuring instruments, I have used the principle in several ways. The matter has not been carried sufficiently far as yet to determine all the points on the subject, but I have used gravity and a spring in both cases. However, I find there does not seem to be any regular law, perhaps any more than there is with an electro-magnet, for the decrease of the effect by distance, except when the distances become very large. The very fact of a change of position changes the relations of the currents themselves—the relations between the two currents,—so that we can hardly regard the problem as any different from the problem of an electro-magnet attracting its armature. When the armature is placed at a certain distance there is a certain distribution of magnetism; when it is taken to another distance the distribution is so changed that we could not consider that the centre of gravity, so to speak, of the magnetism is the same in the two cases, and the re-distribution will depend on the length, the diameter of the core and the size of the armature, so that the problem becomes a very complex one. But I have made a very curious application of the principle in this way: I have taken an ordinary fruit jar and put in it a disc of a certain thickness and attached to it a bulb of glass, and floated it in alcohol or water until the gravitational effect was so overcome by the flotation that it was almost indifferent, but it would just settle down to the bottom of the jar. I then put an alternating current coil below it and passed a current of gradually increasing amount. Gradually the disc would begin to lift itself and at a certain current would float to a certain height, standing in the liquid supported by the repulsion. There we have a very excellent illustration and a means probably of getting at the relative effects of repulsive effort under different conditions.

In regard to the point brought up by Mr. Mailloux concerning the more rapid drop in the current at the end of a wave, I think that he must have been considering the effect of interrupted currents only in that case—the ordinary induction coil—that is, you put a primary current on a primary coil, put on a battery current, and the counter electromotive-force keeps it down and it slightly rises to the current which it would have with the electromotive-force present acting through the resistance only of the primary wire. But when you cut off the current, the secondary current is much more vigorous in electromotive-force but does not last as long. In the primary coil, surrounded by its secondary, when we put on the current or close the circuit, there is an opposing electromotive-force; the battery does not get in its full current for some time and during that time the secondary currents will seek to evolve their energy; that is, they have duration without great force. But when we cut the battery current off and do it with a condenser, which enables us to remove the contact without sparking, or in other words, cheat the current a little and give it another passage for the time being, the secondary then gives out considerable energy.

I may mention an interesting experiment in this connection showing the effects of self-induction on magnets—a very curious experiment tried with a large magnet. It has nothing to do with the repulsive effect; it has to do with self-induction; and the curious effects produced by it in lagging or stopping waves and preventing waves from having their full value. We put a magnet into circuit with the dynamo, and we take a shunt of carbons points—a shunting switch made with carbons as they might be in an arc light. The current comes through this way (illustrating on the blackboard), when the shunting switch is open and goes out. We close the switch, and of course the current gradually leaves the magnet and gradually it flows in nearly full volume over the carbon points in accordance with their resistance. If their resistance is much less than the magnet all the current will flow over the carbon points. Now, the arc formed here instead of being a good, strong full arc, will simply be the tops of the waves of the current, while the steady current will flow through the magnet. That is, you will have a steady current in the magnet and the tops of the waves will be chopped off and sent through the carbon. There is no self-induction in this branch and the current there is steady. In fact the spark you get here and the arc you get here will very closely resemble the spark obtained from the Rhumkorff coil—a thin spark with a considerable aureola and not very hot. I have drawn them three-quarters of an inch long, playing and sputtering, showing that their waves are having their true value, whereas an ammeter put in shows a current pretty nearly the line current.

There was one other point on which information was asked for. It has slipped my mind.

Mr. Prescott—In regard to the secondary battery and the alternating current circuit?

Prof. Thomson—That is a question that I have not investigated at all, but there would be a current of double volume in one direction and a stoppage in the other direction, provided the volts of counter electromotive-force were right. There is a possibility of producing a current of this character by combination of an alternating current machine and a continuous current machine. We may have a current like that (illustrating) produced which would be somewhat the current that you were asking about. Whether applications of such currents will ever be made or not I do not know.

The President—We have with us Mr. Pendleton, President of the New York Electrical Society, who is very much interested in this subject, and we should be most happy to hear from him anything he may wish to say.

Mr. Pendleton—I came here this afternoon more particularly to take a back seat and listen; I am grateful for the hospitality with which you have received me and thank you for the invitation to speak on this subject. The subject under discussion, however, is not one to which I have given much thought, and it has been so thoroughly demonstrated that I feel that there is but little for me to say. In regard to the secondary battery application that Mr. Prescott just suggested, I should fancy the result would be the steady discharge by the battery of whatever charge it might have; but I should think it would be impossible to aggregate chemical energy in the battery under the circumstances. While I was listening to Prof. Thomson's interesting account of his experiments, it occurred to me that—if the actions are sufficiently delicate—it would be possible, in connection with the telephone, to make a recording instrument which might at any rate equal the success of the Edison phonograph. In this case it would be a reproduction of the waves of sound in the same manner.

Mr. Hering—I would like to ask Prof. Thomson how the magnetic attraction compares with the induction. If the closed copper disc were to be made of iron, there would be attraction; now, how does that attraction compare with the repulsion in case the disc is not magnetic. I ask that in order that we may get some idea of the strength of this repelling force.

Prof. Thomson—I have not made any determinations with that object in view, that is, to determine the relation between the two forces mentioned by Mr. Hering. The copper band, of course, uses energy of current flowing in it. If we have a current flowing in a coil attracting an iron core and the iron core is thoroughly divided so as to avoid currents in the iron itself, we would get electro-magnetic attraction pure and simple without necessary loss of energy; but in the case of the copper band there is undoubtedly, where large work is being done, a loss of energy due to the flow of heavy currents in the conductor; but in the case of a disc which is deflected, the disc saves itself that loss by throwing itself more or less at right angles. It is only when you are resisting the motion by a counter weight that the loss amounts to a great deal. Allow the thing to move and it relieves itself of the stress by leaving the point of greatest stress.

Mr. Powers—I had a very interesting experience in the line of Prof. Thomson's address, in respect to the lag of heavy currents, which I wish to bring to your notice, and to be somewhat

Digitized by Google

personal about the matter again. At Troy we are making an alternating current dynamo, producing direct currents from it; in other words, a simple multipolar dynamo, with this exception that the armature is in two layers, the neutral point on one armature corresponding with the maximum point on the other. Those two armatures are connected to a single commutator, there being two bars connected with one armature and the next two bars with the other; the positive of one and the positive of the other, the negative of one and the negative of the other; in that relation, a brush being put on of a certain width, we found some curious results. With plating machines of low tension we found we could increase the width of contact to such an extent that we seemed to collect the entire current from both sides of the armature; the current seemed to be prolonged from each side of the armature, so that we were practically collecting the current from both sides. The moment we used high tension currents we failed. Without apparent lag of the current, whatever that was, the minute we increased the tension of currents up to 300 or 400 volts, we failed entirely. But the point that I wished to bring to your attention was, that we could make that contact of considerable width, and apparently get a larger power from the same amount of material in the machine in low tension work, than we could when we got too high tension, and apparently there existed there this feature of lag of heavy currents which Prof. Thomson first brought up.

Prof. Thomson—I do not think you can say that heavy currents lag any more than light currents. A heavy current is nothing more or less than the flowing around of so many light currents. In the closed circuit of a coil it is the same current going round many times, as compared, you may say, with parallel currents, which represent the current that goes in the fine coil repeated side by side so many times, and the lag ought to be the same in both cases. I find, for example, that it does not matter in these experiments whether I use a copper ring or a closed coil of fine wire; I might use 36 wire provided I could get as much copper into the same space with 36 wire as I could get with a heavy mass of copper. That, of course, I cannot do; but if I could, I haven't the slightest doubt that the high electromotive force closed on this would have the same lag as heavy currents closed on a ring. In one case it has greater length; in the other it has greater volume which lags the current.

Mr. Powers is probably working with high potentials in one case and quite low potentials in the other. Now a high potential machine is a ticklish thing to handle anyhow. You must put your brushes on and carry the coil away not a moment too late or you will have a flash and short circuit of the commutator from one point to the other. I am speaking of the type of machine you refer to. The low potential current, however, permits you to have a considerable variation in the point of connection without provoking bad sparking and flashing; you no doubt need to put the extra over-lap of brushes on coils brought into action at the moment they are developing very low electromotive-force, and taking them out when they are developing nearly no electromotive-force. That you could not do in a machine of that type with high potentials, because if you keep the coils in beyond their time of possessing electromotive-force which could just sustain the circuit, you would have a flash; there would be an alternation at the slot in the commutator which would cause a reverse current.

Mr. Powers—The action I was speaking of was not flashing at the commutator, but the curious growling of the machine against itself; for instance, the relation between 10 volts and 100 volts on the same machine, if you choose to couple them up directly: and the same brushes would give you that slowing down and growling effect, while in the other case the brushes worked smoothly and gave good results.

Prof. Thomson—I misunderstood the point in question.

Mr. Pendleton—The subject has brought up a matter which was of considerable interest to me some time ago in the different action had upon the magnetization of a differential magnet in a lamp that I had invented some three or four years ago, and it may be somewhat analogous to the action mentioned by Mr. Powers. It was an unexplained action so far as I could get at it, but some one may be able to give the reason for it. An ordinary differential lamp, extended poles acting upon an armature which governed the carbon rod, I ran for several weeks upon the circuit of the United States Electric Light Co. to good advantage. The lamp worked well, and the feeding point and polarization of the cores was correct and it worked very satisfactorily. I had occasion afterwards to put the same lamp upon a high tension current, and found that consequent poles were developed in the iron; and the lamp, although it worked, it did so under great disadvantage. Mr. Field at the time examined the lamp, and while he spoke well of its mechanism, remarked one day, "Pendleton, you have got a bug in that lamp." "Well," said I, "I have; but how did you find it out?" "Well," he said, "I had the same difficulty some years ago in meeting with consequent poles." I then told him my experience with the lamp—that with a low tension it ran perfectly well, and then consequent poles were not formed. I remedied it, however, by placing upon each core the two differential coils, on each spool the coarse wire and the fine wire. Now in this action spoken of between the high and low tension currents, I think there may be some similarity of action, and it is a matter that has not been thoroughly ventilated. I have never been able to account for it. I remedied it, but the cause of it I have never been able to ascertain. There are a great many things in the matter of magnetization, simple though it may be, that we are a little foggy about.

At the request of the president, Mr. Shelbourne took the chair, and Mr. Martin read a paper entitled, "A Few Comparative Statistics of Electrical Railways." (See page 227.)

Mr. Martin—This paper is a substitute for the one for which I appear upon the programme. That was to have been prepared chiefly by my associate, Mr. Wetzler, who has been ill and consequently not able to prepare it.

DISCUSSION.

The Chairman; Gentlemen: This question of electric railways is one which is very full of promise; it is something which it seems to me will immediately develop extensively, and that within the next two years we will have five times the number of electric railways in operation that are now in operation.

This morning, Mr. Frank L. Pope, our worthy past president, made some statements in regard to investigations which he had made with reference to that subject, and I at that time felt on the point of asking, as he did not state the location of the proposed railway, nor what storage battery he had calculated upon; whether in his calculations he took as the basis the storage battery that he had investigated, that is the Julien battery, as I understand, and whether he made any estimate as to the comparative percentage of cost for running a car per mile hour with such a battery as compared with horse-power.

Mr. Frank L. Pope—In reply to the chairman I would say that I did not specify the kind of battery used nor the railway that we were making tests for, simply because I did not wish to be regarded as having advertising purposes in view, but I have no objection to giving the information. The investigations were undertaken for the West End Street Railroad Co. of Boston, and the battery, of which we have completed a test, is the Julien battery. I may add that we have devoted much attention to getting, as nearly as we can, in the absence of actual experiment on the road under working conditions, at the probable comparative cost of power of different methods of running, and I think it will come out about seven cents per car mile by accumulators, as against 10 to 11 cents per car mile by horse-power. Experience may modify these figures; but I do not imagine they will be far from the true cost. We have spared no pains or expense to get accurate data on all the points involved. The management of the West End company have shown a most commendable spirit of liberality, throughout.

The Chairman—It seems to be necessary, gentlemen, in order to get through in time this afternoon that we hurry on to the next paper which is by Mr. J. A. Powers, of Troy, on the Installation of Arc Lighting Plants.

Mr. J. A. Powers—Mr. President and gentlemen; there seems to have been a pleasing variety of misunderstanding about my subject. Arc lighting plants are included in my paper; but I had proposed to treat of the installation of central stations, or rather of Central Station Construction. (For Mr. Powers's paper, see page 215.)

The Chairman—A short discussion upon this paper will be in order. The paper seems to be such as to recommend itself to us all, and perhaps everybody will assent to everything that was said, and will have nothing to add in the way of suggestion.

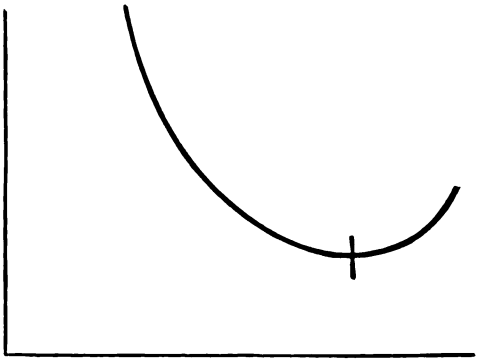
The next paper is on the Change from Negative to Positive of the Temperature Co-efficients of Some Carbon Filaments, by Prof. Anthony.

Prof. Anthony—Mr. President and gentlemen of the association: I am very much chagrined, as I am obliged on this occasion to ask to be excused from reading a paper. We have been at work, for some time, upon this matter, but have only reached some results which I will give to you in a brief way, orally. We have not, so far, reached anything upon which I could make out a written paper, so I will simply state a few facts that have been reached.

We found at first, in the testing of a dozen incandescent lamps for the purpose of determining their efficiency, with paper carbons and filaments—we were simply making measurements for the purpose of determining the ordinary electrical efficiency of the lamps—we found that the curve, representing the relation between potential and resistance, ran like this (illustrating), the potential being represented by the abscissæ, and the resistance by the ordinates. Now, it had been my experience that the resistance of incandescent lamps, or carbon filaments, ran down when the potential ran up, and this was the first instance in which I had found an increase of resistance as the potential went on—as the current increased, and of course as the illuminating power increased. In these particular lamps this change occurred very low in the temperature of the lamp. It occurred when the lamp, in fact, was only just barely red hot,

Digitized by Google

and the resistance went on up to the limit to which the lamps were carried.



Afterwards, we thought this was of sufficient interest to pursue it in regard to other lamps. We have tested a number of lamps, and we have found in some four or five different cases the same general result. Sometimes the curve does not change until we have reached the normal candle power of the lamp, and in many lamps we have tried we never have reached any such change, the curve going on downward as far as the lamp could be carried, and in fact until the carbon began to disintegrate, in which case, of course, if we go back, if we take the points on the curve, in the first place, raising the potential point by point and carrying it up by this (illustrating), if we get to a point where the carbon begins to disintegrate and then go back, lowering the potential point by point, the two curves will not coincide. We have found, in some cases, that the curve went down like this (illustrating), and turned up like that (illustrating), at the lower end; but when we went back we found our resistance was permanently increased on account of change in the character of carbon. But it is certain that in a number of different carbon filaments there is this change of resistance, and in all the carbon filaments that we have tried, except one or two, there is a change that indicates that at some point the curve runs like that (illustrating); that at some point there would be a rise, if we could carry the temperature far enough.

Now, what I hoped to be able to present to this meeting was the determination of something about the character of the carbon filaments, which showed the change early in the temperature of the lamp, where that change began at very low temperature, to determine the difference in the character of the carbon filaments at this point; of the filaments which showed this change, and of those which did not show it, and those which showed a continuous fall of potential. That I have not been able to do; and furthermore, it was a point to determine the actual temperatures of the carbon. Those we have obtained with some degree of satisfaction, but I do not feel that our results are sufficiently trustworthy to present them, and, therefore, I am obliged to ask to be excused from attempting to present anything further on this point.

Prof. Thomson—The observation of Prof. Anthony is quite interesting to me, because one of our men reported two or three weeks ago the same phenomenon as noticed in lamps; that is, that at a certain brilliancy the resistance came to a constant, and then began to rise as the brilliancy was increased. I told him, at the time, to pursue that a little further and let us have some better figures. He reported, too, that all lamps did not appear to do it to the same extent. There is another curious fact that was noticed, and that has been reported to me, in regard to resistance of incandescent lamps. We are building lamps that are run in series on arc light circuits, using 6 8-10 to 10 amperes, and they are put in with the arcs and give a candle power of 32, 65 and 125. We find that when those lamps are run for a certain time, during the early part of the run—for perhaps 200 or 300 hours of the run—the resistance steadily falls. After that it seems to rise steadily, or, in other words, this effect comes in as a sort of an effect of time as well as simple brilliancy. The lamps fall in the volts necessary to carry the normal current through them. It does not amount to a large percentage, but it continues during a large fraction of the life of the lamp, and after that point the resistance begins to gradually rise, and not only has that fact been noticed in regard to the lamps of large candle power and comparatively heavy filaments of low resistance, but it has been noticed that in lamps that have been run on arc light circuits, in multiple groups, the same fall and gradual increase seems to take place; and it led us to imagine that there might be some connection between the arc light current itself and this effect. We have not noticed the same effects on multiple arc circuits, and we have not examined very thoroughly into the matter; but we have no reason to suspect, at least now, that this fall and gradual increase occurs on multiple arc circuits; but it seems to occur oftentimes—not always—in lamps that are put on arc light circuits, either in group or in series, taking the whole current.

The hour of adjournment being so near, the paper of Mr. David Brooks on Lead-Encased Conductors (see page 224), was read by title only.

The President—Is there any business before the meeting?

Mr. R. W. Pope—I have two resolutions that I would like to offer:

Resolved, That the sincere and heartfelt thanks of the American Institute of Electrical Engineers be, and are hereby extended to the American Society of Civil Engineers, and its able and hospitable secretary, Mr. John Bogart, and his assistants, for their continued favors and courtesy tendered to us, beginning with the organization of this society and continued during its progress toward its final establishment upon a firm and enduring basis.

Resolved, That whereas imitation is the sincerest form of approbation, we pledge our efforts to exercise our means and energies to the immediate establishment of a home of our own, in which we hope hereafter to extend our hospitality to all engineers of every branch, who may desire to avail themselves of the information developed, as the introduction of electric industries grows in public importance.

The resolutions were adopted.

Mr. R. W. Pope—I also beg leave to offer the following resolution:

Resolved, That the members and associates of the American Institute of Electrical Engineers, as a slight appreciation of the courtesies extended to them by Mr. Erastus Wiman, president of the Telemeter Company, and Mr. C. C. Martin, chief engineer of the East river bridge, do hereby extend their hearty thanks for the thoughtfulness and hospitality of those gentlemen in providing a most enjoyable scientific and social entertainment in connection with their annual meeting.

The resolution was adopted.

The President—We have all had a day of great pleasure and profit, and we shall go to our regular daily duties refreshed and benefited, and better able to do the work that lies before us.

There being no further business, a motion to adjourn is in order.

On motion, the meeting then adjourned.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

OFFICERS AND MEMBERS OF COUNCIL, 1887-8.

President: T. Commerford Martin.

Vice-Presidents: Dr. Norvin Green, Prof. W. A. Anthony, George C. Maynard, Frank L. Pope, Col. Rowland R. Hazard, Prof. Elihu Thomson.

Managers: Sidney F. Shelbourne, Capt. O. E. Michaelis, U. S. A., Prof. Cyrus F. Brackett, C. O. Mailloux, Charles L. Buckingham, David Brooks, Prof. B. F. Thomas, Schuyler S. Wheeler, Joseph F. Wetzler, A. C. Fowler, William Lee Church and Edward P. Thompson.

Secretary: Ralph W. Pope, 16 Dey street, New York.

Treasurer: George M. Phelps, Jr., 11 Wall street, New York.

LIST OF HONORARY MEMBERS, MEMBERS AND ASSOCIATES, MAY 25TH, 1887.

Adams, H. C., New York.
Allen, George D., New York.
Anderson, H., Peekskill, N. Y.
Abernethy, J. P., Cleveland, O.
Anthony, Prof. W. A., Ithaca, N. Y.

Blake, Edward, New York.
Bruns, Lieut. C. L., Bergen Point, N. J.
Brown, Samuel J. T., Hamilton, Ont.
Bates, D. H., New York.
Buckingham, Charles L., New York.
Bulen, George F., New York.
Bailey, H. L., New York.
Bogart, John, New York.
Beetle, George L., New York.
Berliner, E., Washington, D. C.
Bosch, Adam, Newark, N. J.
Bell, Prof. Alexander Graham, Washington, D. C.
Brush, Charles F., Cleveland, O.,
Brackett, Prof. Cyrus F., Princeton, N. J.
Baker, L. C., St. Louis, Mo.
Blackwell, R. W., New York.
Brown, Walter F., New York.
Bernard, E. G., New York.
Brooks, E. H., Lebanon, Pa.
Bradley, Charles E., Yonkers, N. Y.
Bracken, Wm., New York.

Cheever, Charles A., New York.

TRANSACTIONS OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

VOL. I, 1884.

Historical Preface. Notes on Phenomena in Incandescent Lamps. (Illustrated.) Prof. Edwin J. Houston of Philadelphia. Discussion by N. S. Keith, W. H. Preece and James F. Kelly.

Underground Wires. (Illustrated.) W. M. Callender of New York. Remarks by Mr. Preece.

Synchronism. (Illustrated.) Prof. Edwin J. Houston. Discussion by P. B. Delany, C. O. Mailloux, C. J. Kintner, W. D. Sargent, George C. Maynard.

The Delany Synchronous Multiplex System of Telegraphy. (Illustrated.) Prof. Edwin J. Houston.

The Scientific City Street. (Illustrated.) Rowland R. Hazard of New York.

An Experimental Method of Studying the Dynamo Machine. By Prof. C. F. Brackett of Princeton, N. J. Discussion by N. S. Keith, Prof. Brackett, Elmer A. Sperry and James F. Kelly.

Earth Wires; or the Earth as an Electric Circuit Completer. Thomas D. Lockwood, Boston, Mass.

Telegraphing Without Wires—An Experiment. (Illustrated.) S. J. M. Bear. Discussion by James F. Kelly, N. S. Keith, Aug. Partz, H. L. Bailey, George C. Maynard, W. H. Preece, W. D. Sargent.

Chemistry of the Carbon Filament. Edward P. Thompson of New York. Discussion by N. S. Keith and John Kelly.

Depositing Vats in "Series." H. B. Slater, now of Detroit, Mich. Discussion by N. S. Keith, H. B. Slater, E. A. Sperry and J. F. Kelly.

The Patent Office; its Relation to Inventors and its Needs. C. J. Kintner (now of Philadelphia, Pa.) Discussion by Frankland Jannus, Prof. Houston, N. S. Keith and G. C. Maynard.

VOL. II, 1885.—ANNUAL AND GENERAL MEETINGS, May 19th and 20th, 1885.

The Protection of Electrical Inventions. Frankland Jannus of Washington, D. C. Discussion by F. L. Pope, E. P. Thompson, F. Jannus, T. D. Stetson, E. P. Roberts, T. C. Martin and S. F. Shelbourne.

Cost of Mine Lighting. F. P. Mills of Stambaugh, Mich. Discussion by E. P. Roberts, T. C. Martin, E. P. Thompson and J. F. Kelly.

The Electric Arc Lamp Frictional Clutch. (Illustrated.) Edward P. Thompson. Discussion by E. P. Thompson, S. F. Shelbourne, J. F. Kelly, E. P. Roberts, Prof. W. A. Anthony, Jean Wetmore, F. Jannus, G. A. Hamilton, H. B. Slater, F. L. Pope.

Description of a Large Secondary Battery Plant for General Commercial Distribution. E. P. Roberts, of Cheyenne, Wyo. Discussion by Prof. W. A. Anthony, Mr. Hall, F. L. Pope, R. W. Pope, S. F. Shelbourne, G. A. Hamilton, B. F. Card, T. C. Martin, Col. Rowland R. Hazard, Mr. Carey.

Delany's System of Fac-Simile Telegraphy. (Illustrated.) Prof. Edwin J. Houston.

VOL. III, 1886.—ANNUAL AND GENERAL MEETINGS, May 18th and 19th, 1886.

Underground Electrical Systems. Sidney F. Shelbourne of New York. Discussion by Thomas D. Lockwood, S. F. Shelbourne, C. O. Mailloux, George C. Maynard, Prof. C. A. Young, F. L. Pope, R. W. Pope, Capt. O. E. Michaelis.

The Great Tangent Galvanometer of the Cornell University. Prof. W. A. Anthony. Discussion by David E. Lain, C. O. Mailloux, F. L. Pope, Prof. C. A. Young, R. W. Pope, T. D. Lockwood.

Some Recent Advances in Telephony. (Illustrated.) Thomas D. Lockwood, of Boston, Mass. Discussion by R. W. Pope, S. F. Shelbourne, F. L. Pope, F. W. Jones.

The Patent Office and Patent Office Practice. A. C. Fowler of New York.

Static Difficulties in Telegraph Wires. F. W. Jones of New York. Containing a synopsis, with references to 113 American and Foreign patents for inventions intended to overcome these difficulties.

Secondary Batteries for Light and Power. A. H. Bauer. Discussion by F. L. Pope, C. O. Mailloux, S. F. Shelbourne, Joseph Wetzler, George C. Maynard, A. C. Fowler.

The Wire Gauge. Report of committee, and discussion by C. O. Mailloux, Capt. O. E. Michaelis, S. F. Shelbourne, Joseph Wetzler, R. W. Pope.

Notes on Dynamic Induction. Sidney F. Shelbourne.

VOL. IV, 1887. (In preparation.)—SPECIAL MEETING, Dec. 7, 1886.

Electric Street Cars. T. C. Martin, of New York. Discussion by John Murray Mitchell, Joseph Wetzler, M. Julien, C. J. Van Depoele, C. O. Mailloux, G. W. Mansfield, S. D. Field, J. M. Pendleton, Gen. Stiles; also a communication from R. M. Hunter.

SPECIAL MEETING, Feb. 6, 1887.

The Practical Requirements of Small Motors. Schuyler S. Wheeler, of New York. Discussion by Philip Diehl, Mr. Wing, Mr. Bradley, C. G. Curtis, J. M. Pendleton, G. A. Hamilton, T. C. Martin, F. B. Crocker, Joseph Wetzler.

SPECIAL MEETING, March 6, 1887.

Distribution of Electricity by Secondary Generators. Discussion by F. L. Pope, Dr. Otto A. Moses, Capt. O. E. Michaelis, Prof. Elihu Thomson, Joseph Wetzler, C. O. Mailloux, Wm. Lee Church, E. E. Ries, Alex. P. Wright, S. S. Wheeler, T. C. Martin, G. W. Mansfield.

ANNUAL AND GENERAL MEETINGS, May 17 and 18, 1887.

Storage Batteries in Actual Use. E. P. Roberts, of Cheyenne Wyo. Discussion by F. L. Pope, C. O. Mailloux and E. P Thompson.

Differing Temperature Co-efficients of the Different Coils of a Fine Rheostat. Prof. W. A. Anthony, of Cornell University. Discussion by William Wallace, F L. Pope, Prof. W. A. Anthony, George B. Prescott, Jr., Carl Hering, J. A. Powers, Capt. O. E. Michaelis.

On the Best Ratio of the Section of the Gramme Armature to the Section of the Field Magnets. (Illustrated.) Dugald C. Jackson, of Cornell University. Discussion by S. S. Wheeler, Mr. Bradley, Prof. Thomson, C. O. Mailloux.

Novel Phenomena of Alternating Currents. (Illustrated.) Prof. Elihu Thomson of Lynn, Mass. Discussion by S. S. Wheeler, George B. Prescott, Jr., Prof. Thomson, J. M. Pendleton, Carl Hering, J. A. Powers.

A Few Comparative Statistics of Electric Railways. T. C. Martin, of New York. (With tabular statement.)

Central Station Construction. J. A. Powers, of Troy, N. Y.

On the Change from Negative to Positive of the Temperature Co-efficients of Some Carbon Filaments. (Illustrated.) W. A. Anthony.

Lead-Encased Conductors. (Illustrated.) David Brooks of Philadelphia.

For copies, address,

R. W. POPE, Secretary, 16 Dey Street, New York.

CELEBRATION OF THE ONE HUNDREDTH MEETING OF THE NEW YORK ELECTRICAL SOCIETY.

A dinner in celebration of the one hundredth meeting of the New York Electrical Society, the electrical section of the American Institute, was given on May 11 at the D'Orville restaurant, in the Mills building. A special *menu* was prepared for the occasion, printed in electric blue of two tints on a white ground, with devices representing the electric light, the telephone and the telegraph, the two cards used being tied at the top with red telephone cord.

After the cloth had been cleared, the president of the society, Mr. John M Pendleton, gave a most interesting historical sketch of the work of the body—which now has a membership not far short of 200—from 1881, the date of its formation. Early in the history of the society, a lecture delivered under its auspices at the Cooper Union, by Prof. H. S. Carhart, on "Radiant Energy" attracted an audience of no fewer than 1,500 people. Prof. Cleveland Abbe, of the U. S. Signal Corps, discussed at another time the subject of "Electrical Clocks." Prof. A. M. Mayer, of the Stevens Institute, lectured before the society on "The Laws of Ohm." Prof. Henry Morton, of the Stevens Institute, delivered another lecture on "The Storage of Electricity." Mr. H. A. Sinclair, the electrician of the Government Ordnance Station at Sandy Hook, discussed in a manner that attracted the general attention of the press and public, "Measuring the Velocity of Projectiles." Prof. Van der Weyde during the six years contributed scores of papers, illustrated lectures, memoranda, etc., on the most varying topics connected with electricity; and during the same period the following well-known electricians and experts, also contributed original papers: Messrs. F. W. Jones, G. A. Hamilton, F. W. Cushing, G. B. Scott, H. L. Bailey, J. Hamblet, C. S. H. Small, H. W. Pope, E. A. Leslie, G. K. Winter, A. A. Knudson, C. O. Mailloux, W. P. Phillips, N. S. Keith, S. P. Frier, P. B. Delany, A. E. Dolbear, L. J. Blake, T. D. Lockwood, P. Gannon, J. Wetzler, G. W. Mansfield, J. J. Ghegan, T. Wolcott, A. C. Fowler. This list, as read by president Pendleton, though necessarily not complete, showed how strong had been the interest in the society through several years, and how ready leading electricians had been to place their services at its disposal for the furtherance of its welfare and in the promotion of science.

The address of president Pendleton was followed by speeches from Mr. J. D. Reid, the veteran associate of Morse, in response to "The Telegraph"; Mr. C. O. Mailloux, to "Electro-Chemistry"; Mr. S. S. Wheeler, to "The Electric Motor"; Mr. H. C. Davis, to "Our Guests"—accompanying a brief, pithy reply with a capital, ringing song; Mr. A. A. Knudson, to "The Electrical Transmission of Energy"; Mr. R. Grimshaw, to "Our Sister Sections of the Institute"; Judge John A. Grow, to "Electricity and the Law"; and Mr. T. C. Martin, to "The Scientific Press"—Mr. Martin supplemented his address by the reading of a poem, "The

Digitized by Google

Polychromotelepantophotophonograph," the riotous humor and pathos of which induced in the electricians present an alternating current of tears and laughter. During the evening the secretary read letters of congratulation and regret at absence from Profs. G. F. Barker, E. J. Houston and H. Morton; Secretary W. H. Wahl, of the Franklin Institute; and Messrs. E. H. Johnson, G. W. Hebard, E. H. Goff, T. T. Eckert, W. J. Johnston, F. L. Pope and several others. The whole affair was of a most happy and interesting character, and will be long remembered with pleasure by all who participated.

Much interest was created by the examination during the evening of a volume, now very rare, being the report of the Commissioner of Patents for 1843, containing Morse's telegraph patent, and a description of the system patented by Ezra Cornell of laying wires underground in pipes. It was presented to the society by Mr. W. D. Baldwin, of Washington, D. C., accompanying his letter of regret not to be present.

BROOKLYN BRIDGE FREEZING AND COLD STORAGE CO.

EXHIBIT OF THE TELEMETER SYSTEM.

A very agreeable, and instructive episode, in connection with the meeting of the Institute of Electrical Engineers was supplied by the courtesy of Mr. Erastus Wiman, President of the Telemeter Co., who invited the members of the Institute and a number of other gentlemen, to visit the installation of the Brooklyn Bridge Freezing and Cold Storage Co., Tuesday afternoon, May 17th.

A large company assembled in the rooms under the New York approach of the bridge at 4:30 P. M., inspected the vaults and storage rooms, and after enjoying an elegant lunch provided by the hospitable entertainers, visited the power station of the Brooklyn bridge under the guidance of representatives of the Telemeter Co.

The application of the Telemeter system to the regulation of temperature in the preservation of meats and fruit, as shown in this extensive establishment was extremely interesting. The temperature in the various receiving and storage rooms is maintained at from 12° to 20° F.

Each indicator in the office is electrically connected to a thermometer placed in one of the storage vaults or rooms. There are 30 in all. 4,000 feet of three conductor lead cable have been used in the installation. To keep the vaults and rooms at the required temperature, more than 12 miles of circulating pipes are required. The circulation of the cold brine through these pipes is controlled at the engine room by means of valves and the speed at the circulating pumps, for the proper regulation of which the engineer depends upon the temperature indications given by the instruments in the office.

Order, thoroughness, and the utmost neatness and cleanliness characterize every part of the establishment. All who were fortunate enough to be present will feel indebted to Mr. Wiman, Mr. Hewitt and their associates, for the opportunity of seeing this practical application of temperature regulation by means of electricity, as well as for their generous hospitality.

MANUFACTURING AND TRADE NOTES.

The Standard Underground Cable Co., in April, sold the Western Union Telegraph Co. 10 miles of cable having 19 conductors of No. 14 B. & S gauge, to be strung on one of the west side elevated roads. Also 19,100 feet of 30-conductor No. 14 B. & S. underground cable, to be laid in the Western Union underground five inch iron pipe conduits in Broadway. The Western Union company have now had in use since last year a similar underground cable made by this company, of 50 wires, one mile in length, through which they have been working, with perfect satisfaction, their heavy quadruplex circuits. The test has been a severe one, for the reason that the conduits lie alongside the Steam Heating Co.'s pipes the whole distance. The result is indicated in the above new orders.

The Standard Underground Cable Co., recently doubled the capacity of their factory. Mr. G. L. Wiley, the New York agent of the company, will remove about May 10th, into new offices in the Telephone Building, 16, 18 and 20 Cortlandt street.

The American Electric Manufacturing Co., has bought outright all the plants and franchise of the Gramme and Fuller-Wood Electric companies, and will hereafter operate such portions of these systems as the American may find desirable to put into use. The American had been paying royalties to the Fuller-Wood company running up in the tens of thousands last year, and now the purchase will put the former company in a more secure position, besides guaranteeing a larger profit through the absolute ownership as stated.

The Mutual Electric Manufacturing Co. have removed their factory from Washington and York streets to 292, 294 and 296 Graham street, near DeKalb avenue, Brooklyn. They have four times the room they occupied before, and add to their business the manfacture of the Julien storage batteries.

It is reported that Mr. W. L. Seddon, of 417 Pine street, St. Louis, is fulfilling a contract to put down two miles of his system of electric road at Wichita, Kas. He operates a series system. Unlike Prof. Short's road in Denver, however, or Bentley & Knight's, no conduit is used in his system, but an overhead conductor instead. The plant will be the property of the Riverside and Suburban Railway Co. The power house will be built with reference to a further extension of the line by three miles this summer. The Smith, Beggs & Ranken Machine Co. are building the engines, which will be from 80 to 100 h. p., and another local firm the cars. The Brush Electric Association will supply the dynamo. Mr. Seddon thinks it possible to run street cars by means of electricity at from six to nine cents per car per mile, against a supposed cost of 11 cents—perhaps as high as 18 cents in some cases—by horse.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions, 11 Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From April 19 to May 10th, 1887 (inclusive).

Alarms and Signals:—*Electric Signal for Weighing Scales*, E. S. Enyart, 361,275. *Combined Clock and Alarm for Hotels*, A. B. Harford, 361,511, April 19. *Water Level Alarm*, J. L. W. Olsen, 361,968. *Electric Bell*, E. W. Hazazer, 362,005, April 26. *Electric Signaling Apparatus*, S. Hiyne-Berline, 362,216. *Electric Police-Call Alarm Box*, J. J. Coughlin, 362,477, May 3. *Automatic Electric Danger-Alarm*, J. J. Ghegan, 362,739, May 10.

Clocks:—*Circuit-Controller for Self-Winding Clocks*, C. H. Pond, 362,902, May 10. (See Alarms and Signals.)

Conductors, Insulators, Supports and Systems:—*Branch Conduit for Electrical Conductors*, J. M. Clokey, 361,265. *Subway for Electric-Current Wires or Cables*, J. MacFarlane, 361,276. *Underground Conduit*, I. Paxson, 361,319. *Dielectric Composition*, C. T. Crowell, 361,347, April 19. *Electrical Conductor*, L. Daft, 361,676, April 26. *Electric Cable Clip*, C. C. Gould and W. Smith, 362,376, May 3. *Loop Insulator*, H. Van Sands, 362,682. *Insulating the Terminals of Sheathed Electric Conductors*, D. Brooks, 362,872, May 10.

Distribution:—*Apparatus for Distributing Electrical Power*, E. A. Sperry, 361,843. *Electric Inductive Translator*, W. Main, 361,770, April 26.

Dynamos and Motors:—*Fusible Connection for Armatures of Electric Generators*, J. W. Easton, 361,273, April 19. *Regulator for Dynamo-Electric Machines*, C. G. Perkins, 361,712. *Armature-Core for Dynamo-Electric Machines*, A. Schmid, 361,896. *Commutator for Dynamo-Electric Machines*, E. P. Warner, 361,973, April 26. *Regulator for Dynamo-Electric Machines*, E. T. and D. Higham, 362,510, May 10. *Electric Motor*, J. W. Easton, 361,274, April 19; R. J. Sheehy, 362,322, May 3. *Electro-Dynamic Motor*, C. J. Van Depoele, 362,798, May 10.

Galvanic Batteries:—*Galvanic Battery*, S. F. Walker, 361,794, April 26. *Voltaic Battery*, A. F. W. Partz, 362,531. *Electric Battery*, D. Misell, 362,584, O. Lugo, 362,847, May 10.

Lamps and Appurtenances:—*Electric Arc Lamp*, G. A. Wiese, 361,663, April 19; H. Pieper, Fils, 362,312, May 3. *Electric Lamp*, C. M. Noble, 362,852, May 10. *Incandescent Electric Lamp*, S. F. Van Choate, 362,128, May 3. *Safety Lamp for Use in Mines and Other Places*, M. Settle and D. Lever, 361,455, April 19. *Fusible Cut-Out*, C. G. Perkins, 361,713. *Gas and Electric Lamp Fixture*, J. T. Robb, 361,782. *Safety Device for Incandescent Lamps*, E. A. Sperry, 361,844 *Combined Lamp and Signal Post*, J. E. Smith, 361,901, April 26. *Support for Electric Lights*, A. G. Schlotterbeck, 362,399. *Compensating Mechanism for Regulating Electric Light Carbons*, J. A. Lakin, 362,289, May 3.

Measurement:—*Electric Current Indicator*, P. Lange, 362,451, May 3.

Metallurgy:—*Apparatus for Separating Metals from Ores or Alloys by Electrolysis*, H. Liepmann, 362,022, April 26. *Process of Depositing Iridium and Product of the Same*, W. L. Dudley, 362,257, May 3.

Medical and Surgical:—*Electro-Therapeutic Strength-Testing Machine*, E. R. Whitney, 362,133, May 3.

Miscellaneous:—*Electrical Induction Apparatus*, M. H. Gross, 361,587. *Automatic Electric Damper-Regulator*, E. N. Dickerson, Jr., 361,270. *Lightning Rod*, C. F. Hill, 361,520, April 19. *Binding Device for Electrical Apparatus*, I. W. Litchfield, 361,705. *Electric Covering for Indicating Abnormal Conditions*, G. J. Jewill, 362,010. *Registering Apparatus*, C. F. W. Doehring and C. A. Hoffman, 361,678. *Electric Rope-Coupler*, S. B. Stewart, 361,731. *Electric Valve-Operating Mechanism for Elevators*, G. H. Reynolds, 361,778 and 361,780. *Means for Electrically Controlling the Operation of Elevators*, same, 361,779. *Electro-Magnetic Rock Drill*, H. N. Marvin, 361,829. *Ozone Apparatus*, A. and L. Q. Brin, 361,923, April 26. *Electric Rock Drill*, C. E. Ball, 362,053. *Multiple Subsidiary Ground Terminal for Lightning Rods*, J. W. Cole, 362,062. *Lightning Rod*, E. O. Daniels, 362,064. *Connector for Electrical Appliances*, C. G. Perkins, 362,108. *Polarized Electro Magnet*, J. C. Wilson, 362,135. *Electrical Circuit Closer*, G. E. Thaxter 362,192. *Electric Regulator of Heating Apparatus*, R. L. Guion, 362,212. *Electric Switch*, A. Swan, 362,469, May 3. *Lightning Rod*, F. Westcott, 362,801. *Variable Electric Resistance*. J. M. Stearns, Jr., 362,859, May 10.

Railways and Appliances:—*Electrical Railway*, S. H. Short and J. W. Nesmith, 362,323, May 3. *Railway Signaling*, S. B. Stewart, 361,730, April 26. *Railway Signal*, P. J. Wicks, 362,409, May 3.

Secondary Batteries:—*Method of Working and Forming Secondary Batteries*, W. I. Ludlow, 362,639. *Secondary or Storage Battery*, same, 362,640, May 10.

Telegraphs:—*Telegraphy*, F. Van Rysselberghe, 361,734, April 26. *Duplex Telegraphy*, G. W. Gardanier, 361,356; J. W. Larish and W. Maver, Jr., 361,364. *Method of and Apparatus for Signaling Through Submarine Cables*, M. G. Farmer, 361,498. *Calling Apparatus for Telegraph Circuits*, J. W. Larish, 361,365, April 19. *Switch and Circuit for Telegraphs*, S. Weaver, 361,797, April 26.

Telephones, Systems and Apparatus:—*Telephone*, C. S. Bell, 361,481. *Mechanical Telephone*, M. Garl, 361,499. *Mechanical Telephone Line-Hanger*, G. W. Lord, 361,302, April 19. *Magneto-Electric Telephone Call*, G. A. Wilkins, 361,737, April 26. *Telephone Support*, S. Rosenblatt, 362,115. *Multiple Switch Board*, M. G. Kellogg, 362,217, May 3. *Testing Apparatus for Telephone Exchange Switches*, J. J. O'Connell, 362,652, May 10.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, JULY, 1887.

JUBILEE DAYS.

DURING the last ten days of June, the English jubilee over the fifty years of Queen Victoria's reign has spread its genial influence over the whole civilized world. Rejoicing is contagious. Even those who scarcely comprehend the significance of the festival, or comprehending, are not in sympathy with the ideas and principles thought to be involved in it, are infected with the enthusiasm of the day in some degree. It is with good reason that the world rejoices. The celebration is less for the personal career and length of days of the British Queen, although so amply due thereto, than for the continued prosperity and advancement of the English speaking races along their time-honored lines of careful and deliberate development; a glorification of the method of steady growth in national life, social and political, in contradistinction to the methods of upheaval and revolution; loyalty to the past and present with a steady outlook forward to amelioration of the common lot of the people and the abolition of faults and abuses. In England and America, the periods called revolutionary have resulted from popular effort to secure a return to principles of government running far back in the history of the Anglo-Saxon race, rather than attempts to establish new theories of social and political right. In steadfast adherence to this racial method of growth and evolution lies the hope of the future. After a thousand years on this path, England is the foremost nation of the world commercially and politically, and in much that makes for the happiness and contentment of her people. Her traditions of liberty are having a further and perhaps more rapid development in our own country, but let us not forget, that our marvellous growth in a hundred years into a great and free nation, second only to Great Britain, and fast overtaking her, could not have been achieved without the momentum of inherited traditions and principles of freedom and habits of political action which we derived with her from a common past.

In rejoicing with all Britons during these festival days, and sharing the enthusiasm expressed in the magnificent pageantry of June 21st., in London, we are not unmindful that very much yet remains to be accomplished, not only in Great Britain, but in America, to better the lot of large classes of the population. The real cause for jubilation is that the social and political methods exemplified in English and American history have tended steadily to increase the possibilities of comfort, success and contentment for the whole of the people. Ireland is still unhappy, large numbers of her people suffer hardship and privation for which England must be held largely responsible. But it is clear that much of the best talent in England is laboriously seeking a remedy for Irish troubles, and it can scarcely be doubted that they will succeed. To those people on this side of the Atlantic, from whose eyes the deplorable condition of Ireland shuts out the sight of all that is good and great in England, let us recall the days, not twenty-five years past, when all the world could point the finger of shame and scorn at us. Till we abolished slavery, the United States could not fully justify its claim to be the "home of the free," nor to the principles upon which its government was founded. We should be grateful that many of the wise and good of the world believed in us and our destiny, in spite of our stiff-necked persistence in wrong-doing, and still more grateful that we have in large measure deserved their faith in us. Let us not lose confidence that our kinsmen of England will by patient work, and in good time, find a way to help both Ireland and themselves out of their humiliation and distress.

The coincidence of the royal jubilee with the fiftieth anniversary of the establishment of the telegraph by Wheatstone, in England, and of Morse's caveat for his invention filed in the United States patent office, in the same year, suggests still further the closeness of relation between Great Britain and America.

The honors of the jubilee of the telegraph are properly divided between the two countries. Without failing to honor the inventors and investigators of other lands whose work contributed to the final result, the credit of devising and of establishing the use of electric telegraphs belongs to England and America—Cooke and Wheatstone established their first line in 1837, and Morse worked his telegraph over a line of half a mile in the same year. Development and extension followed in every civilized land at a marvelous rate, continents and oceans were crossed, and after forty years came Graham Bell with his telephone to extend indefinitely the range of every man's voice.

The many and striking applications of electricity in the arts of life that have followed the introduction of the telegraph have elicited the wonder, applause and acceptance of the world. Especially remarkable is the accelerated pace of development in the last fifteen years, which include

Digitized by Google

the reduction to practice of duplex and multiplex telegraphy, the invention of the speaking telephone, the firm establishment of electric lighting as a large industry, and the introduction to a large extent of electricity in the transmission of power for both stationary and locomotive purposes. In carrying forward this work, the inventors and manufacturers of England and the United States have kept their lead. The lines of effort have been somewhat different in the two countries. English electricians have given prominence to the theoretical and mathematical aspects of the problems involved, whilst American ingenuity has been largely devoted to practical experimentation and the invention of new methods and devices. The economic necessities of ocean telegraphy gave rise thirty years ago in England to the elaboration of refined methods of electrical measurements and their practice on a large scale, not only upon the great submarine lines projected and laid through English enterprise, but upon land lines everywhere. Before this, the practice of telegraphy followed relatively crude methods, with small regard to scientific principles of economy. Many of our own electricians will recall the revelation of waste and loss made by the first systematic application of English testing on American lines, twenty years ago, at the hands of Cromwell Varley; as well as the great improvement in the quality and economy of service attained through its continued and intelligent application. The lesson that cleverness and ingenuity, which had carried us through the early days, must be supplemented by accurate knowledge and sound methods, for the achievement of lasting success, was not lost upon us.

Let there be jubilation for all the good work of the last fifty years wheresoever and by whomsoever done—and let us join in celebrating the golden anniversary of the gracious Queen, whose reign has witnessed it all.

THE Institute of Electrical Engineers held the last of its series of special meetings for the season at Martinelli's, Fifth avenue, Tuesday evening, June 28th. As heretofore during the winter and spring, the meeting was preceded by a dinner at six o'clock. The meeting was called to order at 8 o'clock. Mr. Geo. W. Blodgett, of Boston, read a paper on "The Electric Lighting of Passenger Trains." A discussion followed by Messrs. R. W. Pope, Elias Ries, T. D. Lockwood, C. O. Mailloux, W. C Bracken, J. M. Pendleton and Jos. Wetzler. We print Mr. Blodgett's very timely and instructive paper in this issue. Before the paper of the evening was read, the House Fund Committee, through its chairman, made a report of its progress. The subscription had increased to $4,500, almost entirely within the membership, with $1,000 additional virtually pledged by a gentleman greatly interested in the work of the Institute. A most gratifying feature of the report was the committee's statement of the hearty support and co-operation extended to the Institute by the Society of Civil Engineers. The president and secretary of that society had been appointed to confer with the House Fund Committee of the Institute, upon plans for joint use of suitable premises. In the conference that was held, Mr. Worthen and Mr. Bogart in behalf of the Civil Engineers, expressed heartily their sense of the rapid growth of electrical engineering as a department of general engineering, and their desire to ally the Institute with their society for mutual advantage. Civil Engineers were finding it necessary to increase their acquaintance with the applications of electricity, in order to meet the demands upon them of clients desiring to consult them upon questions of electric traction and transmission of power, while the constantly broadening field of the application of electricity calls for much general engineering knowledge on the part of Electrical Engineers. A location in common, an assembly room in common, a union of libraries, with a suitable provision of separate apartments for the use of each society would, it was thought, be of much mutual benefit. It was thought likely that the Society of Mechanical Engineers, would come into such a scheme, and that ultimately all branches of engineering would have a common headquarters in New York. The plan first suggested at the conference of committees, viz., the purchase of a house adjoining the present building of the Civil Engineers, had fallen through, the owner being unwilling to sell. The Institute committee would have a further conference with the Civil Engineers' committee in respect to further plans—among them that of the erection of a suitable house large enough to accommodate both societies.

THE letter of Mr. F. R. Welles, of Antwerp, printed in another column, criticising the wire gauge proposed at the last meeting of the National Electric Light Association, presents a number of weighty objections to the adoption of the gauge; not the least of which is the improbability, not to say impossibility, of getting it into anything like general use. Mr. Welles's relations are of such an international character as to give him exceptional advantages in learning the methods and customs of electrical business the world over.

From the considerable amount of suggestion and discussion that has appeared on the general subject of wire gauges during the last few years it has become very clear, that no attempt ought to be made to introduce any new gauge that is not by general consent superior to any existing gauge. Meantime the practice of designating sizes by mils or by millimeters is steadily increasing, and usually protects purchasers effectually from the confusion of the too numerous gauges now in existence.

WE look with much interest for the first number of the *Western Electrician*, a new weekly journal, announced to appear July 2d., under the management of Mr. W. A. Kreidler, of Chicago, associated with Mr. Wayland Clark, of the same city. Mr. Kreidler has for several years attended to the Western business of the *Electrical World*, and has accumulated valuable experience in electrical journalism. In everything western, one looks for energy and dash, and we make no doubt, that the *Western Electrician* will keep abreast of the current of western life and business, and keep an eye on what is going on in the rest of the world as well.

IT is not our practice to open our columns to personal controversies. It is gratifying that technical discussion so rarely assumes a personal form. The open letter of Dr. Stein, of Frankfort, the friend and associate of Philipp Reis, to Professor Houston, is printed in this issue, in deference to the high standing of the parties and in view of the interest and importance of the technical point in contention. May we be permitted, however, to express our trust that an *odium scientificum* is not to be developed in the hitherto placid courses of technical discussion? Now that the *odium theologicum* has been so long on the wane it were a pity, in the scientific world, to emulate its former virulence.

MR. FRANKLAND JANNUS replies in our columns to the attack upon the United States patent system by Mr. John McClary Perkins, printed in our correspondence last month. We are glad to have the subject discussed, and hope to hear from others acquainted with its merits through professional experience or otherwise. Probably few will agree with the extreme views of Mr. Perkins, and approve the suggested abolition of our system of patent office examinations and a reversion to the methods of England and most foreign countries, though many will be found to participate in dissatisfaction with many features of the administration of the patent system as it is.

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Continued from page 220.)

CHAPTER VIII.—FIELD MAGNET COILS.—(CONTINUED.)

In order to calculate the diameter of the wire by this method, it is necessary to know the mean length of one winding of a magnet coil. But this is itself dependent upon the size of the finished coil which however is not yet known. A formula might, therefore, be deduced which should give the diameter of the wire directly without first knowing the length of a winding, but it has been found that such a formula is too complicated to be of much use to the practical builder of dynamos. In place of such a complex formula the following approximate method will be found to answer equally well, and to be much simpler in most cases.

If the depth of winding, or thickness of a coil, be too great, the proportions of the machine will not be the best, as the outside layers will be very long and far removed from the iron, and although the economy in the iron might be great yet the more important economy in copper will be poor, and the iron will probably be over-saturated. On the other hand if the depth of winding is too small, the economy of iron will be poor, that is, the magnets will be longer and therefore heavier than is necessary, while the economy of copper will be good. There must, therefore, be a certain depth at which the economy as a whole, considering both the iron and the copper, is best. Until more extended experiments have been made to determine more accurately the best proportions, it will be found to give fair results to make the depth of winding about one-third of the diameter of the core, if round, and one-third of the lesser diameter, if oval.

In order to find the mean length of one winding, it will be sufficiently accurate for all practical purposes to assume a depth of winding as described, and from this, together with the dimensions of the cross-section of the core, to calculate the mean length of a turn. If the thickness of the finished coil should then be found to be slightly different from that assumed, it will make very little difference in the mean length, for in an actual case it was found that diminishing the depth as much as 50 per cent. decreased the mean length of one turn only seven per cent.

For an oval coil not too flat the lengths of the inside and outside layers are in the proportion

$$\frac{a+b}{a+b+4c}$$

in which a and b are the length and breadth of the cross-section of the core and c, the assumed depth of winding. From this the mean length of a turn in inches will be

$$l_m = l + \frac{2cl}{a+b}$$

in which l is the periphery of the core or the length of one turn of the lowest layer, all dimensions being in inches. For a circular coil the diameter of whose core is D, the mean length of a turn will be

$$l_m = \pi (D + c)$$

which if c is one-third of D, becomes

$$l_m = \tfrac{4}{3} \pi D = 4.189\ D$$

Having thus found the mean length of a turn, there remains only to substitute its value in the above formula for d, in order to calculate the diameter of the bare wire, which when wound to the proper number of turns will have such a resistance as will enable the proper current to flow through the coils when the exciter has the potential stated at the outset. There is one condition however, which must be fulfilled, namely that the actual depth of winding should not exceed that which has been assumed, as the resistance may otherwise be too great. In general, if the actual depth of winding is found to differ greatly from that which has been assumed it shows that the magnets are not proportioned as well as they might be. It is necessary, therefore, to check the results obtained, and at the same time to see whether the magnet cores are properly proportioned, by proceeding as follows. Having calculated the diameter of the bare wire, as described, find what the outside diameter of the insulated wire is, which may be done by winding closely ten turns around a mandrel, and measuring the length of this small coil in inches and decimals, which when multiplied by 100, will give the outside diameter of the insulated wire in mils; let this be represented by d_1. Dividing this into the length of a core in inches multiplied by 1,000 to reduce it to mils, will give the number of turns per layer, and this divided into the number of turns per coil found at the outset, will give the number of layers, from which the depth of winding is readily found, as it may be taken approximately equal to the number of layers multiplied by d_1 in mils, and divided by 1,000 to reduce it to inches.

If this is found to be about the same depth of winding as that which was assumed at the outset, then the core and coils are properly proportioned, provided other points such as the heating of the wire and the over-saturation of the core have been guarded against. If, however, this actual depth is much greater than that assumed, it shows that the cores or coil spaces are too short, and should be lengthened to such an extent that when the same number of turns are wound around the new core, the depth of the coil will not exceed about one-third of the lesser diameter of the core. If this actual depth is only slightly greater than that assumed, it may not be necessary to lengthen the cores of that particular machine, though it is advisable to make the change on the pattern if it is to be used for other machines; in case it is not changed for that particular machine, it is advisable to make a new calculation for the depth and the mean length of a winding found from the first calculation.

If, on the other hand, the actual depth is found from the calculations to be less than that assumed, the machine may be finished without any alterations in the size of the core; but, as the core in this case is longer than it needs to be, it would be better for the sake of economy of iron, to shorten the cores so that the same number of turns on the shorter core would make the thickness or depth of winding about that which was assumed; the machine would otherwise be uselessly heavy.

It is assumed in these cases that the magnet frames are not over-saturated more than is desired, and that the coils do not heat too much. In order to guard against over-saturation, it is preferable first to make the test for saturation, which will be described in a subsequent chapter, in order to know to what extent the ampere-turns may be increased in case the magnet frame is over-saturated, or the cores improperly proportioned. This test gives the greatest number of ampere-turns which should be used on that machine. If the number of ampere-turns which are required to generate in the armature the required potential and current be found to exceed this limit, it shows that some or all of the iron parts of the machine are too small for the required magnetism, and that, if the machine is to be properly proportioned, the cross-section of the iron parts, measured perpendicularly to the lines of force, should be increased by a certain definite amount which can be calculated as described in chapter vii. If the iron is not over-saturated to a great extent, it may be possible to finish the machine without altering the size of the iron parts, by increasing the depth of winding or the amount of current or potential allotted to the coils, or both, but the machine will then evidently not have the best proportions. If, on the other hand, the number of ampere-turns, which are required to generate in the armature the required potential and current, be found to be much less than the limit obtained from the saturation

Digitized by Google

test, no alterations in the size of the iron parts are necessary, but as this shows that there is more iron than is essential to produce the required results, the machine is uselessly large and heavy, and therefore has not the best proportions. It would be preferable to reduce the cross-section of the iron parts, as described in chapter vii., in order that they may be just at the point of saturation, or slightly above it, if desired, for the sake of steadiness of current.

To guard against heating, the following general rules may serve as a guide: In large magnet coils the current density in the wire may be about .001 to .0015 amperes per square mil or .00079 to .0012 per circular mil[1] of cross-section of the bare wire, which is equal to about 1000 to 1500 amperes per square inch, or 1000 to 650 square mils per ampere, or 1300 to 850 circular mils per ampere. In magnet coils made of fine wire, as in shunt machines, the current density in amperes per square mil may be slightly higher than in coils of coarse wire, as in series machines. The size of the wire should, therefore, also be determined from the current in order to guard against heating, besides being calculated from the formula first given, in which it depends on the allowable resistance. Should these two values for the diameter differ, the larger of the two will have to be taken in order that both the resistance and the heating will not exceed the limits.

But a rule of this kind in which the current is limited only by the cross-section of the wire, although very simple in its application, is not sufficiently general to be relied upon in all cases. While it will give fair results for similarly proportioned coils, not differing too much in the actual sizes, it is less reliable for coils whose proportions and dimensions differ very considerably from those from which the constants were taken, which were ordinary oval machine magnets, not too long, having a moderate depth of winding, and which were exposed to the air on all sides. A much more reliable rule, though less convenient and not as simple in its application, is based on the following considerations: The heat in a coil is developed by the watts or volt-amperes which are consumed in the coil itself; this is a constant and continuous supply of heat which would continue to accumulate and ultimately destroy the coil if it were not continually dissipated from the outside surface of the coil as well as from the outside surface of the iron parts in the immediate neighborhood of the coil. The dissipation of the heat will depend on the temperature and on this exposed or outside surface, which for simplicity in calculations will be limited here to that of the coil alone. The coil will therefore increase in temperature until the heat dissipated is equal to that generated in it. In calculating a coil to guard it against heating too much, it is therefore better to consider only these two factors, namely, the watts consumed in the coil and the outside surface of the coil. The density of the current in the wire, or, in other words, the cross-section of the wire as compared to the current, may be neglected entirely, for it is evident that if the outside surface of the coil, and the number of watts consumed, be the same in any two coils, the heating will be the same no matter what the current per square inch is. For instance, suppose two magnet coils are wound so as to have the same external dimensions, one having two layers and the other one layer of the same sized wire; the resistance of the former will be about twice that of the latter. Now if the current is 10 amperes in the first case and 14 amperes in the second, the energy in watts will be about the same in both cases, and as the external cooling surface is also the same, the heating will be the same, notwithstanding that the current density is very much greater in the second case than in the first. The same result might be shown with coils of unequal sizes and shapes, having different depths of winding. In general, the current density may be greater the less the depth of winding or number of layers.

1. A circular mil is the area of a circle whose diameter is one mil.

In an article by Prof. George Forbes,[2] he deduces the following general laws regarding the heating of coils: In coils of the same size but wound with wires of different diameters, so as to occupy the same volume, the current must vary as the cross-section of the wire, in order that they attain the same temperature. In other words, in such coils the current density in the two wires must be the same. Another deduction is, that in two coils of similar shape (the linear dimensions and the diameter of wire of the one being n times that of the other), the squares of the currents will be proportional to the cubes of the linear dimensions when the heating is the same. In other words, if one coil is twice as large in all linear dimensions as another, and has wire of twice the diameter, the square of the current in the larger one may be made $2^3 = 8$ times as great as the square of the current in the smaller; that is, the current in the larger may be $\sqrt{8} = 2.8$ times that in the smaller, in order that both attain the same temperature.

In the same article he gives a formula which he states agrees with what is actually found in practice. From this the following practical rules may be deduced: A watt of electrical energy will be dissipated for every 800 square centimeters of external surface of the coil, when the temperature of the coil is 1° centigrade higher than that of the air; reducing this to our ordinary units, it is 223 square inches for 1° Fahrenheit. The number of watts which can be dissipated from a given surface of coil increases directly with the temperature which the coil may have above that of the atmosphere; that is, for double the increase in temperature the watts in the coil may be twice as great; or for the same allowable temperature, it increases directly as the surface of the coil is increased. The same rules may also be stated as follows: The rise of temperature above that of the atmosphere will be 1° centigrade for every watt and every 800 square centimeters of surface; or 1° Fahrenheit for every watt and every 223 square inches of surface. For the same surface it increases as the number of watts, or for the same watts it increases as the surface decreases. Every square centimeter will dissipate a watt at 800° C. above the atmosphere, and every square inch will dissipate a watt at 223° F. above the atmosphere. The surface must increase with the watts or decrease as the allowable temperature increases.

All these rules may be expressed by the formula,

$$W = \frac{1}{800}\, t\, s$$

in which W is the number of watts lost in the coil; t is the temperature in centigrade degrees *above* that of the air; s is the outside surface of the coil in square centimeters.

In the other units it will be

$$W = \frac{1}{223}\, T\, S = .004476\ T\, S$$

in which T is in Fahrenheit degrees, and S in square inches.

In place of the number of watts, W, may be substituted the equivalents $C\ E$, $C^2\ R$, or $\frac{E^2}{R}$, in which C, E and R represent the current, electromotive force and resistance, respectively, of the coil, the resistance being that at the temperature to which the coil may be raised. For instance, substituting $C\ E$ for W and reducing, gives

$$C = \frac{T\, S}{223\ E}$$

2. Proceedings of the Society of Telegraph Engineers and Electricians, March 24, 1884.

Digitized by Google

which gives directly the greatest current which can be used in the magnet coils of a shunt machine having a certain potential, in order that they do not heat above an allowable temperature; this current can therefore be calculated even before the winding has been determined, as it is independent of the number of turns or the resistance, if only the size of the external surface is known approximately; this maximum current should never be exceeded.

Numerous other useful formulæ can be deduced in the same way. For instance, if a maximum rise of temperature of 80° F. above that of the air is allowed for the magnets, the greatest allowable current will be

$$C = .36 \frac{S}{E},$$

or if the resistance instead of the electromotive force is known,

$$C = .60 \sqrt{\frac{S}{R}}.$$

Similarly for series wound magnets in which the current is known, the formula will give the greatest resistance which may be given to the coils in order not to heat too much; thus,

$$R = \frac{T\ S}{223\ C^2},$$

and if the limit is a rise of 80° F., the greatest allowable resistance will be

$$R = .36 \frac{S}{C^2}.$$

As these formulæ give the resistance at the higher temperature, allowance should be made for this increase in determining the resistance cold. Every degree Fahrenheit increases the resistance about two tenths of one per cent., (.2 per cent.) therefore at 80° above the normal temperature it would be $1 + (.002 \times 80) = 1.16$ times too great, and should therefore be divided by this number.

The same formula may be used equally well to find what the surface of a coil should be. Thus,

$$S = \frac{223\ W}{T}$$

which for a rise of 80° F. is

$$S = 2.8\ W.$$

As the number of watts to be allotted to the magnets is generally known approximately at the outset, this formula enables one to determine about what the least surface of the coils should be, and as the cross-section of the core is known, and by assuming a depth of winding of about $\frac{1}{3}$ the diameter, the least length of the core can readily be determined. This should, however, be used only as a guide, as the dimensions may have to be larger on account of the limited resistance of the coils.

In general, when the coils are short and have a great depth of winding, or when a relatively large percentage of the total energy of a machine is consumed in comparatively small coils (which is frequently the case in small, cheap, or poorly proportioned machines), the heating limit will determine the size of the coils, as the size calculated from the allowable resistance would give smaller values, which would cause them to heat too much. On the other hand, when the coils are long and have only a few layers, or when the percentage of energy in the magnets is comparatively small (which is frequently the case with large well proportioned machines), the sizes will depend chiefly on the allowable resistance, as the heating limit will generally give smaller values. But these are only general rules; they may vary greatly in special cases.

(*To be continued.*)

FLAD'S OVERHEAD WIRE SYSTEM FOR CITIES.

Much interest is manifested by electricians in the overhead wire system invented by Col. Henry Flad, of St. Louis, as a substitute for the expensive underground systems proposed for large cities. It was a bold and felicitous thought of Col. Flad, to hang electric wires from lofty towers, above the housetops for the most part, and high enough to avoid the difficulties experienced from ordinary pole lines.

The accompanying illustrations will convey a clear idea of the system in its general features.

Figure 1 gives an isometrical view of the towers and cables; figure 2, the elevation and plan of one span.

The towers are usually placed at street intersections, and consist of four iron columns, fixed at their lower ends in a foundation of masonry or concrete, and located at the intersection of the curbs. The posts slant towards the centre of the intersection of the two streets, and on top they terminate in a square frame, of about eight or ten feet side. The height of the towers is determined by the condition that the suspension cables stretched between the towers should, at their lowest points, be still above the uppermost windows of the houses already built, or probably to be built, along the street on which the towers are placed. Their height will, therefore, vary from 80 feet, in the suburbs, to 120, or even 130 feet in the business part of the city. The towers are placed at such distances apart, as will be most economical, either one, two, three, or four blocks, or say from 300 to 1,500 feet.

The steel wire suspension cables, by which the weight of the electric wires and cables is to be supported between the towers, are never less than two in number, and where two suspension cables only are used, their ends are fastened to the tops of adjoining towers in such a manner that they can be lengthened or shortened at will, within certain limits. This is necessary in order that the two cables of every span may be adjusted to the proper elevation and curve. When so adjusted, the two cables are parallel, and have the same elevation throughout the whole length of the span. The horizontal distance between the two cables is generally from 8 to 10 feet, and a vertical plane passing through the centre line of the street will pass through a line midway between the two suspension cables.

At short distances apart, say at every 25 feet, measured horizontally, the two suspension cables are connected by a stiff bar, or pipe, which will hold them at the proper distance apart when the wheels of the truck, hereafter to be described, pass over it, or when the wind or some other outside force tends to produce oscillation of the cables. On these cross bars, or tubes, are carried the electric cables and wires, resting on proper supports. At the centre of each cross-bar or tube, on all lines consisting of but two suspension cables, a vertical strut is attached to the lower side of the cross-bar, and from the lower end of this short strut, iron tension rods pass to the ends of the cross-bar or tube. The lower ends of the struts attached to all the cross bars, may be connected by a small wire, to keep them in a vertical position, under the effect of high winds. When a conducting wire is to be carried from the cross-bar to a house, it is first attached to the bottom of the strut, and thence to the house. Lines with only two suspension cables are used when the number of electric wires and cables to be supported is small, and may be designated as auxiliary lines.

On lines which have to accommodate a greater number of wires, a third steel wire suspension cable is added, which is stretched parallel to and about 8 or 10 feet below the two main suspension cables in a vertical plane passing through the centre line of the street. To the ends of the cross bars iron frames are fixed, and instead of the short struts used on the auxiliary lines, a long strut is used, extending from the centre of the crossbeam to the lowest point of the frame, and there strongly connected

Digitized by Google

with it. At the lowest point of the frame a fork is fixed, in which the third suspension cable can move freely up and down, while it is held by it against lateral motion. The frames carry, at short distances apart, insulators, to which single wires can be attached. When a wire is to be taken to a house, the single wire is led from its insulator on the side of the iron frame to the third cable, and thence, after having been attached to that cable, carried to the house, so that it shall not be in the way of the traveling truck, which will hereafter be described.

When the capacity of the line is to be still further increased—which will be necessary in but few cases—two more suspension cables are fastened to the towers, and stretched parallel to, and directly under the two first main cables, at such a distance below them that they are about the middle of the span of the main lines. When the two lines pass each other (at the lowest point of their catenaries), the suspension cables of the auxiliary line are so stretched that their lowest position is a little below the lowest point of the short strut attached to the cable cross-bar, when the main line, crossed by the auxiliary line, consists of but two suspension cables; and a little below the lower end of the frame on lines composed of three or five suspension cables. The two lines crossing each other are connected in such a manner that they can have an independent motion vertically, but steady each other against lateral oscillations. On very long spans, and when no auxiliary line crosses at the centre of the span, it might sometimes be necessary to steady the suspension cables against high wind, by attaching a wire at the lowest point

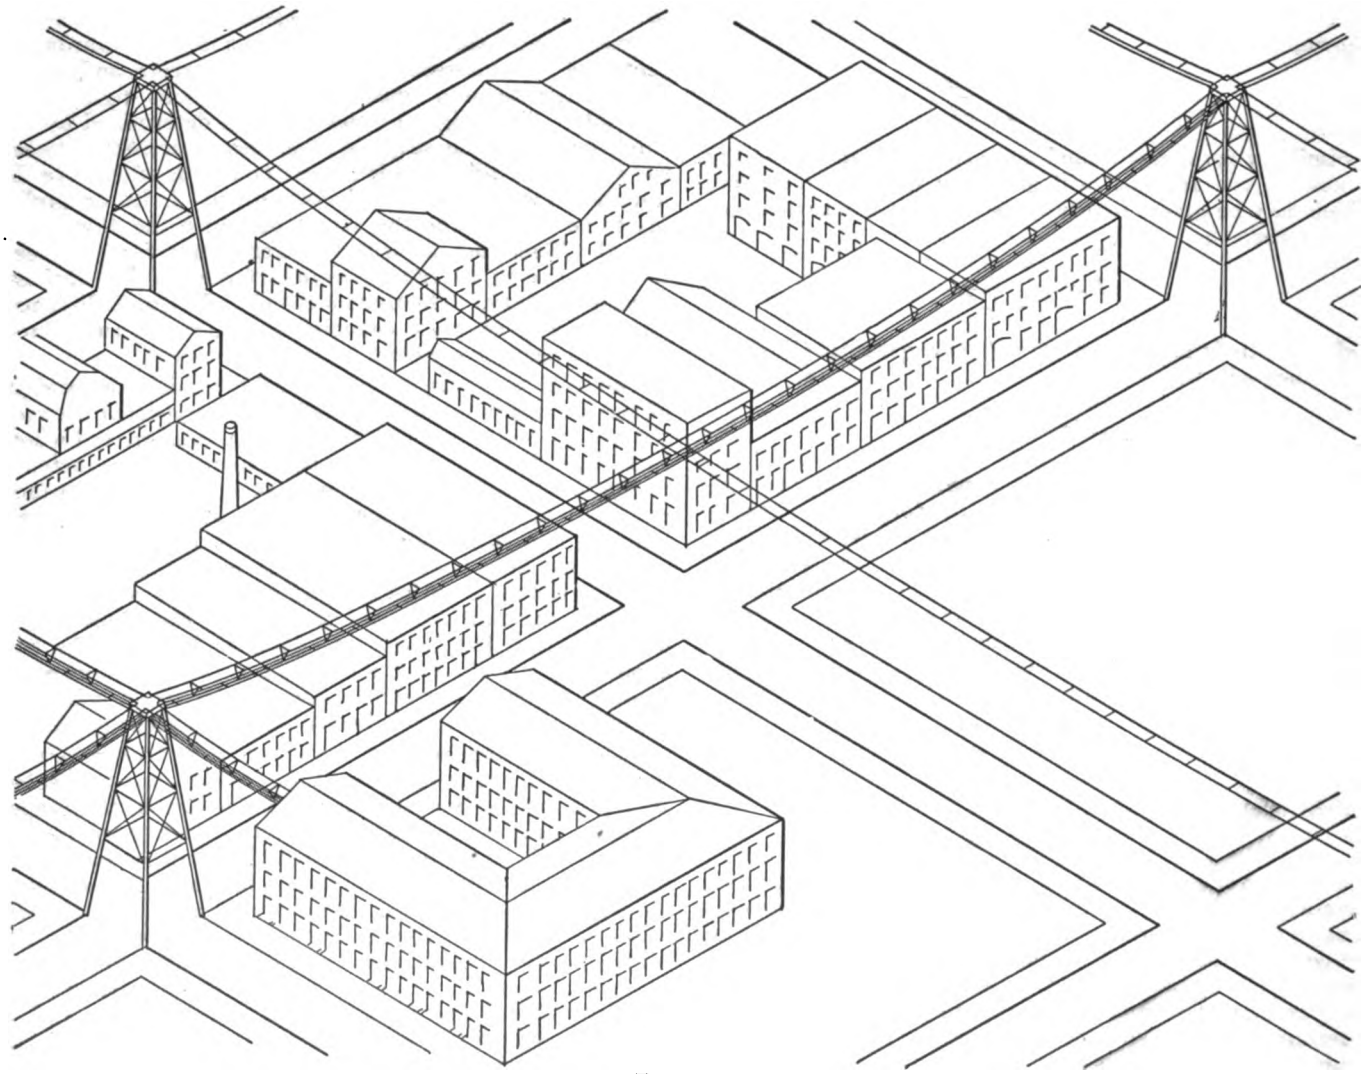

FIGURE 1.

on a level with the lower ends of the iron frames. These two suspension cables are connected together by cross bars, like the upper suspension cables, and their cross bars pass through forks attached to the lower ends of the frames; these forks allowing a slight vertical motion of the lower set of parallel suspension cables, but preventing lateral motion. The suspension cables are stretched to a catenary, having a very short versed sine, and, therefore, are under great strain, which, however, they are fully able to stand, being composed of the very best steel wire, but to which no other metal could be subjected. The suspension cables, in consequence of this small versed sine, are not much exposed to lateral oscillation from the effect of wind. But, for additional security, the lines, wherever practicable, are so arranged that the auxiliary lines pass through to each suspension cable, and fastening the other ends of the wires to vertical way posts, erected for the purpose.

The whole system of towers and cables may be so arranged that any line can be gradually transformed into one of greater capacity, without interfering with the electric service, while the change is progressing. In this way the first cost of the lines can be kept low, the lines being constructed of a capacity for the requirements of the present, or of the near future, and gradually brought to their ultimate capacity by reducing the spans (by the erection of intermediate towers) and by increasing the number of suspension cables from two to three, four or five.

The advantage over the conduit system derived from the facility of gradually extending the capacity of the

Digitized by Google

system, without changing the plant already in place, without interrupting the electric service, and without causing any interference with the streets or with traffic (except what would be caused by the erection of intermediate towers, requiring a hole 6 to 10 feet square at each of the four curb intersections) must be apparent. Conduit systems require frequent disturbance of streets and interference with traffic, unless at the start they be made large enough for their ultimate capacity, which is impracticable on account of cost.

TRUCKS.

To enable the linemen to place and repair the wires and cables, and to make connections with houses, it is intended to use trucks with four wheels, supporting a light platform. They are to be placed on the two upper horizontal suspension cables, and the latter are to act as rails, on which the truck runs. The wheels of the trucks are broad, and have very wide flanges, to prevent the trucks running off the track. The wheels are provided with rubber tires, to prevent injury to cables. One truck of this kind is to be provided for every span, and, in some cases, two. The cars, when not used, are fastened to the towers. They may be moved by the workmen to any point of the span, either in the ordinary way by use of an endless rope or in the following manner: a steel wire, of say three-eighths of an inch diameter, is stretched at the same distance above the two upper parallel suspension cables as the groove in the two rollers attached to a frame placed at one or both ends of the platform of the truck. These rollers carry cog wheels on their axles, so that when one is revolved by means of the crank, they rotate in opposite directions. The frame carries on its top, a screw, by means of which the distance between the rollers may be adjusted. A spring is interposed between the end of the screw and the block (moving between guides) to which the axle of the upper roller is attached. By giving the screw a turn to the right, the two rollers are made to take hold of the steel wire, with any desired force; and if the truck is to be moved from the towers towards the lowest point of the catenary, the speed of the descent may be regulated either by use of this screw, or by the crank. To ascend towards the towers, the pressure on the wire is, by means of the screw, brought to such a point that sliding of the wire through the grooves is prevented, and then by turning the crank, the car is made to travel up the incline. The car may be held in position at any point of the span, by stopping the motion of the crank, and increasing the pressure on the wire.

The platform being only a few inches above the devices for attaching the cables and wires to the crossbeams, a

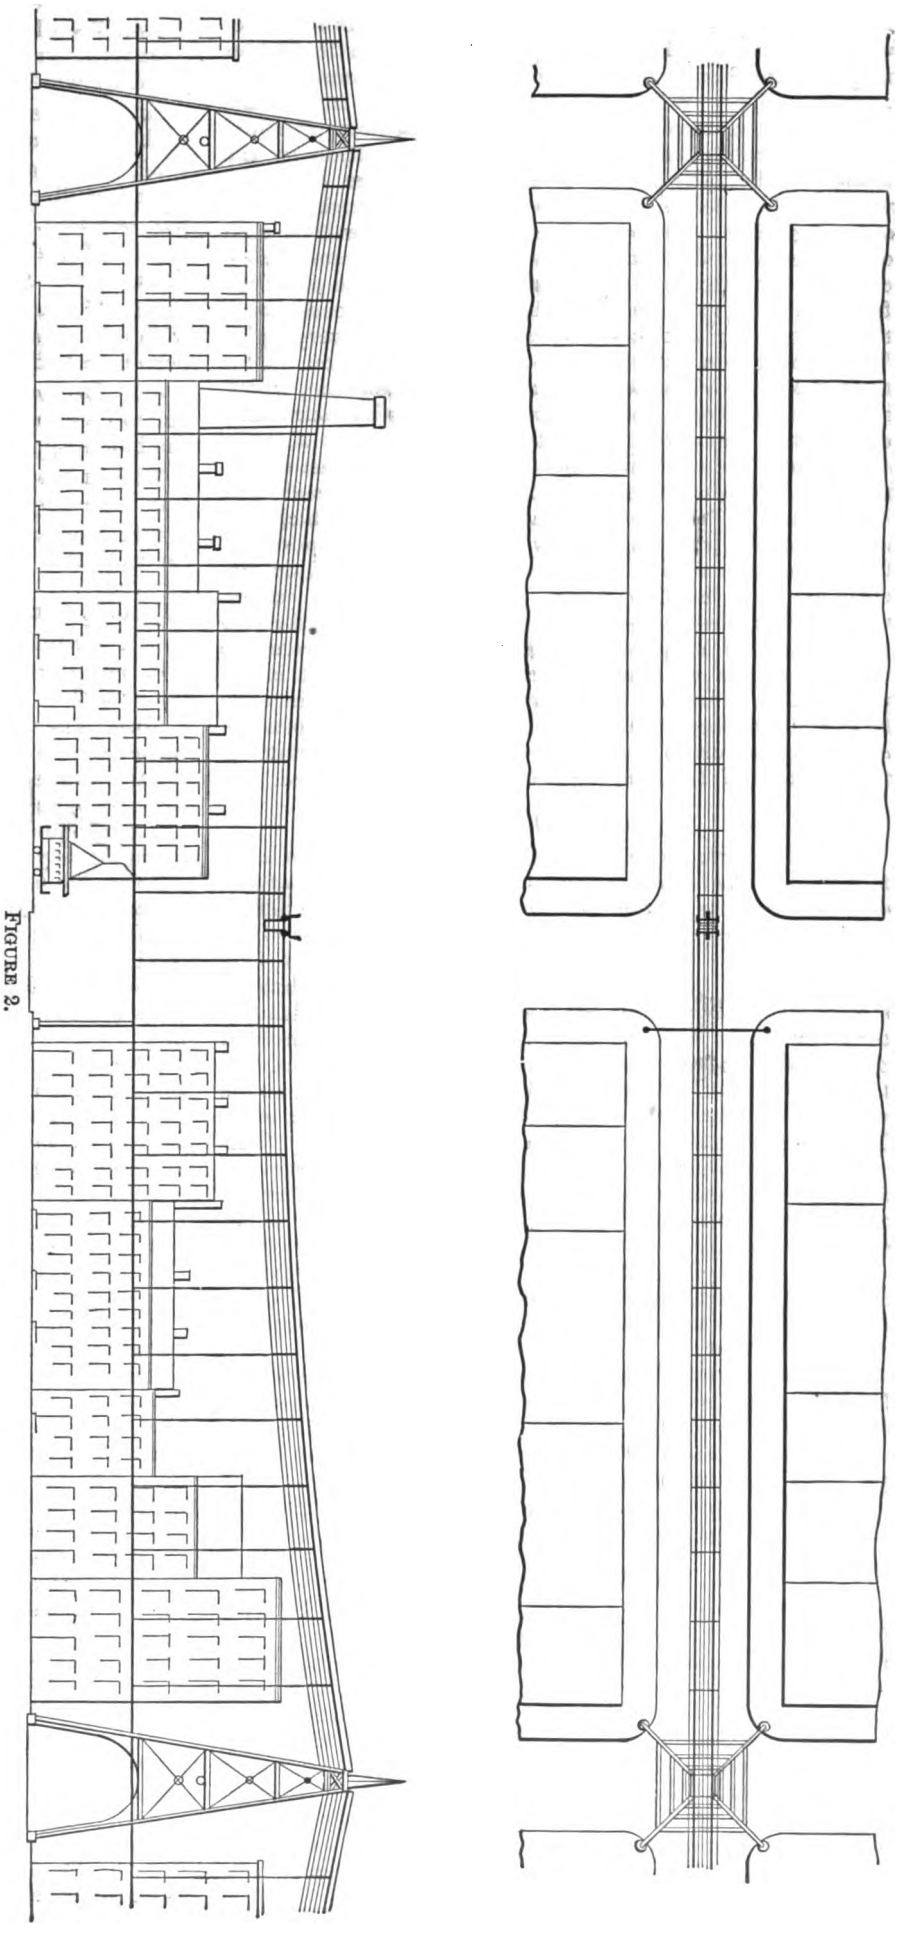

FIGURE 2.

Digitized by Google

workman sitting or lying on the platform of the car can inspect or repair them or make the attachments to houses with ease and speed. In laying cables or wires the latter may be placed on a reel and the work may proceed almost automatically. When the wire reaches the towers the reel is carried across the tower on a platform provided for that purpose and placed in its proper position on the truck of the next span. Even two or more cables or wires might thus be laid at one trip, saving much in cost of laying wires. The car as herein described will be used on lines composed of only the two parallel upper suspension cables. For auxiliary lines two trucks must be provided for each span, as a truck in this case cannot pass across the main line; but these trucks can be made very light. When the line consists of three or five suspension cables the truck is provided with a platform on each side, which is suspended from the axles of the wheels by four links, and at such elevation that both platforms are at a slight elevation above the third central cable. Workmen standing on these suspended platforms can easily reach and handle any of the electric cables and wires which are carried on the iron frame, or where lines are composed of five suspension cables, also those cables deposited on the cross bars of the two lower parallel suspension cables, while the cables and wires on the cross bars of the two upper parallel suspension cables are reached from the upper platform of the truck as before. When it is expected that a line of two suspension cables will in time have to be changed into a line of three or five suspension cables the truck is constructed with a view of admitting the addition of the hanging platforms when required.

COST OF PLANT.

This, of course, depends on the extent and kind of electric service required, on the plan and topography of the city in which the system is to be introduced, on the height of its buildings, on the greater or less compactness of its improvements. To obtain some idea on this point, Col. Flad assumes the system introduced in a city having streets 60 feet wide and 300 feet apart, and comprising a territory about two miles long and one and one-third miles wide, giving a total area of about 1,500 acres, and that the number of houses to be supplied with telephone wires is 10 to every 360 feet of streets, or 150 per mile. The total length of streets being over 80 miles. This gives 12,000 houses to be supplied with telephone service, all to be connected with one central station. He further assumes that an electric arc light be installed at every second street intersection and supplied with electricity from the same central station as the telephone service, and that a certain number of conductors for all other electric purposes, to be supplied from district stations, will be required.

On these suppositions he has calculated the number, height, weight and cost of towers, the cost of cables and trucks, and found that the average cost of plant, if every street is fully provided for, will not be more than $3.00 per linear foot of street.

Col. Flad expects to give the calculations for publication in a later paper.

STREET CAR SERVICE.

The towers and cables of this system may also be used for supporting above ground conductors to supply electricity for electric motors, used in operating street cars. (See figure 2.)

The waste of the electric current will be much smaller under this arrangement of conductors than if the latter are placed in an underground conduit. All danger,—even with currents of high tension, is avoided, and the additional cost of plant, when arranged for street car service, will be but a small percentage of the cost of an underground conduit, which is to accommodate the electric conductor for a single street car line.

Col. Flad claims the following advantages for his system.

1st. The electric conductors are supported at such short distances apart that there is no danger of their being injured by wind or by the accumulation of sleet.

2d. For the same reason they cannot come into contact with each other.

3d. The system allows electric conductors to be placed at proper distances apart from each other so that induction will be small.

4th. There will be less retardation than on underground lines.

5th. If a wire should break it cannot come into contact with any other wire, with a house, or with any vehicle or person traveling on the street.

6th. Every house has its own connection, and no wire has to be carried over any lot of ground not belonging to the house supplied.

7th. In case of the house burning only its own connection is destroyed; all others remain unaffected.

8th. The wires are carried so high up in the air and so far from the houses that they cannot be injured or destroyed by the heat arising from a conflagration of adjoining houses.

9th. Neither the towers nor the suspension cables interfere with the operation of the fire department in placing ladders, &c.

10th. The laying and repairing of cables and wires will be much less costly than at present.

11th. Naked wires can be used to a great extent and the cost of insulation avoided.

12th. The system can be extended without removing or changing any part of the plant.

13th. No interference with, or injury to the wires by malicious or ignorant people is possible.

14th. The towers may be used for carrying rods protecting surrounding property from lightning.

15th. Stand pipes may be erected, in connection with towers, which will protect surrounding property in case of fire.

16th. The towers allow electric lights to be placed at the most effective points and at the proper elevation.

17th. The towers will be ornamental, and the archways, having a clear height of 35 or 40 feet, will not prevent the passage of any vehicle or obstruct the view.

18th. Every tower dispenses with 40 to 50 telegraph poles from one to two feet in diameter.

19th. The four columns of a tower are so located that they do not interrupt the travel on sidewalks, while the present poles greatly obstruct them.

20th. The system allows electric motors to be used for street railroads, without underground conduits.

21st. The additional cost arising from arranging the system for carrying the electric conductor to supply motors on the street railroad will be so small, when compared with the cost of conduits, that the electric motors may be universally introduced and the use of horses dispensed with.

22d. The cost of the plant, under this system, will be so much less than that of underground lines, and the interests to be accommodated by it of such number, that a law enforcing all electric conductors to be placed on the cables would work no hardship to any interest.

23d. The use of this system will leave room under the streets and sidewalks for gas pipes, carrying cheap gas (the fuel of the future), water pipes, &c.

24th. No danger to life or property can occur from conductors carrying high tension electric currents for furnishing light or motive power.

25th. The prices to consumers for electric service of all kinds can be reduced without loss to companies.

26th. The more general use of electric power will be assured by the cheapness of the plant.

ELECTRICAL DISTRIBUTION BY ALTERNATING CURRENTS AND TRANSFORMERS.[1]

BY RANKIN KENNEDY.

(Continued from page 188.)

I.—SYSTEMS.—(CONTINUED.)

THE distribution of power by continuous currents of electric energy and electric motors requires motors which conform to exactly the same laws of action as far as their counter E. M. F. is concerned as alternating current transformers, in fact, an electric motor is simply a transformer, and its actions, government and regulation, are similar in every respect to those of a well designed induction coil transformer.

A system of distribution in parallel connection with constant E. M. F. supply demands a motor which shall have a counter E. M. F. very nearly equal to the E. M. F. in the supply conductors when no load is on the motor, and this counter E. M. F. should fall directly as the load is thrown on, and if this fall of counter E. M. F. is proportional to the load thrown on and sufficiently great, then the motor becomes self-regulating, always supposing this action to take place at a constant speed of rotation of the armature.

It is easy to calculate the required fall in counter E. M. F. to meet any given load thrown on to the motor with any given E. M. F. of supply. On the other hand, motors to be run in series order in the circuit of a constant current supply should be so constructed, that when no load is on the motor there should then be no counter E. M. F., or at least an amount of counter E. M. F. too small to be taken into account in the motor, and this counter E. M. F. should increase directly and proportionally as the load is thrown on the motor.

Motors constructed to satisfy these conditions even approximately would solve the problem of the distribution of small powers by electricity. I know not whether the method of winding motors with demagnetizing regulating coils brings about this rise and fall of counter E. M. F. in motors, but I think that is the intention of winding them in such a manner.

I make these remarks here on the transformation of electric energy into power, or work, for the purpose of drawing attention to the similarity existing in the problems of transforming electric energy. The control of the counter forces is the only important point to attend to in constructing electric motors for transforming and distributing electric energy for motive power purposes; and this very point having been neglected may explain why not a single installation of electric motors driven from a common supply yet exists anywhere in this country.

To return to our subject, I may point out an error which some writers have fallen into when speaking of working alternating current transformers in series order. They say "a high tension current of small quantity passes through the whole system and this high tension current is transformed at the points requiring the lights into a current of low tension and larger volume;" now such language cannot be used in relation to a series system of distribution. In a series system the high tension exists only at the generator; at the terminals of the transformers the potential may be anything less than the potential at the generators; that depends entirely on the work being done in the secondary circuit.

In speaking of the series system we should remember that transformers working at constant current supply are designed, or rather ought to be designed to transform a constant current into a current which may be less in volume or greater in volume than the original current; they are then current transformers.

In speaking of the parallel system we should remember that in this system the potential at the terminals of the transformers is constant and high, and this constant high potential is transformed into a constant low potential in the secondary circuit; transformers in this system should be called electromotive force or potential transformers.

We want a current transformer for the series system, and a potential transformer for the parallel system.

As an illustration of this error in speaking of these systems of distribution, I may refer to page 185 of Gordon's work on electric lighting, where it is stated in connection with a series system of distribution, that the current is conveyed as a small current at high pressure, and an induction coil is placed in each house to transform this high pressure current into a current of more quantity and less pressure. Now, any system of distribution is not worth considering unless a large number of consumers can be supplied from one circuit, and supposing a pressure of 2,500 volts to be maintained at the generator as a maximum pressure, we should require about 40 amperes of a constant current in the mains *and also in the primary circuits of all the transformers* to distribute a little over 12,000 incandescent lamps.

Would 40 amperes be a small current capable of being carried without loss through a long thin wire? No. Again, it is obvious that a good many houses would do with less than 40 amperes, and in these cases a transformer there would have to generate a secondary current of *greater pressure and less quantity* than that in the primary circuit of the transformers; the word *pressure* should not appear at all in connection with transformers in series. The sentence in this book describing the system should read, "An alternating current of *constant* quantity is sent into the primary and induces in the secondary a current of more or less quantity to meet the demand according to number of lamps in use." Even the pressure at the generator would not be always *high;* the pressure there would be extremely low sometimes, say during the day when only about 50 lamps might be in use in the system.

Then, again, it is stated that the primary wire is a thin wire and the secondary a thick wire; in transformers in such a system that is also a mistake. Whether you use the thick wire for the secondary and the thin for the primary, or *vice versa*, depends altogether on whether you want a greater or a less current in the secondary than the fixed constant current in the primary. If the fixed constant current was 40 amperes and only 10 amperes wanted for use, it would be absurd to make the secondary wire carrying the 10 amperes thicker than the primary wire carrying 40 amperes; and further, given a good constant current transformer, it would be quite possible to light a large area with transformers in series, every one of which would have a thicker wire and a greater current in the primary circuit than in the secondary circuit.

A current transformer has yet to be invented, but fortunately for electrical distribution, all induction coils, converters, secondary generators, transformers or transformators, by whatever name they may be called, are potential transformers from the first one made by Faraday, 50 years ago, down to the latest development; they are all naturally applicable for working in parallel connection and for transforming high potentials or low potentials, but this fact lay ignored or unknown until 1883, when I published my discovery of it in these columns.

Since then even the most enthusiastic of the promoters of the so-called series systems have quietly adopted the parallel system after meeting with the inevitable failure which awaits every attempt to apply the induction coil as a current transformer.

The series system is now abandoned, and we find Gaulard and Gibbs working the parallel system in the United States and in France, Zipernowski and Deri working the same system in Milan and Rome, and Ferranti working the same system in London.

Zipernowski and Deri's patent comes first after 1883, and is dated 16th March, 1885, No. 3,379. Figure 1 is taken from this, and illustrates the parallel system; here we have a

1. From the *Electrical Review* (London).

Digitized by Google

system of mains at high potential, M, N, and at I., II., III., we have systems of low tension mains supplied through transformers; at C, in plan III., we have a regulating transformer in series with the low potential circuit.

In this specification is described a very effective and ingenious method of regulation, whereby the electromotive force at the terminals of the dynamo-electric generators is maintained constant; this is done by using a transformer with its fine wire circuit in series connection with the main wires, M, N.

The current in the secondary circuit of this transformer is of low tension and large volume, and it varies in volume directly in proportion as the high tension current in the mains varies; this low tension current is made to flow round the field magnets of the generator in one direction by means of a commutator, and hence an increase of current in the main conductors is accompanied by an increase of strength in the magnetic field of the generator.

The next patent is Ferranti's, dated 11th December, 1885, No. 15,251, and to show what can be put into a British patent and give an idea of the contents of the specification, I give the whole claims here complete.

1. The improved means for distributing electric energy consisting in providing high tension mains and low tension mains, and causing each low tension main to be fed from the high tension main through two or more converters which are connected and disconnected as required.

2. The combination of electric circuits and apparatus substantially as described in respect to figure 1 of the annexed drawings.

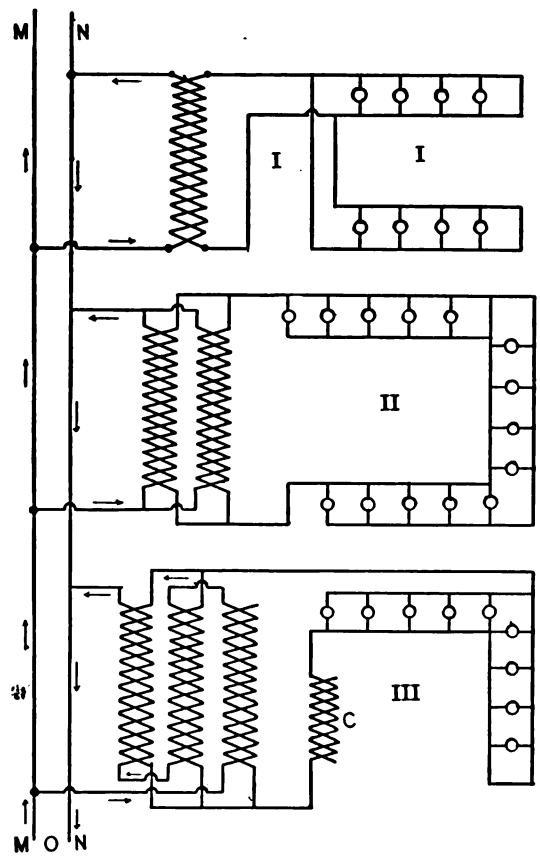

FIGURE 1.

3. An electric main consisting of two metallic tubes drawn one over the other with insulating material between forming part of the same circuit and maintained at a suitable difference of electric potential.

4. The method substantially as described for forming joints in electric mains.

5. The combination with a system consisting of a high pressure circuit, feeding low pressure circuits by the aid of electric converters connected by branches with the high pressure circuit; of fuses or automatic cut-out apparatus in the said branches operating to open the branch circuit when short circuiting occurs.

6. The combination of a high tension circuit, converter, low pressure circuit and fuse in the high tension circuit, substantially as described.

7. The application of fuses in combination with high and low tension circuits and converters substantially as described in respect to figures 6, 7, 8 and 9.

8. The combination of the dynamo a, producing alternating currents, the electric mains a^1 a^2; the two electrometers u u, and the earth connection v; the whole forming an arrangement in which an accurate indication of any leakage in the mains is obtained.

9. The combination of a dynamo producing alternating currents, a converter connected with the primary of the

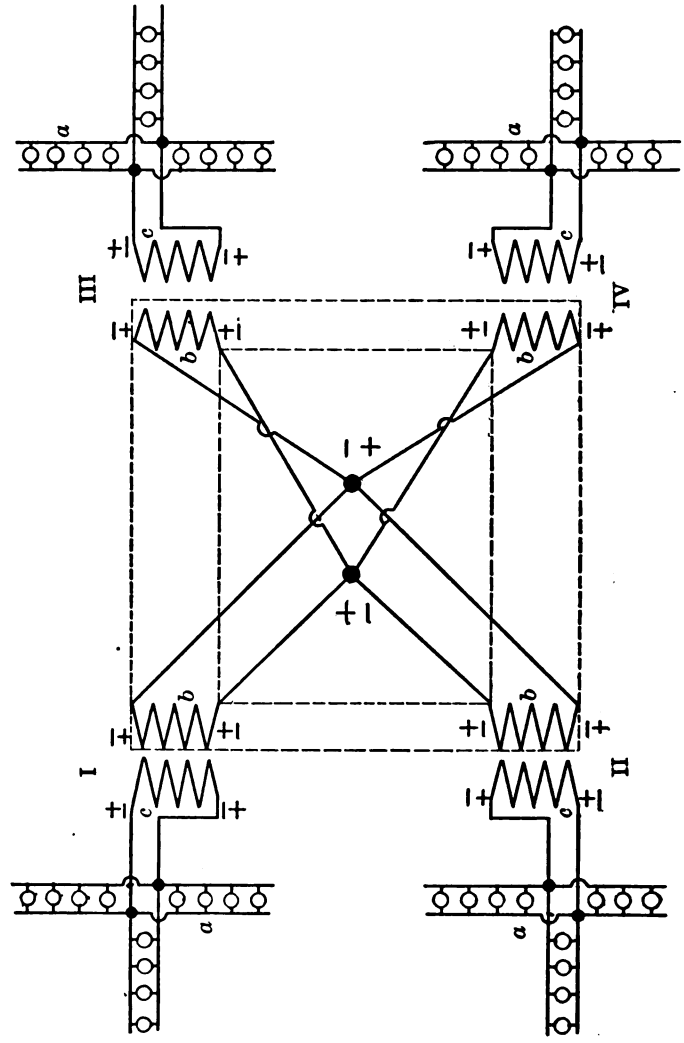

FIGURE 2.

dynamo, a wire in the secondary circuit of the converter expanding and contracting with the variations of the current therein and operating to correct any variation from the normal condition substantially as described.

10. My improvements substantially as described in the means for distributing electric energy.

The eighth claim is for a useful application of two electrometers to detect leakage in the mains.

The ninth claim is for a system of regulation by means of a converter placed in series order in the main wires as is done by Zipernowski and Deri, with this difference, that the low tension current is passed through a Sir William Thomson's regulator, a wire which expands or contracts as the current varies, and this expansion or contraction operates regulating apparatus—may for instance govern the engine which drives the dynamos.

Digitized by Google

Claims 1 and 2 may be compared with Zipernowski's prior specification; claims 3, 4, 5, 6 and 7 are interesting, as appearing in a patent for the distribution of electric energy.

The next patent follows Ferranti's 19 days later, and is by Messrs. Siemens and Halske, dated December 30th, 1885, No. 16,038. This specification shows no knowledge of the self-regulating effects of the counter electromotive forces in the generators themselves. The patent is purely for a system of laying mains and feeders from a central supply station and has some value as such, although for wide distribution it is hard to see how to apply this system. Figure 2 shows the system.

In the specification of Edwards and Normandy, 1878, a proposal is made to employ a converter for raising the potential of the dynamo-electric current, and from this converter to supply the other converters in the system; the same idea is thrown out by Ferranti in the specification hereinbefore referred to. Neither of these proposals have been put into practice, in fact no plan or method of carrying out the idea is described or claimed in either specification.

In 1886, I, with another, took this system in hand, and after a searching examination and practical testing adopted the arrangement illustrated in figure 3, which supplies electric energy from two large transformers to a three wire system; we may add another transformer and have four wires, and thus form a network of supply wires. The large transformers are preferably of a new type, which shall be explained under the head of "transformers;" they raise the pressure from 50 volts to 2,000 volts or 1,000 volts with a loss of less than two per cent., and they are fed from one or more dynamos.

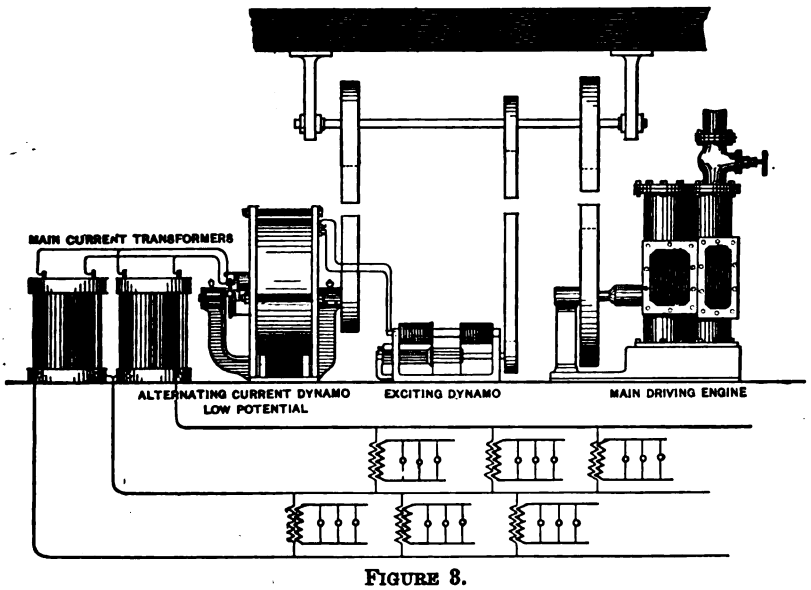

FIGURE 3.

It may be thought at first sight that the use of transformers to raise the pressure is somewhat like the fifth wheel to a cart, but we have reason to believe that there is more loss and less reliability in high pressure alternating current generators than there is in a combination of a converter with a low pressure alternating current dynamo-electric generator.

This completes the list of published specifications in Britain. In America the subject is just now attracting considerable attention; Gaulard and Gibbs having obtained a patent there for parallel connection. The current year will no doubt bring forward further developments, and by the end of it no doubt the parallel system will be in full swing on a large scale in this country as well as abroad.

TRANSFORMERS.

A system employing continuous currents in the main conductors at constant E. M. F. has often been proposed, notably by T. A. Edison, in 1883. In this system the primary currents in the transformers are rendered alternating by a rotating commutator. Enquiries have been made during the last year in every likely quarter, and numerous experiments have been made, but no information can be obtained as to how we are to construct the very pith and marrow of this system, namely, the commutator, which is

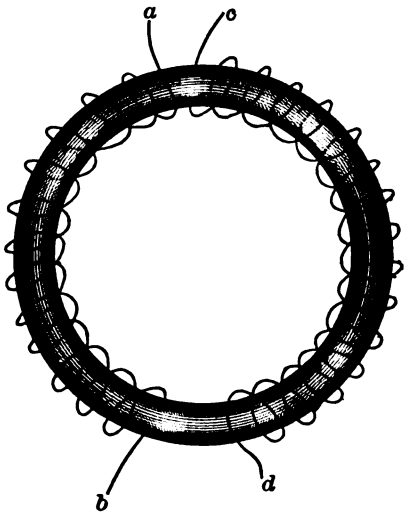

FIGURE 4.—FARADAY, 1835.

to reverse currents of 5 or 10 amperes at the rate of 120 reversals per second with a pressure of 1,500 or 2,000 volts. This patent is no doubt of great value as a patent, but

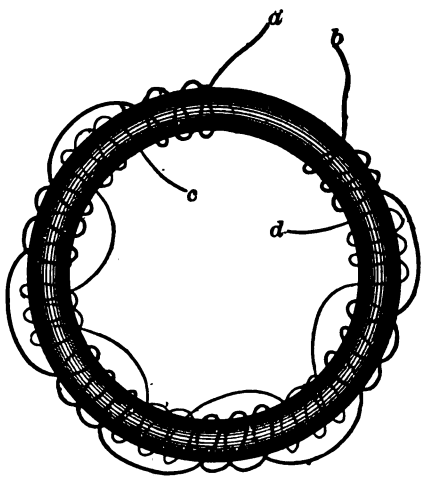

FIGURE 5.—KENNEDY, 1883.

somebody has yet to invent that commutator, and after that the inventor of it would be called up as an infringer if he put it into practice.

A far better system of generating alternating currents from a continuous current was invented by Mr. Henley many years ago; the instrument is described in Noad's Electricity, by W. H. Preece, page 358. If the commutator difficulty were overcome this machine, with a slight modification, would work well in a continuous current system.

We shall now see what has been the history of the transformers themselves; they have been developed by a true process of evolution from the original transformer of Faraday shown at figure 4. In this transformer we have all the elements of the best type of transformer; first, an iron core, which forms a magnetic circuit completely closed or formed of iron throughout; second, a primary conductor, A, B; third, a secondary, C, D.

In 1842 Rhumkorff's coil, figure 9, was invented; in this transformer we have an iron core forming a straight bar, and the magnetic circuit is completed through the air; we

Digitized by Google

have also the two conductors, A, B, and C, D. This form has received great attention during the last 40 years, and was employed by the earlier inventors in distribution systems up to 1883, notably by Jablochkoff and Gaulard and Gibbs. Like the series system with which it was connected, it has now been abandoned in favor of the transformer invented before it by Faraday, namely, the transformer with a magnetic circuit entirely of iron.

In transformers as in dynamos, it has been found neces-

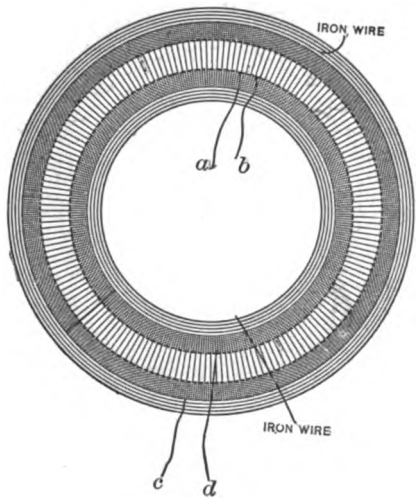

FIGURE 6.—FERRANTI, 1885.

sary to reduce the resistance of the magnetic circuit to the smallest possible value ; this is done in three ways—making the circuit entirely of iron, reducing the circuit in length as much as possible, and increasing its cross-section.

In 1883, I employed a Gramme ring as a transformer, figure 5, and found the advantages of the closed magnetic circuit very great. This transformer is practically the

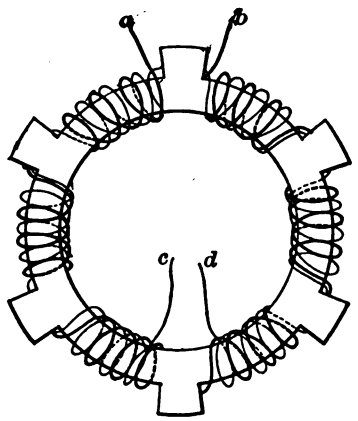

FIGURE 7.—STANLEY, 1886.

same as Faraday's with the improvements in the core ; in Faraday's transformer it is of solid iron, in mine the core is of fine iron wire.

Following me in 1885, Zipernowski and Deri patented the ring which I had used in 1883 ; lately, however, they have disclaimed this patent.

Ferranti improved the ring, figure 6, by winding an iron wire or strip on the peripheries, thereby somewhat reducing the magnetic resistance.

Stanley made a transformer of the Paccinotti ring, figure 7, but it is no improvement, as may be readily seen ; the projecting teeth have some reason for existence in an armature for a dynamo, but I can see no reason for them here and none is given by the inventor.

Dick and Kennedy make a transformer of a Paccinotti ring, figure 8, and give the teeth a very important function to perform, by winding a sheathing of iron wire on the outer periphery. The teeth with this magnetic sheath form short magnetic circuits for each pair of coils as shown at E.

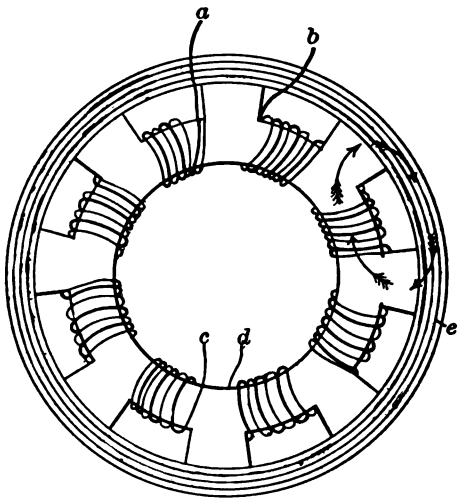

FIGURE 8.—DICK AND KENNEDY, 1886.

This evolution is very interesting, and forcibly illustrates how far important practical results depend on apparently trifling improvements ; thus we have Faraday with a solid

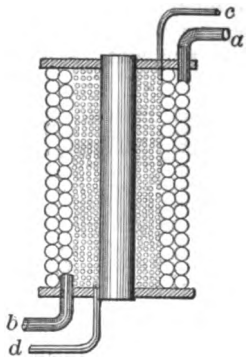

FIGURE 9.

iron cored ring, then follows the ring with fine iron wire core, then with an outer and inner iron sheath, then with teeth without a sheath, then with teeth with a sheath added and wound in magnetic contact with them.

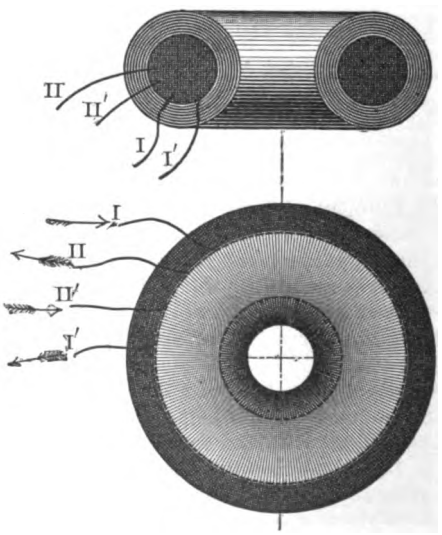

FIGURE 10.

The addition of the sheathing in the Ferranti ring reduces the magnetic resistance in the ratio of about 2 to 1; the sheathing in the Dick and Kennedy ring reduces the magnetic resistance in the ratio of about 6 to 1, and this

Digitized by Google

reduction could be carried further. These are all the developments of the simple ring form ; the improvements are altogether in the magnetic organ of the transformer.

In the 1885 patent of Zipernowski and Deri, we have the most novel development of the ring, producing the highest class of transformer and reducing the magnetic resistance to a very small value ; this invention consists in forming the two conductors into a core of ring form, and then overwinding them with iron wire ; in fact, it is the transformer of Faraday's turned inside out, instead of the conductors enclosing the iron, the iron encloses the conductors.

Figure 10 shows this construction, the ends of the conductors I, I′, and II, II′, coming out through the sheath of iron wire.

FIGURE 11.

The sheathed forms of transformers have one practical objection, and that is, when a fault occurs in the insulation or in the conductors, the whole of the winding has to be undone to make a repair ; this has been overcome in later transformers.

The Zipernowski and Deri ring transformers, consisting of an inner core of two insulated conductors, one of which forms the primary circuit and the other the secondary circuit of the transformer, with an outer sheathing of iron wire forming the magnetic circuit of the transformer, is shown in the finished form ready for use, figure 11. The terminals at the bottom are the secondary ; the terminals at the top are the primary ; the four terminals at the top are for the purpose of conveniently inserting two fuses in the primary circuit to protect the fine wire

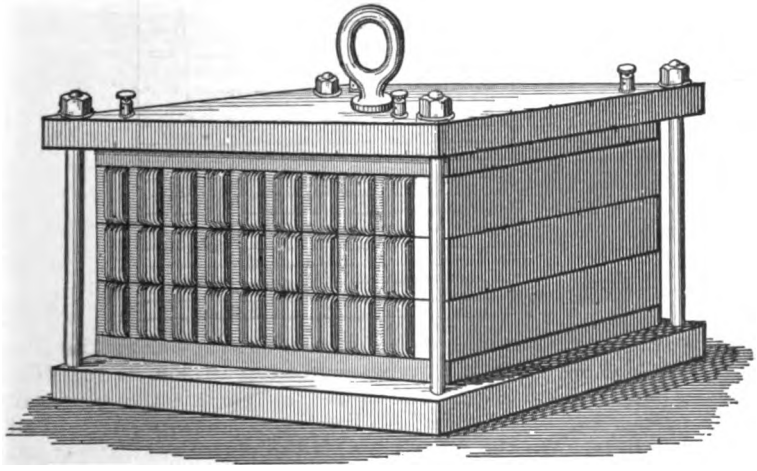

FIGURE 12.

from accidents, such as short circuits in the secondary circuit. This form of transformer leaves nothing to be desired in the matter of simplicity and efficiency, but a slight fault in the circuits inside cannot be rectified without the complete undoing of the whole affair. The magnetic circuit has an extremely low magnetic resistance, being short and of great cross-section ; therefore, self-regulation is perfect, and the heating of the iron arising from the rapid reversals of its magnetism is dissipated from the large outer surface exposed.

In figure 12, I have shown a Dick and Kennedy transformer of the subdivided type in its complete form. In this transformer the magnetic circuit is of the lowest possible resistance giving perfect self-regulation. The core, *g*, *g*, is formed of laminated iron having spaces cut out, as shown at figure 13. Into these spaces are wound the primary and secondary wires, so that each forms a

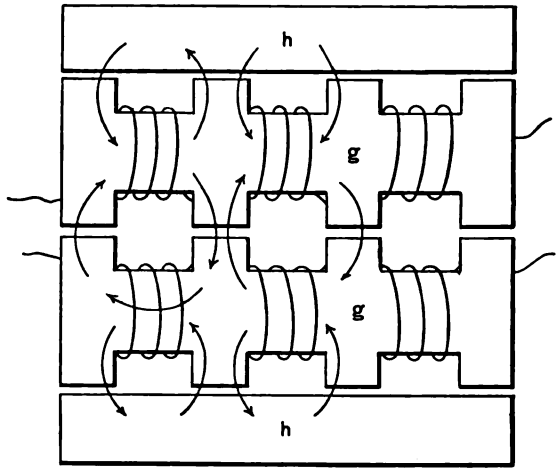

FIGURE 13.

complete little transformer, having its own short magnetic circuit independent of the others. A number of cores containing any number of transformers may be piled one on the other, the bottom of the pile commencing with a laminated plate, *h*, ending with another laminated plate on top ; a fault occurring in any of the little transformers does not entail the undoing of the whole, in fact, a fault in one of them may be cut out while working, by short circuiting it across or cutting it out of the circuit altogether.

The arrows in figure 13 indicate the short path of the magnetic currents. It will be seen that this transformer is a further development of the Pacinotti ring, and it is now necessary to point out this departure in making

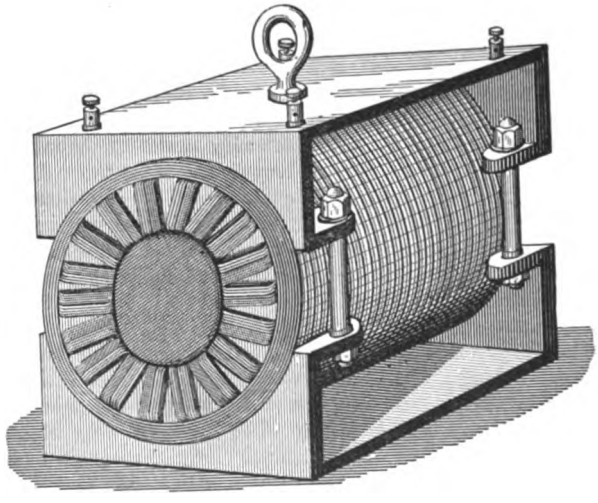

FIGURE 14.

transformers as commencing a new type. We have first Faraday's transformer, a plain iron ring enclosed by two conductors, then in my ring transformer of 1883 we have the same things, with wires or conductors subdivided into

Digitized by Google

many sections, all having a common core or magnetic circuit. In the Ferranti we have the same things again with the additional outer and inner magnetic sheathing, but still the magnetic circuits are common to all the coils or sections of the primary and secondary.

In the Pacinotti ring, with the sheath of iron wire as made by me, we have an iron core carrying the two conductors in sections; but each section has its own independent magnetic circuit. Figure 14 shows a complete transformer on this plan.

In figure 12 this new type of transformer is more perfectly put into practice, and there are other methods than this of carrying it into practice, so that we may conveniently call this type the subdivided transformer to distinguish it from those types having a magnetic circuit common to the whole of the two circuits of the conductors.

The chief advantage of the subdivision of the magnetic circuit is that it obviates the use of long magnetic circuits, and also the magnetic lines of force in the circuits are of very low density, being that due to the conductors enclosed by it only.

The ideal subdivided transformer contains a great number of small magnetic circuits, each enclosing one turn of secondary wire, and 10, 20 or 30 turns of primary wire, as the desired ratio of reduction of potential may require.

Transformers of potential are here classed, according to their magnetic circuits, into three types:

Faraday types. Closed magnetic circuit, common to all the coils or sections.	Faraday, 1835. Kennedy, 1883. Ferranti, 1885. Zipernowski and Deri, 1885. Stanley, 1886.
Rhumkorff types Magnetic circuit closed through air.	Rhumkorff, 1842. Gaulard and Gibbs, 1884. Jablochkoff, 1876. Fuller, 1878. And many others.
Kennedy type, 1886. Magnetic circuit subdivided so that each section has a complete magnetic circuit of its own.	The Pacinotti ring with sheath. The square pile of coils on grooved core (figure 12).

PRACTICAL NOTES CONCERNING THE CONSTRUCTION, USE AND MANAGEMENT OF STORAGE BATTERIES.[1]

BY A. RECKENZAUN.

(Continued from page 178.)

SINCE the specific gravity of the acid rises and falls in proportion to the amount of charge put into the cell or withdrawn therefrom, it is evident that the hydrometer may not only serve as a continuous charge and discharge indicator, but this simple instrument can, by means of certain attachments, automatically make or break the circuit at any desired point during the charge or discharge. Mr. J. S. Sellon had, in 1884, devised an apparatus which consisted of an hydrometer floating freely in the electrolyte of a cell, and which had a silk thread attached to its upper end; the silk thread was passed over a grooved pulley, and had a weight suspended on its end; the action of this arrangement is similar to that of a wheel barometer. Other inventors have constructed instruments based upon this principle; such indicators seem to work all right in the laboratory, but we do not know of an extensive electric light installation where they may be seen in constant use. There is a difficulty about their application in so far as the space between the plates does not permit of the insertion of an hydrometer, and if the latter is placed at the end or the corner of a cell it does not indicate exactly the specific gravity between the plates where all the action is going on. Unless accumulators are especially constructed to receive an apparatus depending upon the density of the electrolyte, we can only accept the indications as approximate.

The spaces between the plates are, for obvious reasons, very narrow, and it is customary to make the cells little larger than necessary for the reception of the plates; as a rule the distances between the plates are about equal to their thickness, and then, according to the most approved practice, acid of 1,170° should be used when first filling the cell containing thoroughly "formed" plates. By spacing the plates farther apart weaker acid can be used, but the internal resistance will then be slightly higher.

If, at any time, the acid is removed from the cells, for purposes of repairs or inspection, care should be taken in noting the specific gravity so that when replacing the plates the same specific gravity is maintained. If, for instance, fully charged plates are taken out of a cell, and on replacing them new acid of, say, 1,120° is used, then it will be found that on charging up for the first time, the strength

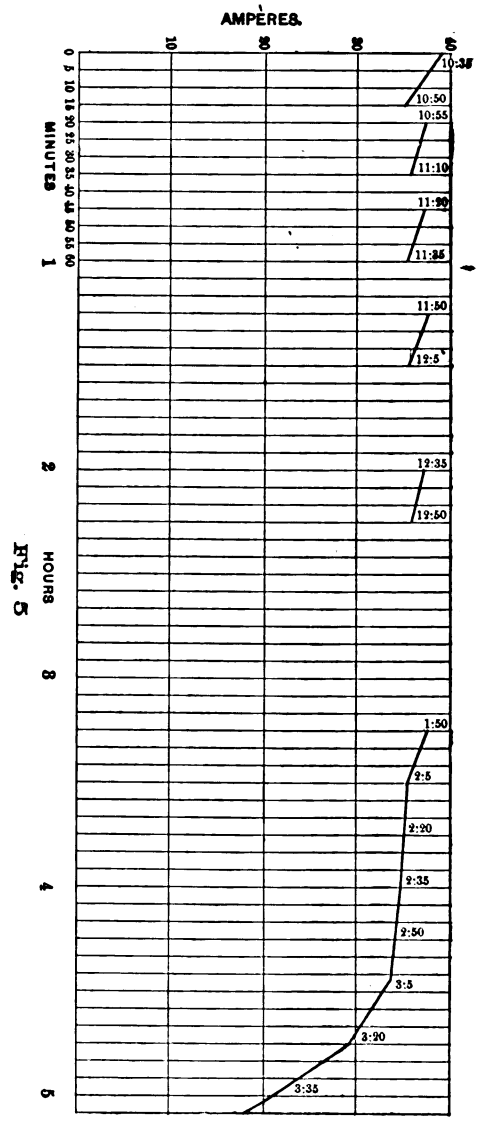

Fig. 5.

of the acid does not rise appreciably, yet during the discharge the specific gravity will drop to something like 1,060° and this would be too weak. The positive plates in this case are thoroughly oxidized, and therefore devoid of sulphate. On the other hand, if the plates are discharged before removal, then they must be put back into the same, or else acid of a strength corresponding to that measured before removal.

"PICKING UP."

We have already stated on page 175 and again on page 177, that by interrupting the process of dis-

1. From the *Electrical Review* (London).

Digitized by Google

charging and allowing the plates to stand idle, the original power is to a great extent restored, and this "picking up" of a cell during repose is closely connected with the formation and removal of a non-conducting film.

To illustrate this we made experiments, the results of which are embodied in table v. and diagram figure 5. The cell under observation was discharged at nearly double its normal working rate. Commencing at 10:35 A. M. we observed a current of 39.4 amperes, it dropped to 36 at the end of the first quarter of an hour, then we allowed the cell a rest for five minutes, when on restarting the ammeter indicated 37.3, and in 15 minutes it fell to 35.9 amperes. Next we gave it a rest for 10 minutes, and on starting the current stood at 37.4, dropping again in 15 minutes to 35.6, a little lower than before. Then we increased the interval of rest to 15 minutes with similar results, and these were scarcely altered when 20 minutes rest was allowed, and this part of the experiment concluded at 12:50 P. M. On resuming the discharge when the clock hands stood at 1:50 P. M., the current was once more at 37.4, it gradually fell without further stoppages, until 3:05 P.M., and between that hour and 3:50 P.M. a rapid decrease took place, so that finally only 16.25 amperes could be got

TABLE V.—INTERMITTENT DISCHARGE.

Time.	Current.	
10 35 A. M.....	39.4	Started.

3 20 "	29.5	"
3 35 "	21	"
3 50 "	16.25	Stopped.

with a constant external resistance. These results lead us to the conclusion that the "picking up" of an accumulator occurs within a comparatively short space of time, and that there is hardly any difference whether the period of rest is five minutes or one hour. This recuperative power is in many respects of great advantage, especially in the case of propelling tram-cars, which require so much force at starting, and each stoppage supplies the requisite initial effort by virtue of this "picking up" property of the cells.

VOLUME OF ACID RELATIVELY TO VOLUME OF ACTIVE MATERIAL.

If the electrolyte is too weak, or if there is too little of it, then it becomes absorbed by the lead or exhausted at an early stage, when water only is left. The volume of the acid must bear a certain ratio to the volume of active material, and this ratio had to be ascertained by practice. Referring to page 105, we find that the cell (*a*) of 150 ampere-hours capacity contained 23 plates, 11 positives and 12 negatives. The volume of peroxide in the positives was 36.9 cubic inches, and that of spongy lead in the negative plates 30.23 cubic inches, giving a total of 67.13 cubic inches. The displacement of the 23 plates, including their supports, however, was 105 cubic inches. The contents of the box occupied 280 cubic inches when the level of the liquid reached ¼ inch above the top edges of the vertically arranged plates, consequently we had 175 cubic inches left for the acid of 1,170° density. We had thus 2.6 cubic inches of acid for every cubic inch of *active* material, and 1.666 inches of acid for every inch of plate, including supporting frames and terminals. The results obtained in practice with these cells justify us in regarding the above proportions as advantageous.

EFFECTS OF COUNTER E. M. F. OF A MOTOR ON THE RATE OF DISCHARGE.

The results of experiments which we collected in tables i. and ii., and diagrams, figures 1 and 2, have given us comparative values of the effects produced upon the E. M. F. of accumulators when the same were discharged at various rates through different external resistances composed of homogenous conductors.

If, instead of discharging the currents through wires or lamps, we actuate an electro-motor, then the E. M. F. of the battery will vary with the counter electromotive force of the motor, whilst the actual resistance of the external circuit is constant. The current flowing through the motor when its armature is prevented from rotating, will, of course, be $C = \frac{E}{R}$, where E represents the difference of potential at the terminals, and R the resistances of the wires in the machine; but as soon as we allow the armature to spin round the current, C, will decrease, because then the machine begins to work as a dynamo; it will generate a counter electromotive force, *e*, which is, of course, smaller than E; but the faster the armature revolves the nearer will *e* approach the value of E, and as this opposing E. M. F. rises, so the current, which we shall call *c*, diminishes in proportion. The accumulator, therefore, is no longer discharging through the known resistance, R, but against an E. M. F. which has the same final effect, as far as the current rate is concerned, as a resistance of some conducting material inserted between the poles of the battery.

The counter electromotive force we calculate by means of the well-known formula:

$$e = \frac{C - c}{C} \times E_1.$$

To illustrate this phenomenon we have prepared table vi., giving the results of experiments made with a series-wound motor whose coils offered a resistance of .4 of an ohm taken between the terminals immediately after running it. Two E. M. F's., therefore, had to be ascertained, viz., E of the battery with only the volt-meter in circuit, and E_1 of the same when the motor was doing mechanical work at the expense of a current, *c*, measured simultaneously.

TABLE VI.

DISCHARGE THROUGH A SERIES-WOUND MOTOR.

No. of cells in circuit.	Revolutions per minute.	Current *c* in amperes	E on open circuit.	E_1 on closed circuit.	Electrical H.P.	Brake H.P.	$\frac{E_1}{E}$	Counter E.M.F. *e*.
48	1014	31.35	95.5	88.0	3.7	2.8	.921	75.4
"	720	42.9	"	85.7	4.92	3.6	.897	68.5
60	1360	31.4	117.6	107.8	4.6	3.6	.916	89.0
"	950	42.9	"	104.4	6.1	4.6	.896	86.6
70	1200	42.9	139.6	125.0	7.2	5.5	.895	107.7
"	1080	47.8	"	122.5	7.85	6.0	.877	103.4

We commenced with 48 cells, joined in series; these gave 95.5 volts on open circuit; after connection was made with the motor, and the brake loaded to absorb 2.8 h. p. the E. M. F. dropped to 88 volts; the current rate, taken at the same time, was 31.35 amperes. On increasing the load to produce 3.6 h. p. at the motor shaft, 42.9 amperes of current were consumed, when the E. M. F. of the battery fell to 85.7 volts.

Tests were made with 60 and 70 cells in series, and these gave similar results; in all cases when the brake was loaded with weights corresponding to 42.9 amperes, the value of E_1 came to about 89 per cent. of E; and with 31

Digitized by Google

amperes the E. M. F. on closed circuit amounted to over 91 per cent. of that on open circuit.

We see thus that E_1 is a quantity which varies with the load, and, therefore, in making preliminary calculations, the available E. M. F. should not be fixed as two volts, for instance, irrespective of the current rate; indeed, the last experiment, with 47.8 amperes, showed that only 122.5 volts were available out of 139.6 which the battery gave on open circuit. The ratio, $\frac{E_1}{E}$, is tabulated for each test, as also the calculated counter electromotive force of the motor.

EFFECT OF COUNTER E. M. F. OF A BATTERY UPON THE DYNAMO CHARGING IT.

Although a shunt-wound dynamo can only produce a certain maximum E. M. F. at a given speed, yet it will accommodate itself to any counter electromotive force below that maximum. As we increase the number of cells, and with it their counter E. M. F., so the current diminishes until it falls to zero, when, with the least decrease of speed, the accumulator overpowers the dynamo and discharges itself through it, with the result of converting the generator into a motor, running in the same direction. Tests made with a shunt-wound Brush machine proved this conclusively. This dynamo could charge 30 cells at the rate of 22 amperes when making 800 revolutions a minute, but when one extra cell was put in circuit the current dropped to zero, because at this speed the machine could not give more than 68 volts, and the counter E. M. F. of each cell at the time of this experiment was 2.25 volts.

Table vii. refers to this Brush dynamo charging 20, 25 and 30 cells; and table viii. shows the results of similar experiments with a Siemens machine charging 60, 65 and 70 cells.

RISE OF E. M. F. WHEN CHARGING SECONDARY BATTERIES.

At the commencement of the charge the E. M. F. required is very little more than two volts per cell, but as the operation proceeds this E. M. F. increases, until at last, when gases are given off freely, it may rise to 2.5, and even more per cell, according to the charging *rate*. The dynamo, therefore, will have to be so constructed that if it had to charge 50 cells in series it should be capable of giving 125 volts at the terminals of the battery. Assuming that the speed of the generator is constant, the current will also remain nearly constant, for when at the commencement of the charge the counter E. M. F. of the cells is low, their internal resistance is correspondingly high, consequently these two influences partially counteract each other. We have seen from figure 4, page 177, that the specific gravity of the acid rises and falls in proportion to the amount of current sent through the cells, or withdrawn therefrom, and that the "curves" traced by plotting the hydrometer readings are practically straight lines. The rise of E. M. F., however, does not appear to occur in exact proportion to the amount of charge put into the cells, as will be observed from the curve, figure 6, which was constructed by Messrs. Drake and Gorham to illustrate certain statements in a paper read at the British Association meeting of 1886. This curve shows the rise of E. M. F. during the charge, the current being throughout kept constant at 22 amperes. It will be seen that at the commencement the charging E. M. F. was only 2.02 volts, that after 220 ampere hours had been put in, representing about one-half the capacity of the cell experimented upon, the E. M. F. had risen to 2.13, and that when the cell was giving off gases freely the E. M. F. was as high as 2.53 volts. This curve

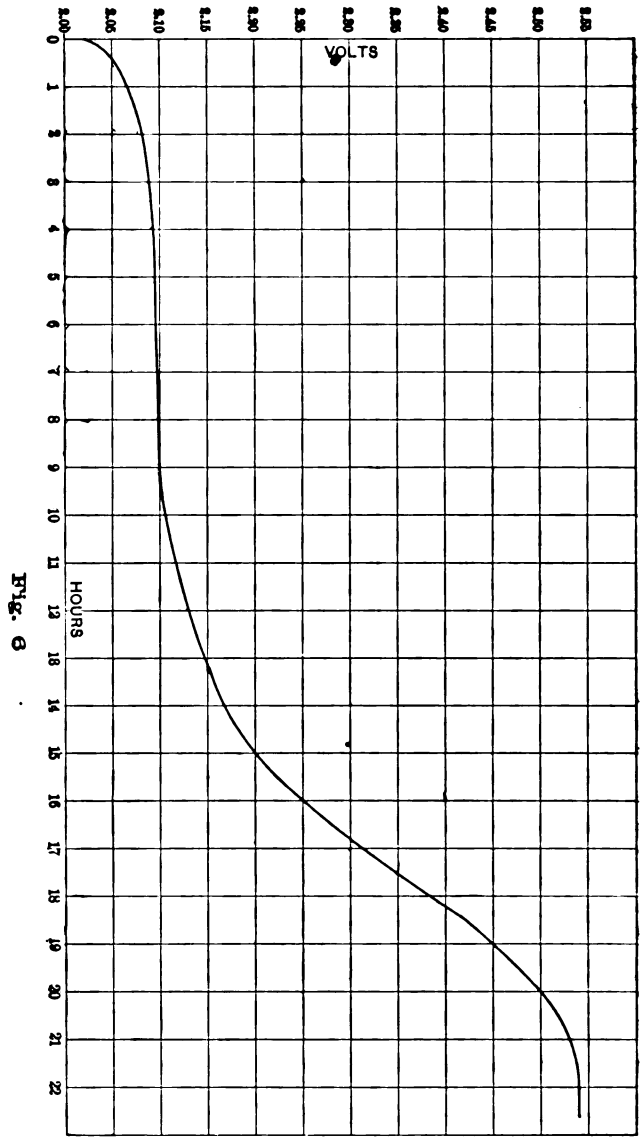

Fig. 6.

does not by any means represent a proportional augmentation of pressure; for in the first hour a rapid rise of E. M. F. takes place, then it goes on gradually until the 13th hour; for the next seven hours the pressure goes up very fast, and during the last hour no perceptible change takes place, indicating that the cell was fully charged with 462 ampere hours. This shows clearly what provision must be made in dynamos for use with secondary batteries when the current is to be kept constant. Sir Thomas S. Bazley suggested in the *Electrical Review* of March 19th, 1886, that the charge of secondary batteries can be tested not only by the hydrometer, but by the alteration (the dynamo speed being constant) of both current and E. M. F. He considered that the gradual rise of E. M. F. during charging

Digitized by Google

is an unfailing indication of increased storage; at any rate, when a certain reading of the voltmeter (determined by previous trials) has been attained, no further efforts of the dynamo can augment it; and it is, therefore, fair to assume that this maximum E. M. F. corresponds to a full charge of the battery. In order to insure that the voltmeter readings really correspond to the amount of charge, it will be necessary to count the number of revolutions of the dynamo each time such readings are taken; this involves more trouble, and it is, perhaps, less accurate even than the hydrometer test.

VARIATION OF E. M. F. WITH GENERATOR RUNNING WHILST THE BATTERY IS DISCHARGING.

We have seen, from the results tabulated on page 264, that within certain limits the E. M. F. of a shunt-wound dynamo will adjust itself to the counter electromotive force of the cells which it charges, and as this counter E. M. F. is increased, the speed being constant, so the current rate was diminished, and *vice versa*. We have also observed from experiments collected in tables i. and ii. that the E. M. F. of a battery varies with the rate of discharge.

Secondary batteries can only be charged, safely and conveniently, by means of dynamos having a constant magnetic field, such as shunt machines, magneto machines, or dynamos whose field magnet coils are separately excited. But such dynamo machines do not give a constant E. M. F. when the external resistance, or, what comes to the same thing, the current rate is varied within wide limits. In the case of electric lighting installations the accumulator is coupled in parallel with the dynamo, and it frequently occurs that the latter is kept running whilst the cells supply current to the lamps; one, in fact, supplements the other. Now, so long as the number of lamps in use is constant, the E. M. F. of the dynamo and with it the cells will be constant, but when more lamps are switched on, demanding a greater current, then the E. M. F. of the dynamo will fall in proportion to the slightly diminished counter E. M. F. of the cells. To explain this we take two extreme cases: the dynamo, for instance, is giving 40 amperes; if a current of one ampere were flowing through the lamp circuit, 39 amperes would have to go into the cells, and when 39 amperes are required by the lamps then only one can be utilized by the cells; in the latter case, owing to the diminished resistance of the lamp circuit, the E. M. F. of the generator will fall very considerably unless the resistance of the battery is very much less than that of the lamps and leads.

In practice the battery resistance is always less than one-tenth of that of the lamps, consequently there is a large margin for compensating any irregularity. Mr. Augustus Littleton, in his extensive installation at Sydenham, has made some interesting experiments on this point, also published in the *Review* of May 19th, 1886. There we find that, when the dynamo was running at 600 revolutions per minute in conjunction with the accumulator, the E. M. F. was 117.5 volts with 16 amperes, 110 volts when using 38 amperes, and only 96.5 volts at the moment when a current of 62 amperes was flowing through the lamp circuit. The resistance of the armature is stated to be .119 of an ohm, and this, no doubt, has a great influence upon these fluctuations; if this resistance were less, then a more uniform result could be obtained, but this great variation in the E. M. F. as the current rate is altered, the makers of the dynamo declare, is "the proper condition of things required for charging accumulators when the power is supplied by a gas engine (as in the case of Mr. Littleton's), or by any prime mover where the delivery of power is in the nature of emphasized intermittent pulsations."

Sir David Salomons, whose wide experience in the application of secondary batteries for electric lighting is universally recognized, says "the action of the cells in steadying the light, when the prime motor is irregular in speed, depends on two conditions, one acting when the cells are charging, and the other when the dynamo is running and doing work on the lines, but sending very little or no current into the cells, or when the cells are discharging to line at the same time, which is the case when the E. M. F. of the dynamo and the cells are equal." Sir David calls this latter condition "the balancing point," and he also contends that the steadiness of the light (or E. M. F.) depends on the relation between the resistance of the cells to that of the line, and on the "characteristic" of the dynamo. The less the resistance of the cells and the steeper the "characteristic curve," the steadier will be the light during charging.

SECONDARY BATTERIES AS REGULATORS.

We have already stated that the resistance of the generator has a great influence upon the steadiness of the light when the speed of the prime mover is somewhat irregular. There is, or has been an impression among engineers, that an accumulator, however small, would suffice for the purpose of regulating the flow of current from a dynamo of any dimensions. This would only be true if the E. M. F. of the cells were constant with varying rates of discharge. But we know that the rate of discharge must be proportioned to the capacity of the accumulator, and this capacity, we have explained, depends upon the active surface of the plates. The internal resistance of the cells has, in a measure, some influence upon the regularity of the discharge, but the supply depends mainly upon the rapidity with which the chemical action may take place upon the plates. The volume of active material, as well as its distribution within the cells, determine the rate at which the current can be furnished; therefore, in order that an accumulator may furnish the maximum current that may be demanded from it in an electric light installation, its capacity must be large enough to allow the action to be going on without any diminution of the E. M. F. in the battery.

If the speed of the prime mover could be kept absolutely constant with varying loads, then we could obtain an ideal regulation by means of a dynamo having an infinitely small internal resistance, so that this dynamo, and not the accumulator, can supply all the extra current required by additional lamps. The characteristic curve of such an ideal shunt dynamo would be a straight, horizontal line, since its E. M. F. must be constant, at a given speed, whilst the current may be varied *ad libitum*. Unfortunately, such a dynamo would not suit an accumulator whose counter E. M. F. is 20 per cent. higher at the completion of the charge than at the commencement. The current rate would naturally fluctuate between very wide limits with the least variations of the counter E. M. F. of the cells. Thus with a shunt dynamo having an armature of an infinitely small resistance joined to an accumulator of extremely large capacity, we can obtain in the lamp circuit any amount of current at a constant potential, assuming an absolutely constant speed. An almost imperceptible diminution of speed, however, would lead to disastrous results in so far as the battery whose E. M. F. balanced that of the dynamo so nearly, would then discharge itself through the latter and drive it as a motor which, in its turn will assist the prime mover for a moment, until its velocity rises and overcomes the counter force. A small per cent. variation in speed will render such a method of regulation as defective in practice as it is perfect in theory.

In the other extreme case, again, of a shunt machine whose armature has a very high resistance, the speed may vary considerably without seriously affecting the E. M. F., but as soon as we increase the current through the lamp circuit the dynamo E. M. F. drops, the excess of current demanded has to be supplied by the accumulator alone, with the result of a general lowering of potential throughout the circuit. The characteristic curve of this dynamo approaches a vertical line. Between these extreme cases we may, however, find some happy medium

Digitized by Google

which will give us the key to the solution of a difficult problem. To facilitate description we have constructed characteristic curves of two dynamos with which actual experiments were made. Neither of these approaches the ideals set forth in the preceding argument, yet both are employed in installations which have proved successful. We have drawn the *external characteristics* only with the amperes measured in the external circuit, the volts between the terminals, and both plotted as shown on diagram figure 7. The steeper curve refers to a Siemens S D, dynamo, whose armature resistance was .32 of an ohm, and which ran at 1,380 revolutions per minute. The more horizontal characteristic curve represents the conditions observed by running an Edison (old L type) dynamo at

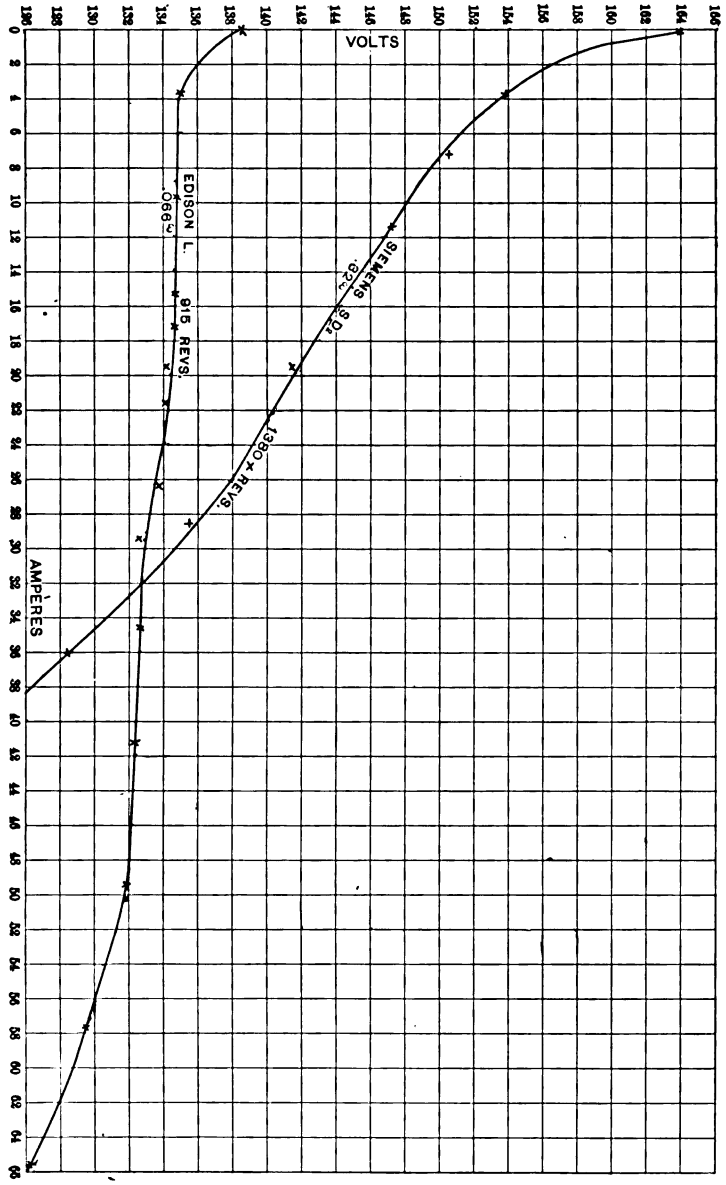

Fig. 7.

915 revolutions; the armature resistance of this, taken between opposite brushes, measured .066 of an ohm. For the purpose of comparison we take the points of similarity in each, using the differences of potential within the limits of 135.3 and 126.1 volts.

To avoid complications we have omitted the *internal characteristics* of these shunt machines, but we may state that the current through the shunt varied from 6.8 to 5.8 in the Siemens, and from 7.5 to 6.8 amperes in the Edison, within the potential extremes of 135.3 and 126.1 volts respectively.

The curves of these widely different dynamos, it will be seen, meet at one point only, where each furnishes a current of 32 amperes with 134.8 volts; from this intersecting point the characteristics diverge above and below at an angle of about 37°. With a difference of potential of 126.1 volts the Siemens dynamo gave 38.3 amperes, and the Edison 65.8 amperes; with 135.3 volts the former furnished a current of 28.3 and the latter 3.5 amperes. The currents, therefore, in the one fluctuated only to the extent of 10 amperes, whilst that of the other differed by 62.3 amperes, within the limits of E. M. F's indicated; and these limits would represent, with a battery of 55 cells in series, a variation of from 2.29 to 2.46 volts per cell; just enough to overcome the counter E. M. F. of the accumulator when partially and fully charged. (*Vide* curve, figure 6, page 264, *ante.*)

No current passed through the external circuits when the E. M. F. of the Siemens dynamo rose to 164 volts and that of the Edison to 138.3 volt, both working at their normal speed.

It is evident that the machine with the steepest characteristic curve will be the most suitable to work in conjunction with an engine having an irregular speed. Supposing we know the lowest number of revolutions the engine would make with a maximum load, we can gear the dynamo accordingly; if, for instance, we wish to charge the accumulator at the rate of 32 amperes with a minimum E. M. F. of 134.8 volts then this Siemens machine must have a minimum speed of 1.380 revolutions per minute. Any augmentation in speed will have the effect of increasing the current in almost the same ratio as the E. M. F. This ratio would be exactly the same if the angle, which the curve makes with the horizontal, were one of 45°.

In the case of the Edison dynamo, the slightest changes of the E. M. F. cause a very great fluctuation of the current rate, consequently with this machine we should have to provide a far more constant engine speed.

The present example of a Siemens dynamo will be found most suitable for an installation where the accumulator can be charged all day and furnishes a large current for a few hours in the evening; whether both are working in conjunction or not, the cells will have to supply the bulk of the current, since the dynamo current is limited. The Edison machine, on the other hand, if used with the same accumulator, will allow of a much greater margin in the current supply provided that there is ample power to be got out of an engine with a constant speed.

Regulation in the one case is effected by means of an accumulator whose capacity is large in comparison with the power of the dynamo, and in the other case the dynamo supplies the excess of current which the accumulator is incapable of supplying without loss of potential. In any case, therefore, the characteristic of the dynamo has to be determined with due reference to the nature of the engine which furnishes the motive power. The generally accepted analogy between an electric accumulator and a hydraulic accumulator, or a gasometer, as the case may be, is only true within certain limits, and we shall endeavor to consider these presently.

(*To be continued.*)

THE ELECTRIC LIGHTING OF PASSENGER TRAINS.[1]

BY GEO. W. BLODGETT.

A BETTER method of lighting passenger trains is demanded by considerations of economy, comfort and safety. Economy is a question which chiefly concerns the railroad

1. Read before the American Institute of Electrical Engineers, June 28, 1887.

Digitized by Google

management, but comfort and safety concern all their patrons. There are two ways in which we may seek these; either by improving the present system or by substituting a better one. It is doubtful whether oil lighting can be much improved and still be reasonable in cost, and whatever danger attends its use would probably still remain. I have made careful inquiry among my railroad friends without finding any instance within their personal knowledge where the ruins of a railroad wreck were set on fire by the lamps in the train (indeed these are usually instantly extinguished), but such an instance was said by one of the survivors to have occurred in the late disaster at Hartford, Vt., and another was mentioned at a recent meeting of the New England Railroad Club, where the explosion of a lamp set a sleeping car on fire, and it burned with nearly all the occupants. It is however certain that a pile of splinters deluged with oil will burn more fiercely and be much more difficult to extinguish, than if in their normal condition.

It is therefore desirable to get rid of oil lamps for the harm they may do in *aiding* the progress of a fire, even if they do not cause one. The discomforts of oil lighting, in point of amount, distribution, unsteadiness and color of the light, corruption of the air, and the great heat given out by a large number of lamps in a car are other reasons why a change would be welcome to both the railroad management and the public, if a reliable substitute can be found. Some of the objections enumerated above apply with equal force to lighting by gas, the others are partially, but not wholly eliminated. *Electricity*, however, offers a means of lighting which comes nearer to meeting all the requirements of a perfect light for passenger cars than any other yet discovered.

There are several ways in which we may produce the electricity for car lighting. It is possible to light a car successfully by any one of them, but further experiment is necessary to determine which is the very best to adopt, and we have already found some much better adapted than others to our American trains. The different methods will be considered in order.

1. By batteries. I know only one experiment successfully going on at present. A train has been running for nearly a year between Paris and Brussels, the cars of which are lighted by electricity from a bichromate battery. It lasts for five trips of seven hours each—that is, 35 hours of lighting—without renewal, which is said to take only five minutes. No accurate estimate of cost, or more detailed information is yet at hand. There are several other batteries in the market which appear well, and if the motion of the train does not have a deleterious effect, would seem possibly adapted to this work. My own experience is conversant with only one trial of this kind which did not succeed. Forty cells of a battery which had worked well in several house installations were put in boxes suspended from the bottom of a car, and 16 (?) lamps of 16 c. p. each, put up in the car. The lamps burned well for one night, but the next night there was the appearance of a sudden and enormous increase of internal resistance in the battery, and it was removed for further experiment before trying to light cars. An attempt was made two or three months ago, to light a N. Y. C. passenger car with batteries of some kind, which also failed as I am told. [Note A.]

2. By a dynamo machine. There are three ways in which this has been done. A small dynamo and engine have been mounted on the boiler or tender, and the latter run by steam from the locomotive boiler. The great objection to this method is that there is no light until the engine is attached to the train, nor if it be temporarily removed. To obviate this difficulty a separate boiler, engine and dynamo have sometimes been carried in the baggage car or on a platform car at the head of the train. It would seem that the danger from fire in this arrangement would be quite as great as by the stoves in the cars. A method tried with some success in a few instances in England and elsewhere abroad (but only once in this country to my knowledge), is to run the dynamo from one of the axles of the train, the proper speed being obtained by suitable countershafting and belts between the axle and the pulley of the dynamo. Since there would be no light when the train is at rest or when the dynamo was running at too low a speed, a battery of accumulators is added, sufficient to keep the lamps lighted for the longest time when the train is standing in the station, or elsewhere. When the train stops, or is at too low a speed for the dynamo to light all the lamps, they are automatically switched to the circuit of the accumulators where they remain till sufficient speed is again attained when they are switched back on the dynamo circuit. During the day when the train is running the dynamo charges the accumulators and keeps them full. They are sufficient to light the train several hours if need be. On one train in Germany, the dynamo and 26 accumulators weighed 1,350 pounds, and cost about $625; operating 12 lamps cost about two cents per hour, or one-sixth of a cent per lamp per hour. The London, Brighton & South Coast Railway Co. fitted up four trains in this way. In one train of 11 cars there are thirty-two 16 c. p. lamps, absorbing 40 amperes of current. The accumulators are stated to hold 500 amperes (probably 500 ampere-hours is meant), and when fully charged are stated to be sufficient to maintain the lamps for eight hours. This train has been running since December 19, 1883; during the first 11 months it made 2,352 trips, and ran 27,322 miles. No failures are reported. A train on the South Eastern Railway has even run a longer distance. The dynamos on these trains have an E. M. F. of 45 volts and give 56 amperes of current. Two pairs of brushes are mounted on a rocking frame so contrived, that when the train runs in one direction, by means of a lever loosely connected with the dynamo axle, and varied in position by attraction of the pole pieces of the field magnets, it tilts the frame in the direction to bring one pair of brushes in contact with the commutator. If the train runs in the opposite direction, the other pair of brushes are brought to bear on the commutator. A vessel containing mercury has revolving within it a coarse threaded screw driven by a belt from the dynamo-axle. At each end of the vessel is a vertical tube, at the upper end of which is an adjustable contact screw. When the dynamo and, consequently, the screw revolves in one direction, the mercury rises in one tube. If the motion is reversed, it rises in the other tube, and when it makes contact with the adjustable screw, the shunt circuit of the dynamo is joined up, the field magnets are charged, the lever is drawn up and one pair of brushes brought to bear on the commutator, which completes the circuit for charging the accumulators. When the lamps are lighted and the train is in motion the dynamo feeds them, the accumulators merely acting as a regulator. If more current is being generated than the lamps require, it goes to the accumulators. If less, the balance is given out by them. When the speed of the train slackens, the fall of mercury in one of the tubes, breaks contact with the adjustable screw, the field magnet circuit is broken and the brushes are removed from the commutator, the lamps continuing lighted by means of the current from the accumulators.

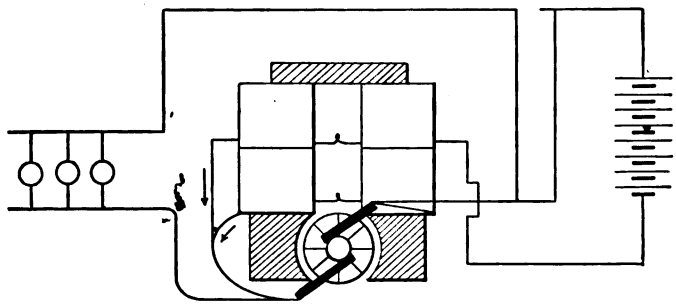
The apparatus can be used for several weeks with no attention beyond lubrication, and at the end of this period only a re-adjustment of the commutator brushes is necessary, which puts the machine in condition for a like longer period. The weight of the apparatus is about two tons.

The connections between the cars are made by coupling

NOTE A.—Most batteries furnish a continuous current for so short a time without renewal, that their use is debarred on this account. Some others will not bear the shaking up produced by the motion of the train. I have myself experimented for a considerable time, but thus far without finding a battery which will run on a closed circuit longer than two or three weeks, and at the same time can be carried on a train. When such a one can be found, which at the same time gives a current strong enough to light a series of lamps, it will have a great field of usefulness.

Digitized by Google

two cables together. A slightly different arrangement of circuits has the field magnets of the dynamo wound with two wires in opposite directions, one of which is in shunt to the armature, as if the dynamo were an ordinary shunt machine. The other is wound in the reverse direction as if the dynamo were a compound machine, and the accumulators are in series with this wire. The lamps are also in shunt with the armature.



There is a cut-out to break the circuit of the armature when the dynamo runs below a certain speed ; this prevents the cells discharging themselves through it and burning it out. If the dynamo does not furnish current enough for the lamps, the accumulators supply the balance, and in doing so, strengthen the field magnets and cause an increase of current in the dynamos. When this reaches a greater amount than that needed by the lamps, the surplus goes to the accumulators, and at the same time decreases the magnetism in the field magnets so as to preserve the balance. At the maximum speed of the machine, the cells are receiving their maximum charge, and the current to the lamps is of normal amount. Two sets of brushes are here necessary as in the other case. Mr. Barrett, of Springfield, Mass., has fitted a train of three cars on the Connecticut River Railroad, with electric lights to be run from a dynamo in something the same way as these just described. The peculiar arrangement of the trucks under an American car renders it a matter of difficulty to obtain the proper speed of the dynamo, and I am told Mr. Barrett has had much trouble with the connections between the axle and countershaft. If these are not kept tight the cable slips. If too tight it breaks. An ingenious device like a friction clamp transmits the power from the countershaft axle to a pulley upon it. This is governed by centrifugal weights balanced by stiff springs. When the dynamo runs at its normal speed these just balance the friction of the clamp and there is no slip. Any increase of speed then causes the friction to diminish, and the pulley slips upon the shaft, till equilibrium is restored. Twenty-four Julien accumulators are connected with the circuit as a regulator, and to keep the lamps lighted when the train stops. A centrifugal governor breaks the circuit of the accumulators when the speed slackens.

A third arrangement of electric car lighting is by accumulators on the train to be charged by a dynamo at a central station or terminus of the road. In England a Pullman train has been running some years, lighted by electricity supplied from accumulators charged when the train is at rest by a dynamo driven by a gas engine. The Pennsylvania Railroad Co. experimented more than two years ago with accumulators charged at one end of the line. When the train arrived at Jersey City, the trays containing the cells were removed from the car to a charging room, their places being supplied by spare cells previously charged. The empty ones were charged to be replaced in the first car needing its batteries changed, and these in turn to some other car. The changing of the cells in a car took about 10 minutes. These experiments were in the main satisfactory, but the weak point was the life of the cells, the plates of which after a time buckled and fell to pieces. These cells were furnished by the Brush Electric Co. for these experiments, but they declined to send out any more to be used in the same way until the Pennsylvania railroad experiments should be ended.

The estimated cost of fitting a car with 10 lamps and batteries for 70 ampere hours was about $300 per car.

In the month of January of the present year, the Julien Electric Co. placed 60 cells of their accumulators in boxes on car No. 90 of the Boston and Albany Railroad, and put ten 16 c. p. lights in the car. These proved to be insufficient and the number was afterwards increased to 24, of which 20 were on the car and four over the platforms. This car was run some two months as an experiment with such excellent results that in March and April the trains leaving Boston and New York at 4:30 P. M. every day were fitted up with the same system. (These trains are also heated with steam from the locomotive, and there are no fires or oil lamps in any of the cars.) Each coach and parlor car is fitted with twenty-two 16 c. p. incandescent lamps, of which two, are over the platforms, 16 in the body of the car and the rest in the vestibules and toilet rooms. The lamps in the car are arranged opposite each other in two rows in the top of the car, and are on two circuits entirely independent of each other, each of which has a switch of its own by which the lamps may be turned on or off. The platforms are so arranged as to be lighted from either end of the car. They may, if desired, be lighted only just before reaching a station and extinguished just after leaving it.

Sixty cells of Julien accumulators are arranged in boxes under the car, 30 cells on each side. The weight is about one ton. The boxes are neat and ornamental in appearance, and the 30 cells on each side of the car are entirely independent of those on the other side, and are separately wired as far as the switch-board.

The cells have a capacity of 150 ampere hours and 60 volts on each side of the car. As 60-volt lamps are used, the accumulators on either side of the car will run all the lamps, but of course for only half the time the whole will do it. They are arranged in trays of six cells each, furnished with handles ; they weigh 200 pounds and can be raised from the ground and put in the car by two men. The trays are fitted on the outside with stiff brass springs, which, when the trays are in place bear against each other, and form the connection between each tray and the next. When the trays are in place in the boxes the connections are all made. There are, therefore, no wires to disjoin or connections to make when it is desired to remove a tray for examination or otherwise. From the boxes on each side of the car, wires are carried underneath the car to a switch-board in one of the toilet rooms, which also receives the terminals of the lamp circuits. The switch-board is so arranged that the number of cells in use can be varied from 27 in series to 30 in series, the others being added from time to time, to keep up the candle-power of the lamps, as the E. M. F. of the cells falls. Experiments are now being made to do away with the necessity for this, and if it is found practicable, it will be discontinued.

Two terminals underneath the middle of the car on either side serve to connect by means of plugs a pair of cables connected with wires leading to a dynamo in a lighting station a little way off. These terminals are of different size so that no mistake can be made in the connections. When the accumulators are charged the whole 60 cells are placed in series, when they are connected to the lamps there are two series of 30 cells coupled together. In order that there should be no confusion or errors in doing this, I designed a switch which should, by a single movement in one direction, of four levers coupled together, throw all the cells in series and connect them to the dynamo circuit. In this position they are entirely detached from the lamp circuits and no current can pass to the lamps. When this switch is thrown in the opposite

Digitized by Google

direction the cells are cut off from the dynamo, coupled in two series of 30 cells each, and connected to the lamp circuits, which, however, do not light until turned on by the special switches for that purpose.

It is quite unlikely that an accident to either of the lamp circuits or the batteries on one side of the car would disable the other. By turning out the lamps on one circuit, therefore, the others may usually be kept burning till the train arrives at its destination. In two instances this arrangement of circuits has proved very valuable.

All the cars except one are fitted with Weston incandescent lamps said to take 1.1 amperes. The remaining car has Edison lamps, which are proving so satisfactory that it is quite probable all new work will be equipped with the Edison apparatus. The cost is also much less than that of the Weston lamps.

When the train arrives at Boston it is put on a side track near which a line of poles has been set, and the dynamo wires strung upon them. Opposite each car a pair of terminals serves to make connection with the car, and the charging begins. A current of 18 amperes is run in for several hours, dropping to 12 and sometimes 10 amperes toward the end of the charge, which is now 180 ampere hours, to the 60 cells in series. If there were no loss we could draw out 360 ampere hours in the lamps. Assuming that the lamps use 1.1 amperes each, we actually use about 22 × 1.1 ampere × 9 hours = about 216 ampere hours or 60 per cent. of what is put in. If the lamps are required an extra hour or two there is plenty of reserve for them. [Note B.] The attempt was made to reduce the charge to 140 or 130 ampere hours, but as some of the batteries were not in first-class condition the results were not so good.

The intention is always to have a surplus of current in the battery. For the present the trains run a round trip to New York and return with one charging, but it is not yet quite certain that it can be done in the long nights of winter.

The cost of fitting these cars with accumulators and lamps was, when complete, about $900 per car. Others fitted in the same way would cost less, as on this work the men were all inexperienced and there were no plans or precedents. The cost of operating the lights is not far from $2 per car per day, or about one cent per hour per lamp. When the lights are needed a longer time, as in the dark days of winter, the cost per lamp hour would diminish. This is about 10 times that of oil, and very nearly the same as for gas, but taking into consideration the amount of light obtained, electricity is the cheapest of the three, and immeasurably the most convenient. The light is very brilliant, well diffused, steady, and satisfactory beyond all expectations. A very noticeable feature of these cars is, the entire absence of heat, and the purity of the air, which is as fresh and sweet in the car at the end of its trip as before it leaves the first station; this, together with the absence of danger from fire, especially commends it for sleeping cars.

The Electrical Accumulator Co. have also lighted some cars with success, for the Fitchburg and Old Colony Railroads at Boston.

The electric light has come to stay. It is the only one which anywhere near fills the conditions of a satisfactory light for railway trains. It can be readily adapted to almost any conditions to be met with in practice.

Oil lamps, and stoves in cars, must follow where the old couplers and hand brakes for passenger trains have gone in this country, until electricity and steam heat have made the roasting alive of scores of people pinned fast in a railroad wreck as impossible as the air brake and Miller platform have made the telescoping of a train into a shapeless mass of ruins, as happened formerly so often. Not many years hence, we may well hope, one will be as uncommon as the other.

NOTE B.—Mr. A. Reckenzaun in a recent article on storage batteries, gives the average efficiency as not less than 70 per cent. The Julien company claim, I understand, 80 to 85 per cent. for theirs. Doubtless this can be realized under special conditions, but my own experience would not warrant me in assuming so much in car lighting,—at least until the most favorable conditions of use are better understood.

ABSTRACTS AND EXTRACTS.

ON REVERSIBLE LEAD BATTERIES AND THEIR USE FOR ELECTRIC LIGHTING.[1]

BY DESMOND G. FITZ-GERALD.

(Concluded from page 197.)

FOR, a true "battery equation" is of course independent of the resistance of the circuit, and indicates a definite E.M.F. Conversely, if the E.M.F. alters—temperature and certain other conditions remaining the same—we know that the given battery equation no longer applies, that the original chemical reaction has given place to or has become complicated by another chemical reaction.

I take two strips of platinum, to be used as negative elements with a positive spongy lead in an electrolyte of dilute sulphuric acid. One platinum strip (A) I coat with a paste of electrolytic peroxide of lead; the second strip (B) I coat with a paste composed of one part of electrolytic peroxide of lead and one and one-third part of sulphate of lead (equivalent weights, roughly), mixed together and with water. The couples are circuited, consecutively, through 60,000 ohms and a reflecting galvanometer of high resistance. The A couple, as soon as the negative becomes moistened by the electrolyte, gives a steady deflection of 130 divisions, corresponding to an E.M.F. of about two volts. I short-circuit this couple for 30 seconds, or for ten times this period—of course the deflection falls to zero; but, when the short-circuit is broken, the spot of light moves back to 130 within a few seconds. The B couple, which contains sulphate of lead in addition to the peroxide, gives 128 divisions, falling steadily, within a few minutes, to 72 divisions, corresponding to rather more than one volt (this through a resistance of over 60,000 ohms). I short-circuit this couple for one second: on breaking the short-circuit, the deflection is 20 divisions, becoming in five minutes 67 divisions. A strip of plain platinum gave a deflection of 56 divisions, falling in five minutes to 42. It must be admitted that the result obtained with B was somewhat better than this; nevertheless, the effect of the sulphate in reducing the efficacy of the peroxide is sufficiently striking.

Still more so is its effect in the case of solid peroxide (lithanode), not in contact with any other simple conductor within the electrolyte. But in order to judge of the effect in this case, we must be able to analyze the lithanode chemically at the outset, and also when the E. M. F. between it and the spongy lead has fallen to any given extent.

A convenient and, with due care, an accurate method of determining the percentage of lead peroxide in "lithanode," or any other active material containing this oxidant, is to add cautiously the finely powdered material to the solution of a known weight of crystallized protosulphate of iron, acidulated with somewhat more than half an equivalent of hydrochloric acid, until the solution no longer gives a blue coloration with a drop of potassic ferricyanide solution, or red prussiate of potass. It is advisable to triturate the powder in a mortar containing the acidulated ferrous solution at a temperature over 100° Fah. Of course it is generally possible, especially after a rough preliminary trial, to add at once sufficient of the powder to nearly convert the whole of the ferrous salt into ferric salt; afterwards, the powder is added in minute portions until the blue coloration is no longer produced. If too much of the powder be added, free chlorine and a distinct brick-red coloration are observable. In regard to the numerical data, 7.8 grams of the ferrous salt ($FeSO_4$ 7 H_2O) are equivalent to 1 gram of chlorine or to 3.36 grams of PbO_2.

I took a fragment of one of my old lithanode plates (marked X), of which the capacity was about 16 ampere hours (at a potential not lower than 1.8 volt), and found by the above method that it contained 70.7 per cent. of PbO_2. I then made use of another similar fragment of the plate as a negative element, until the difference of potentials between it and spongy lead fell to 1.8 volt. This fragment having been washed, and slowly dried at a low temperature, was reduced to powder and found to contain 55 per cent. of the PbO_2 originally present. Only 22.2 per cent. of this quantity of peroxide had become reduced, 77.8 per cent. was apparently unaffected: and yet the reaction upon which the E. M. F. is dependent had become in some way modified, since the electrometric indication on open circuit had undergone a permanent diminution to the extent of about 10 per cent. Let us examine this result.

1. Read before the Society of Telegraph Engineers and Electricians, London, March 10, 1887.

Digitized by Google

The weight of peroxide present in one pound avoirdupois of the original plate was $\frac{16 \times 70.7}{100} = 11.3$ oz. In becoming exhausted to the extent of no longer giving with spongy lead an E. M. F. above 1.8 volt, 1 pound of the plate will lose 2.5 oz. of peroxide. To what number of ampere hours does this weight of peroxide correspond?

The ampere hour equivalent for silver, according to Lord Rayleigh's latest determination, is 62.137 grains; this equivalent for peroxide of lead would therefore be :—

$$62.137 \times \frac{239 \text{ (\textit{i. e.}, mol. wt. of Pb } O_2)}{216 \text{ (\textit{i. e.}, twice at. wt. of Ag.)}} = 68.75 \text{ grains.}$$

Now the number of grains in 2.5 ounces avoirdupois being $2.5 \times 437.5 = 1{,}094$, the number of ampere hours corresponding to 2.5 ounces of $Pb O_2$, or to 1 pound of the "X" lithanode will be—

$$\frac{1{,}094}{68.75} = 15.9.$$

It may be admitted, therefore, that when, as in the case of lithanode, local action in the negative element is entirely eliminated, the yield of the battery in ampere hours is strictly proportionate—as might have been anticipated by theory—to the quantity of peroxide reduced in each cell.

This experimental result is interesting from other points of view than that of the electro-chemical equation of the lead storage battery. From the present standpoint of practice, 16 ampere hours of useful capacity per pound of negative element is a splendid result. With lithanode of more recent manufacture it has been surpassed; but it has never, I think, been approached with any other form of negative element. And yet, from the theoretical standpoint, what a poor result: two and a half ounces of peroxide utilized in one pound of negative plate containing eleven and a third ounces of the peroxide! It is not likely that we shall stop here: I for one, do not intend to stop here: there is ample room for further improvement.

It might perhaps be expected that I should suggest a battery formula in substitution for that to which I have objected. I am sorry that I am unable to do so, or even with any degree of confidence to attempt an explanation of the fact that so large a percentage of the peroxide present in a negative element should remain useless and inert for all practical purposes. I have thought it possible that the residual peroxide of lead might be in a state of combination, that a comparatively inert sesquioxide of lead might be formed according to the equation

$$2\,PbO_2 + 2\,H_2SO_4 + Pb = Pb_2O_3 + PbSO_4 + H_2SO_4 + H_2O.$$

But although this view, on the assumption that the sesquioxide formed may resist or be protected from the action of the sulphuric acid present in the electrolyte, may explain the recovery of apparently exhausted plates when they are left in contact with the acid, I have not been able to bring it into general accordance with the results of experiment and with those obtained by chemical analysis. It should be mentioned, however, that, although the equation is in opposition to the experimental results obtained by Gladstone and Tribe, this view is in some measure at least confirmed by those obtained by Schenck and Farbaky. These investigators found that, in charging a lead secondary cell, 2.23 grams (34.426 grains) of H_2SO_4 become liberated per ampere hour current; and that, in the discharge of the cell, 2.25 grams (34.736 grains) of the acid enter into combination. Now the ampere hour equivalent of sulphuric acid is 1.826 grams (28.192 grains); and we may assume that at least this quantity enters into combination with the spongy lead positive in the production of the ampere hour current. There would remain, therefore, only $34.736 - 28.192 = 6.544$ grains of H_2SO_4, or .23 of the equivalent, to combine with monoxide of lead reduced from the peroxide in the negative element. The ampere hour equivalent weight of oxygen would be derived from this element, an ampere hour equivalent of lead monoxide would be produced; but only .23 of the latter equivalent would become converted into sulphate, leaving .77 of the equivalent in admixture or in combination with residual peroxide of lead.

Having had some experience of the behavior of sulphate of lead when used as a depolarizer in batteries of small E. M. F., I have thought it possible also that this salt might undergo an initial effect of reduction; but this view again has not been confirmed by any experiments I have been able to make. What is required is discussion on these matters; this will probably provoke other suggestions which may lead to the extension of our knowledge.

I fear I have already trespassed too far upon your attention; but I have yet to submit to your consideration, as briefly as may be, a scheme for the supply to private householders, who may be desirous of adopting the electric light on a small scale, of the electrical energy necessary to realize their wish. This would be supplied from central stations (but without any outlay for insulated conductors beyond the "wiring" of the actual domiciles to the extent rendered necessary by the number and position of the lamps required) in the form of charged plates—the positives being conveyed in a closed receptacle and in a damp condition, and the negatives in a dry state. Sulphuric acid also would be required; the quantity per horse-power hour electrical being, according to the accepted theory, 3.12 pound of H_2SO_4. I think, however, that it will be found that considerably less than this quantity—say two pounds of the strongest commercial acid—will suffice. This acid would be supplied by the carboy; and a measured quantity would be added to each cell when the exhausted elements are replaced by fresh ones.

For each horse-power hour electrical supplied - corresponding, we will say, to three 20 candle lamps maintained incandescent for five hours—we should have, in the stage which the practical solution of the problem has at present reached, to transport about 40 pounds of battery plates It may be safely said that the total weight to be transported will be under 45 pounds, and I hope that before long this weight will be considerably reduced. The maximum distance to which this weight would require carriage would probably be under half a mile—for it would be more economical to multiply stations than to augment this distance. On the return journey, the exhausted plates and their receptacles, practically the same in weight, would have to be conveyed.

One ton weight of plates distributed would correspond to at least 56 h. p. hours electrical. The question is, what would be the cost, under conditions of practice which admit of considerable latitude, of distributing this weight of material? Upon the answer to this question depends the extent to which this system of distributing electrical energy could be commercially developed. A small percentage of the general public, if safeguarded from all trouble, would be willing to pay even as much as 1s. per horse-power hour electrical. A very large percentage indeed, I am convinced, would pay 4d. for the same quantity of available electrical energy Anywhere between these two limits a considerable amount of business might probably be done. Nothing but an actual trial of the system, on a small scale perhaps, but extending over a considerable period of time—so as to give some scope to the capacity for organization, which has accomplished such marvels in our postal department—will give a conclusive answer to the above question. It is easy to suggest figures which would show the system to be absurdly impracticable; but, as I have elsewhere observed, it would be easy also on the same lines to show that the milkman, who, anywhere in his district, will send horse and cart, man and can, to deposit even a ha'p'orth of milk at the area door, must be financially in desperate case. But there may be some, here or elsewhere, who have had experience of work analogous to that which I have in contemplation; and their opinion, as well as the suggestions they might possibly offer, would be entitled to respect, and might be of considerable value.

In reading over what I have written, I find I have not said anything as to the spongy lead positive element of the lithanode battery, because the main difficulties—the real points of importance—to be overcome have been in the negative element of the couple, which is often erroneously termed the positive element or plate, because it happens to be the positive electrode in charging the battery. To manufacture an efficient positive from the lithanode unconverted material or otherwise, was comparatively an easy matter; and there is a choice of several positive elements which leave little or nothing to be desired.

I would draw your attention to the two electroliers consisting of five lamps each, which are before you. They were made by Messrs. Faraday, and the lamps are supplied by 14 cells, weighing about 10 pounds each, and having a charging capacity of $\frac{2}{3}$ h. p. hour.

The discussion was commenced by

Dr. J. H. Gladstone, who replied to Mr. Fitz-Gerald's comments upon the work of himself and Mr. Tribe. In regard to the *lapsus* in connection with the question of local action, he assured Mr. Fitz-Gerald that if the "white sulphate" had not existed, the Planté or Faure battery would have never been known, and that it really was a friend as well as an enemy. No doubt a misconception in regard to local action had arisen from the example given in the book not being in sufficient detail. The peroxide did not touch the lead plate at merely one or two points, but really presented, as shown by the microscope, a roughened surface with millions of points of contact and intervals, the whole being wet with dilute sulphuric acid. There was not a symmetrical flat plate of peroxide by any means, and the dilute sulphuric acid permeated the whole of it, and caused a thin coating of sulphate of lead to be partially deposited on the metallic plate, and so impeded the action of the cell. If that coating of sulphate covered the whole surface of the plate, its action would not only be diminished but reduced to zero. Mr. Fitz-Gerald's chemical formula very nearly corresponded with their electrolytic formula, but he strongly protested against Mr. Swinburne's stricture that chemists did not properly apply their knowledge to the study of electrical questions, but that in the book referred to it was supposed that they, Messrs. Gladstone and Tribe, had treated a salt as a compound of an oxide with an acid. That was a notion of antiquated chemistry, discarded some 30 years ago, and was not admitted by modern chemists. The reason why the full value of complete re-action was not obtained in the Faure and Planté

Digitized by Google

cells was that the mixture of the sulphate of lead interfered to a large extent with the ready reduction of the oxide of lead. Mr. Tribe had looked very carefully for the existence of any of the lower oxides, but had been unable to trace any indication of them. Much remained to be done in connection with secondary batteries, at present there was nothing final in regard to the study of them, and much investigation had to be made, among other things, as to the conducting power of the mixtures employed in batteries, intended for practical purposes. He hoped that the result of the labors of men who, like Mr. Fitz-Gerald, combined a practical knowledge of the subject along with a knowledge of chemistry, would be to enable a true theory to be arrived at in regard to reversible lead batteries.

Mr. W. H. Preece said there was a physical side of the question in addition to the chemical side which had been treated by Mr. Fitz-Gerald. His experience with cells for three years showed that by the use of hydrometers the variation of the density of the solution indicated the chemical action which took place. When a cell was charged it reached a point of greatest density and had dissolved the greatest quantity of sulphuric acid. When a cell was discharged the sulphuric acid was transformed into sulphate of lead and its weight was thereby reduced. Cells that he had in use showed that there was a fall in the hydrometer of one degree for every nine ampere hours taken out, and it was perfectly easy to ascertain by the hydrometer what charge had been taken out, and what remained in, if proper readings were taken. Mr. Fitzgerald might abhor the existence of "white sulphate," but it was impossible to obtain a cell without it Sulphating always existed, but he (Mr. Preece) had adopted Mr. Barber Starkey's plan of using carbonate of soda to dissolve it, and found that the method was very effective,

The President announced that the discussion would be resumed at an extraordinary meeting to be held on March 17th, and the meeting adjourned.

DISCUSSION, CONCLUDED, MARCH 17.

The adjourned discussion on Mr. Fitz-Gerald's paper was continued.

Prof. G. Forbes drew attention to the fact that in the Union cell the capacity appeared to be greater for a slow than for a quick discharge; a great feature in the battery was its lightness compared with its storage capacity. The nature of the material of which the electrodes was composed was remarkably good, mechanically. The plates, which had been in extensive use, appeared to be quite as good as new ones, there being no deterioration apparent. It was noticeable that white sulphating never took place. He considered that very great forward strides had been made by Mr. Fitz-Gerald. There were several features in the cell which deserved notice, viz., the way in which the plates were supported and the way in which they were kept apart by the use of celluloid. Platinum was used for contacts and also mercury cups; he did not consider the latter an objectionable feature; in fact, the mercury was used because it was found to answer the required purpose well. He would like to have more information about the celluloid, as it appeared to be a very useful material. The employment of platinum was the one objection he saw in the cell, as it must be expensive. The results of all the tests showed that a considerable advance had been made. He was puzzled at a peculiarity which he had noticed in the battery; in the ordinary storage cells it was found that when they were being charged they had an E. M. F. of 2¼ volts, but while being discharged this E. M. F. fell at once to two volts, consequently there was a loss of efficiency in the ratio of 2¼ to 2; in Mr. Fitz-Gerald's battery there was no such difference; what the cause of the difference was he was not prepared to say—was it due to the hydrogen sticking to the plate? If it were so, the new plates would appear to depolarize like the plate in a Smee's cell.

Prof. Silvanus Thompson said that he had tried one of Mr. Fitz-Gerald's cells and it had behaved exceedingly well; that is to say, it had not sulphated and no buckling had taken place; there were also no signs of deterioration. He was a little disappointed at the rate of discharge in comparison with the size of the plates; a higher rate would probably be obtained if the metal in connection with the lithanode was of larger area, but inasmuch as platinum was used the cost difficulty would arise. Lithanode itself was not a sufficiently good conductor to enable a large backing to be dispensed with, such as was used in "grid" batteries. He disagreed upon the sulphating question; there are two sulphates, viz., the grey and the white. The Pb SO_4 was easy to oxidize, but if formed in a cell and reduced to Pb O, then this became Pb_2 SO_5 when the battery was idle and choked the cell. Mr. Preece had recommended the use of the hydrometer for testing the charge in the batteries; he could heartily endorse this, but he differed from the figures given, as these must depend upon the bulk of liquid present. If we know the E. M. F. of an accumulator we ought to be able to calculate the chemical action, *i. e.*, the latter ought to correspond to the calculation if correct. There were five formulæ which had been suggested, and the question was, which was correct; the first was as follows:—

$$+ H_2 \mid O - \tfrac{1}{2} Pb\,O \mid O - \tfrac{1}{2} Pb \mid O$$
$$68000 - 6070 - 25150 - 37200 = .81 \text{ volts.}$$

The 2d gave 1.77 volts; the 3d, which was practically Mr. Fitz-Gerald's, gave .96 volts; the 4th was the commonly accepted one, and was as follows:—

$$+ Pb \mid O - (H_2\,O) + (Pb\,O \mid SO_3 \mid Aq) - Pb\,O \mid O) + (H_2\,O) + (Pb\,O \mid SO_3 \mid Aq)$$

the thermal equivalents of which were

$$51060 - 68800 + 24840 - 12140 + 68800 + 24840 - 88600 = 1.93 \text{ volts.}$$

This was therefore a fair representation of what happened *finally*, though not at first.

The 5th formula was as follows:—

$$+ Pb\,O \mid O + Pb \mid O$$
$$52400 + 51060 - 103460 = 2.2 \text{ volts,}$$

which was, therefore, the true action. Sulphating takes place in two stages, as shown by Planté's experiment in contradiction to what Dr. Gladstone says.

Mr. Sellon did not consider that storage batteries were still in their infancy as suggested in Mr. Fitz-Gerald's paper. There were not many points in which improvements were possible except as regards care in their manufacture and in their management. Practically no advance had been made in the general principle since the batteries were first brought out. The highest result shown in the tables given by Mr. Fitz-Gerald did not exceed those attained in 1881. The good working of a battery depended greatly upon the uniformity of the electrolyte, and the method of daily replacing plates would not enable this to be attained. He did not think that high capacity and durability could be maintained after a time in the solid peroxide plates, as clogging up will take place, and the unequal distribution of the charge which will ensue will eventually spoil them. The distributed lead of the grid in the ordinary plates played an important part, which was absent in the lithanode. He considered that the local action which was so often spoken of was a mere bugbear. The figures which were given of the various accumulators proved that the E. P. S. cells gave 30 amperes per pound weight of active material, and under exceptional conditions as high as 47 amperes as against 16 amperes for the lithanode. He believed that four-fifths of the lithanode plate was practically inactive.

Mr. Andersen stated that an examination of the figures proved the comparatively low results obtained from the lithanode plates.

Mr. Bernard Drake thought the question with regard to this new battery from the consumer's point of view was one of first cost and durability. What people wanted to know now-a-days was whether they could obtain a cheaper battery which would give them reliable results in working and entail no trouble. Time alone would show whether the battery before them met these requirements. Mr. Sellon complained that progress in improvements in secondary batteries was slow. If this was so, the reason was that whenever modifications were made it was necessary to wait many months before any idea could be formed as to whether the alteration was an improvement or not. Even then experience had shown that one was almost certain, if guided by any single experiment, to fall into some error ten times worse than the one which was being rectified. He thought it impossible to determine a fixed output for each maker's cell, as any one could increase the capacity at the sacrifice of durability. For instance, with the E. P. S. form it was usual to vary the output between four and six ampere hours per pound of plate. The figures given by Mr. Fitz-Gerald seemed to include the connections as well as the plates. This, the speaker also thought, was not a fair basis for comparison, as the connections were often made larger than necessary in order to reduce the internal resistance of the whole battery, the resistance of the connections being quite as serious a consideration as the internal resistance of the cell itself. He was glad to see that Mr. Fitz-Gerald agreed with the theory propounded by Mr. Gorham and himself at the meeting of the British Association as to the grid being protected by a dense coating of peroxide. This conclusion was arrived at after a great number of experiments, and he was of opinion that the protecting coat was almost, if not perfectly, dry when a plate was in good condition. If a plate was exhausted, he thought the coating of peroxide became moist, and local action immediately took place. Prof. Forbes had shown a table of some tests with the lithanode plates, in which the capacity of the cells varied considerably, according to the rate of discharge. Had Prof. Forbes taken into consideration in these the recuperative power of the cell? He thought the capacity was not materially affected by the rate of discharge, provided the cell was constantly allowed to recover itself. The proposal to carry the plates backwards and forwards to a charging station was very similar to temporary lighting, with which he had had considerable experience. Although the figures as to cost incurred on any one trial installation would seem to show that this class of work might be undertaken and made to pay its way, yet as the result of a whole season's working with about 25 tons of cells he had found that the price would have to be such as would prohibit any very general use of the system. Mr. Sellon and his engineer had given them comparisons between the E. P. S. and the lithanode

Digitized by Google

plates. These were scarcely to the point, as the whole of the capacity was taken as coming from the active material alone in the E. P. S. plates, the weight of the grids being omitted entirely, whereas about a quarter of the total capacity could be obtained from the grids alone, left unpasted. Prof. Thompson's explanation of the action of the battery was both clever and interesting.

Prof. Ayrton agreed that as regards the capacity per rate of discharge, Mr. Drake was correct in his surmise. He would like to ask whether with the lithanode plates the current kept constant, and then eventually suddenly fell off, and whether this was due to fall of E. M. F. or increase of resistance. He objected to the use of the expression horse-power hour capacity, as it was like speaking of living at the rate of £100,000 a year for a minute when one buys a watch. What was really required was the total number of watts which could be obtained for £1, and not for one pound, as weight does not matter, except in the case of tramcars. Mr. Drake's statement that carting about does not pay on a large scale probably meant that there were not enough people willing to pay so as to make it worth a system being carried out on a large scale. He thought it very advisable for some definite names to be given to the plates of accumulators, as the names anode and cathode are not very happy terms.

Mr. Fitz-Gerald, in replying, said that he wished first to correct an error which had been made at the end of his paper, where the weight of the boxes should be stated to be 20 pounds and not 10 pounds. He and Dr. Gladstone were substantially in agreement, as he had misunderstood the terms used by him; he would accept Gladstone and Tribe's formula except as regards the initial action. He appreciated Mr. Preece's remarks as regards the value of the hydrometer; such experiments threw considerable light upon the question of the amount of sulphuric acid combining with the lead plates. As regards the suggestion that experience would prove that the formation of lead sulphate was a necessity, his own experiments proved quite the reverse; he had charged and discharged one of his cells 80 times, and had never seen any formation of lead sulphate. The rate of discharge of the lithanode elements could be varied within very wide limits. He did not believe that it could be proved that either the capacity or rate of discharge of the lithanode elements was less than that of other batteries; it was exceedingly difficult to take in all that had been said upon this point, and therefore he could not argue the question out on the spur of the moment.

Mr. Swinburne (Communication): I was sorry to be too ill to attend the discussion on Mr. Fitz-Gerald's paper. If Mr. Fitz-Gerald's lithanode is half as good as it looks, it is certainly the greatest advance in secondary batteries since the days of Planté. Many seem to have tried to make plates of peroxide of lead so as to avoid local action, but they have not been commercially successful. The late Mr. Tribe started the idea, but his peroxide seems to have been too soft. The writer tried to make peroxide by electrolysis of an alkaline solution, but his peroxide on the other hand was too dense and impervious. Mr. Fitz-Gerald seems to have solved the problem, and to have got over the chief fault, that is if lithanode is itself durable. Mr. Fitz-Gerald does not say how he makes lithanode, but it is presumably a mixture of lead sulphate and peroxide, the sulphate being the binding material. If the lead sulphate is the only binding material it seems probable that it will be eventually turned into peroxide if the cell is overcharged, as in practice all cells are, when the plate will fall to pieces. The material must be either impervious or pervious, or it may be formed of pieces of impervious material with chinks and crannies so as to expose a large surface. Thus if the particles were examined under the microscope one might expect to find lithanode made up of innumerable little lumps agglomerated together with interstices between, so that there is an enormous surface exposed. The material might thus be almost impervious, and the thin film being converted into peroxide would give the plate enough output. The peroxide made from alkaline solutions is almost impervious, but on discharging a very thin film of sulphate is formed; it seems, therefore, as if the peroxide must always be to some small extent pervious. The sulphate in the lithanode cannot be exposed to the acid at any points, for if it were, it would be converted on charging or overcharging into peroxide. The sulphate must therefore always be protected by the peroxide, just as the lead in an ordinary plate is; the cementing material on which the whole life of the plate depends, is therefore protected from the acid in just the same way as the lead is in an ordinary battery. It would thus seem that there is no reason to suppose that lithanode will last any longer than an ordinary lead plate. This always assumes that lithanode is merely lead peroxide cemented together by lead sulphate, and I hope my reasoning or my premises may be wrong. There is, however, one fundamental difference, that is, that lithanode can only be injured by overcharging, while the prejudicial action in lead plates goes on practically always.

Mr. Fitz-Gerald's theory that the lower electromotive force is due to the formation of a sesquioxide of lead seems improbable. Some time ago I objected to this theory, that even if such a compound can be formed, it cannot be formed in the presence of sulphuric acid. It seems much more likely that the fall in electromotive force is due to the acid in the interstices being used up, so that there is only very weak acid or water available. Perhaps basic salts are formed; this would account for the fall in electromotive force if they were formed in one plate or both.

The failure of cells is more often due to the reduced plate than is generally supposed. Before drawing any conclusions, it is always advisable to test the plates with proof plates, as described in my paper a week or two ago. I would suggest that the experiment with the platinum plates, one having peroxide and the other peroxide and sulphate mixed, does not definitely prove anything. The sulphate may have merely insulated the peroxide in the plate. It also seems strange that such cells could give anything like two volts.

Dr. Gladstone has to some extent misunderstood me. I certainly did not refer to him when I spoke of chemists forgetting their chemistry when working with electricity, as is evident from the context, more especially as it was Messrs. Gladstone and Tribe who brought people to their senses and reminded them that lead oxides did not remain in the presence of sulphuric acid. Dr. Gladstone goes on to say, however, that to view lead sulphate as containing lead oxide was very antiquated chemistry. I do not think he can have understood the drift of what I said. The most modern chemists certainly often write such a compound of lead as the sulphate Pb O SO_3, as if it were a compound of Pb O and SO_3. Though Dr. Gladstone may not write Pb O SO_3, surely he writes the reaction as if the peroxide and the spongy lead were first converted into lead oxide, and the lead oxide were then acted on by the acid to form sulphate with the elimination of water. What I tried to show was, that if such an action took place, the only energy available as electrical energy would be that due to the algebraical sum of the energies of the formation of lead oxide; but energy equal to that due to the formation of lead sulphate from lead oxide would be converted into heat, and would not be available in the outer circuit. If the lead and lead peroxide were converted into Pb O, and a secondary action with the electrolyte then took place, one would expect to get the same electromotive force from lead cells whatever the electrolyte. Of course I am aware that the energy of combination does not fully account for the electromotive force of cells, and it seems probable that there are what might be called Peltier effects of enormous magnitude. For instance, if water is decomposed, and with platinum plates, and also with a zinc cathode and peroxide anode, the electromotive forces required are very different, while the chemical and physical changes are the same in each case. Dr. Gladstone lays stress on the value of lead sulphate as it prevents local action in a cell while standing, and points out that its formation is therefore necessary to the life of the cell, but he does not say that the high electromotive force of a sulphuric acid lead cell is due to the strong affinities of the electrolyte and coatings.

Mr. Preece mentions that he has tried sodium carbonate to remove lead sulphate as proposed by Mr. Barber Starkey; it surely would be better not to wait till a lot of sulphate is formed and then reduce it, but to put a little sodium sulphate, not carbonate, in the cell at first, to prevent the accumulation of sulphate, as proposed in my paper. It cannot be a good plan to put much sodium sulphate in a cell, as creeping may result.

ELECTRIC MEASURING INSTRUMENTS.

At a special meeting of the Glasgow Philosophical Society, held in the physical rooms of the University on Wednesday, the 20th of April, Sir William Thomson described and showed a "double chain of electric measuring instruments," which contained various features of novelty and great interest. Sir William stated that he had been engaged in devising a chain of current measuring instruments, which should measure currents through the whole interval, from a millionth of a milliampere up to 1,000 amperes, and a chain of voltmeters which should measure up to 40,000 volts. Six of the instruments shown were modifications of the old principle of the attracted coil, weighed in a balance. In the double acting volt balance there is a coil fixed to each end of the beam of the balance so that in the neutral position it lies between two fixed coils, parallel and co-axial with it. The balance is adjusted to its zero position by a weight, movable along the beam by means of a screw, while the adjustment for sensitiveness is obtained by a vertical screw and weight. The balance is made by a sliding weight, which moves along a scale forming part of the beam of the balance. When the zero position is nearly attained by this means, the reading is taken by means of a multiplying lever index, attached to the beam and scale. The requisite re-

Digitized by Google

sistance coils for the potential instruments are attached to them, and their variation with the temperature determined, four different weights being provided with each instrument proper to the temperature 15°, 20°, 30° respectively. In the current instruments, the resistance coils are, of course, omitted, the attracting coils being of thick copper. One most important novelty common to all the balance instruments, is the mode of suspension, by fine copper wires passing round cylindrical axes, giving the appearance between the axes of a miniature weaver's reed, which takes the place of the ordinary knife edge arrangement. This invention bids fair to oust the knife edge balance entirely, and not merely in electrical instruments, combining as it does, the advantages of great stability, strength and delicacy. Various other arrangements were shown in the case of the balance instruments. One had a scale pan for weights; a second, a series of cross bars at various distances from the middle point of the beam, on which weights were hung; while the weights in a third were hung in chains from the beam, each link being raised into position by a separate lever. Another new form of voltmeter was the marine instrument, which consisted essentially of a soft iron ellipsoid in the field of the coils, fixed to a vertical stretched platinoid torsion wire, an index pointer attached to the ellipsoid indicating the rotation of the ellipsoid when the current passes. This form, as its name indicates, is meant for marine use, the readings being unaffected by very considerable oscillations, such as it might experience on shipboard. An electrostatic voltmeter, which is a remote relative of the quadrant electrometer, was shown, for measuring high potentials. These instruments, together with the tangent galvanometer for small currents, will cover the entire interval, both of current and of potential measurements.—*Industries.*

DON'T TAKE A BACK SEAT.

MAKE up your mind that you will have a front seat in life, and attract to you the powers that carry you to the front seat. If (in mind) you take the back seat, you get only the back seat. The confident, determined mood of mind, steadily kept up, brings to you other confident people. Confidence, in the business world, means both cash and credit.

Don't be a screw! What keeps thousands of noses on the grindstone of hard times is that they have no confidence or courage in themselves to take risks or responsibilities. They keep a poorhouse in their minds and live in it. They aspire to be only a screw in the business machine, instead of striking out and making a machine of their own. The screws are book-keepers, telegraph operators, clerks, and all who never hope or plan for anything beyond a situation and steady wages. Confidence and brains combined find such screws ready made by the thousand. They make the screw do as much work for as little money as possible. When one screw is worn out they throw it aside and get another.

The screws find fault with the monopolist. Their real slavery is in their own minds. They never think, aspire, plan or demand in thought to be anything but screws. They think there is no place for them at the head of a business. Their first and great step towards staying permanently at the tail of a business lies in thinking that they must remain at the tail.

Real business does not lie alone in being industrious. The goody-goody books and maxims have only told half the story about industry. A great deal depends upon what you are industrious about. If you spend all your time in polishing pans or blacking boots, your industry wont carry you very high. The industrious mind in a rested body plans in an hour what brings in more money than a tin pan polisher may earn in a year. People who work only, or mostly, with their bodies have as good a right as the capitalist to work with their minds. The world always wants new things, more curious things, more improved things, more amusing things. No workman in any trade, any art, any profession, should be content with doing what some one else has done before him, even though he does it well. He should aim at doing something better than any one has done before him. When he can do this he must next push it on the world's notice.

Push is a talent as much as skill in any art. You can commence pushing by imagining yourself a pusher. Keep yourself before yourself in your mind as a pusher, and such a frame of mind will at length make you push. There is a power of continual imagination of yourself in any certain character which does make you more and more like such character. Imagine that the best belongs to you and you will find the best coming to you. Imagine the worst—see yourself in the poorhouse—and the poorhouse comes to you. Success, like charity, must commence at home—in the mind.

If now you are compelled to live in a poor room and on poor fare, do so only under protest. Keep your mind on the better room and the better fare. Don't say, "I s'pose I must always take up with this." I say rather, "I am going to have better things than these." You are then creating for yourself strength, not weakness. You are then ever strengthening this inexplicable mental attraction which will bring these things to you.—*Roller Miller.*

ENGLISH SALUTATIONS TO THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

The following genial article appears in the *Electrician* of London, June 17th.

OUR AMERICAN COUSINS.

The meeting of the British Association on the American continent in 1884, and more particularly the visit which many of the members paid to the States on that occasion, have been not merely conducive to good relations between kindred races but productive of fruitful results to the community of science. In May of that year the American Institute of Electrical Engineers came into existence, and it was honorably represented at the Association's gathering at Montreal in the following August. A month later the Association furnished representatives to attend the Electrical Exhibition at Philadelphia. There is little doubt that from one of these points the society which in America corresponds nearest to our Society of Telegraph-Engineers and Electricians practically dates its active career; and equally probable is it that the English visitors contributed to make its beginning a hopeful one. At all events, the two societies are working on similar lines and for the same ends: and we may confidently assure the younger society of the sympathetic good wishes of its elder cousin in England. A more substantial proof of good-will would, we have no doubt, be forthcoming should the American Institute find it necessary to ask for it in the shape of subscriptions to their building fund—or to speak in the American manner, their "Permanent Quarters'" fund. If we hope that no such appeal may be necessary it is simply because we should prefer to see the money subscribed on American soil in proof of America's sincerity in patronizing—to quote the native language again—"the development of Electric Arts."

The position of the British and American societies is identical in respect to their indebtedness to an external society—that of the Civil Engineers in both cases—for their places of meeting. The former, it is true, possesses a separate establishment, liberally endowed, and already possessed of offices and reading room, with probably the finest electrical library in the world. At these premises, too, are held the Students' meetings, which have been only recently started, although the admission of students to the privileges of the Society dates many years back. We incidentally mention this fact for the benefit of our American friends, some of whom seem to have been much exercised on a point of dignity by a proposal to add to their roll a class of "Juniors." These juniors are spoken of disparagingly as boys who have no serious interest in the objects of the Society. We are naturally diffident in offering a common-sense suggestion to our hard-headed transatlantic relations, but it does seem to us that were they to call these "boys" *Students*, and take steps to make them live up to it, the question of dignity would be satisfactorily disposed of, as it has been here.

Except for the purposes above named, however, the English Society of Telegraph-Engineers and Electricians has been dependent during the whole of its lifetime, dating from 1868, upon the

Digitized by Google

generosity of the Institution of Civil Engineers for the use of their splendid theatre, in which the Society's fortnightly meetings during the spring and winter months of the year are held. The American Society, on the other hand, although only three years old, aspires already to own a separate "house" all to itself, and the cost of which is to be $30,000. The sum is not extravagant, and the charge for maintenance, exclusive of personal service, is estimated at only $2,000. Of the prime outlay it is thought that a third can be collected, the remaining two-thirds being borrowed at 4 per cent. interest, which is included in the figure mentioned for maintenance. The scheme is a bold one, considering the present numerical strength of the Society; but the Council are confident of largely augmenting its members, and more especially when it enjoys the advantage of possessing an establishment of its own "where men engaged in the same pursuits could freely interchange ideas and afford each other mutual encouragement." A library is also in contemplation, the general plan being "to establish an institute of such repute that it will become the natural custodian of valuable collections of books and apparatus which are now so frequently scattered when their owners pass away."

In commending this scheme to the favorable attention of our readers we cannot abstain from noticing the eminently sound and practical character of the American Institute of Electrical Engineers. Casting a glance over the list of papers brought under its notice between May 1884, and the corresponding month of the present year we are struck by the invariable utility of the subjects dealt with; and this impression is confirmed by such of the discussions as have been reported in American journals coming into our hands. But we have also been struck by the long-windedness of the speakers. It seems to be the custom of American electricians to invigorate their bodies during the session by frequent social gatherings, which take the form of dinners, and, if we may judge by what happened at the Philadelphia Electrical Exhibition, to obtain relaxation for the mind by indulging in infinite jest when the serious business is ended. These customs now recur to our memory in this relation, as explanatory of national traits which we had never been able to account for before. In one of the grotesquely humorous primers published at the fag-end of the exhibition there occurred the following description of electric lights, which, it was said, were of two kinds, namely, "Our kind, and the other fellow's kind." Our light is much brighter than the other fellow's light. The other fellow's light is surrounded by a cloud of non-luminous verbosity." Now, irreverent and unseemly as this sort of caricature may appear, it is not wholly useless or impertinent. For simple verbosity our American fellow-workers—or, more correctly speakers—incontestibly carry off the palm. When we take up an American technical paper we have always first to wade through or skip an exhausting oration. This we now very gladly attribute to the dinners. But for English verbosity of the "non-luminous" kind we have only one explanation to offer, namely, the absence of that humorous faculty which is ever alert in the native born American. On this side of the water we should be saved from many a non-luminous infliction if we were equally endowed with the sense of the ridiculous; and it is probably the American's superiority in this respect that has kept their electrical engineers strictly to the practical aspect of their profession, so soon as the preliminary orating has been got over. We have not obtained, and we hardly expect to receive from America any supremely valuable contributions to our stock of mathematical and scientific knowledge; but she has supplied us with much that is in the highest degree valuable in the domain of practical and applied science; and we are the more thankful for it, because its diffusion here may counteract our tendency to wander into fields of abstract speculation. The American Institute of Electrical Engineers has a very useful career before it; and the venture on which it is just now embarked deserves, and will receive, the best help we can give it.

UNDERGROUND TELEGRAPHY.[1]

BY CHARLES T. FLEETWOOD.

In the year 1816, Mr. (afterwards Sir Francis) Ronalds laid his first experimental line underground in his garden at Hammersmith, and convinced himself, at least, of the practicability of establishing telegraphic communication by means of insulated wires placed beneath the earth's surface. A small book published by him in 1823, entitled "Description of an electric telegraph, and of some other electrical apparatus," gives a full account of the experiments referred to. A trough of wood about two inches square, well lined inside and out with pitch, was placed in a trench 525 feet long and four feet deep; lengths of stout glass tube were joined together by means of shorter lengths of similar tube of somewhat greater diameter, the joints being made with soft wax to allow for expansion and contraction caused by the variation of temperature. A copper wire was drawn through the glass tube, and the tube was embedded in pitch, the covering being screwed down while the pitch was hot. Mr. Ronalds further suggested that wires should be buried in iron troughs, in trenches six feet deep, in the middle of the high roads, and if there was any fear of the communication being interfered with by any mischievous person or persons, two different routes should be chosen. Testing stations should be established along the route, and linemen stationed at these points ready to start out after faults at any moment, should there be a necessity for so doing. He recommended that offices should be opened all over the country, and evidently foresaw the immense advantages that would be derived by the government, as well as by the commercial world, in the employment of what he considered so "diligent a courier" as electricity.

Messrs. Cooke and Wheatstone took out their first patent in 1837, for "Improvements in giving signals and sounding alarms in distant places, by means of electric currents transmitted through metallic circuits." In this patent they included a plan for laying down subterranean wires, and in the same year established communication between Euston square station and Camden town, by means of five copper wires let into five grooves cut longitudinally in a piece of timber, the wires being covered with cotton and passed through a preparation of resin, and after being placed in the grooves, tongues of wood were placed over them to make all secure, and the whole was then covered with pitch and buried in the earth, up what is known by the railway men as "the incline," between the above-named points.

The second patent taken out by these pioneers included placing wires, made up into cables, in iron piping; this was in 1838. During the following year a line of five wires, in an iron tube, was put down on the Great Western Railway from Paddington to West Drayton, and afterwards on to Slough.

Conductors, covered with cotton and passed through different solutions, were tried in a variety of ways, some being suspended and others buried in pipes, but very great difficulties were experienced in preserving the dielectrics; weak places being traced would be repaired with India-rubber tape and a solution of the same material. This kind of work was being done near the Stepney station, on the Blackwall railway, when Mr. Hatcher—then engineer to the Electric Telegraph Company—introduced to the lineman a piece of lead tubing containing several wires covered as above.

The first line of wires erected upon poles for commercial purposes, was from Nine Elms to Gosport; this was before the London and South Western railway was extended from Nine Elms to Waterloo station. The Electric Telegraph Company opened its first office at 345 Strand, and decided to lay the wires underground from that point to Nine Elms station. Two lead tubes, about half an inch in diameter, covered with tarred yarn, each tube containing four copper wires wrapped with two layers of thick cotton, and the tube filled with a mixture of tar, resin and grease, were drawn into a three-inch cast-iron socket pipe. The lead tubes were originally fifty yards in length. After the wires had been joined, a piece of lead tube of larger gauge, encircling the pipe, was drawn over the joints and soldered at each end. A portion of this tube, recently dug up, was found to be in excellent condition, the tar being quite fresh.

In the year 1842, a specimen of gutta-percha was first introduced into England by Dr. W. Montgomery, but up to 1845 only a few hundredweights had been exported from Singapore. Since that date many thousands of miles of wire have been covered and buried beneath the surface of the earth, or submerged in the sea. The quantity of gutta-percha imported into London alone during the three years ended December 31, 1886, amounted to 6,700 tons. Messrs. Keene and Nickels received a small quantity of gutta-percha from Singapore during 1845, and this appears to have been the first imported into England. This firm ultimately sold their patent for processes in working gutta-percha to the Gutta-Percha Company, Wharf Road, City Road.

During the following two years Mr. Hancock took out patents for cutting, cleansing, and pressing gutta-percha through rollers; but no mention is made of covering telegraph wire in any patent up to the end of 1847.

To Professor Faraday credit has been given of having announced that gutta-percha was an excellent dielectric, and in the beginning of 1848 patents were taken out for covering wires with it. The first patent taken out in England for this purpose, so far as I can learn, was by Messrs. Barlow and Foster, the plan suggested being as follows: The wire was placed between two heated fillets of gutta-percha, and made to adhere by passing between two rollers In the same year Mr. John Lewis Ricardo, chairman of the Electric Telegraph Company, patented a machine with a pair of grooved rollers, through which the wires passed, placed parallel between the fillets, the action of the rollers being to bite nearly through the gutta-percha and allow of the several wires so covered being easily separated.

These early machines did not do their work with the same regularity as those in use at the present time, for it frequently happened that instead of the covering being smooth and uniform, it was found to be thicker at intervals—so much so, that it had to be pared down with a sharp knife.

The directors of the Electric Telegraph Company, having dis-

1. Paper read before the Society of Electricians and Telegraph Engineers, London, May 26, 1887.

Digitized by Google

covered that the Strand was not the best position for their chief office in London, resolved to build a central station at the end of Founders' court, Lothbury. This was formally opened on the 1st of January, 1848. From this office a circuitous line of three-inch cast-iron socket pipes was laid, chiefly under the footways.

When these pipes were first laid down, wires covered with cotton, passed through one of the preparations in use prior to the introduction of gutta-percha, were drawn into the pipes; but these wires were soon substituted by the wires covered with gutta-percha.

The first section of line in London into which gutta-percha covered wires were drawn was from Lothbury to Shoreditch, in 1849; and this was followed by the line to Euston and King's Cross. The wires that were first drawn in were covered with gutta-percha by one of the processes already described, and failed, owing to the gutta-percha seam opening longitudinally and exposing the conductor.

At this date a large number of experiments were made: wires of iron, brass, and copper were covered with gutta-percha; in some cases single wire, in others three wires, and as many as seven wires were enclosed in a solid core. Great improvements were rapidly introduced, and copper wire of No. 16 B. W. gauge was covered with solid gutta-percha of excellent quality, up to No. 1 and 8 gauge; and by August, 1854, no less than fifteen miles of pipes, containing 350 miles of wire insulated with gutta-percha, had been put into working order in London alone for the Electric Telegraph Company.

The pipes used by this company were of cast iron, three inches in diameter, and cast with a flat surface on one side, upon which were the initials E. T. C. Across Hyde Park the pipes were of earthenware, the joints being made with clay.

In 1850, the success of the Electric Telegraph Company induced some enterprising capitalists to form rival companies, one of which—the Submarine and European Telegraph Company—laid a line of six gutta-percha covered wires from London to Dover. This line was completed by the 1st of November, 1852. In 1853 the British Telegraph Company commenced burying six gutta-percha covered wires along the high roads from London to Liverpool, via Birmingham and Manchester, the latter place being reached by the 1st of March, 1854, and Liverpool during the same year.

The Magnetic Telegraph Company, in 1853, laid ten wires as far as Liverpool, and six wires between Liverpool and Portpatrick. Underground wires were also laid between Cork and Queenstown

These wires were buried in a wooden troughing of about three inches outside, with a groove about one inch square, having a lid of the same material; this was fastened down with nails after the wires had been placed in the troughing. The iron troughing was of about the same dimensions externally, but, of course, allowed more space for the wires inside; the lids were of iron.

When cast-iron pipes were used in towns, they were very similar to the iron troughing, being cast in two pieces; they were patented by both Mr. Reid and Mr. Henley, and are known as Reid's and Henley's split pipes The wires were in some instances laid in troughing without any protection beyond the gutta-percha, but in other cases they were protected by two layers of tarred yarn laid on in opposite directions. The whole of the stores appear to have been of the very best quality.

The underground line of the Electric Telegraph Company, laid along the side of the London and North Western Railway, from London to Manchester and Liverpool, was somewhat different from those just described. The pipes were of earthenware, the joints being made with clay. At intervals of fifty yards split earthenware pipes of larger diameter were fixed, to allow of the wires being drawn in. An iron wire was passed through the pipes as they were being put together, for the purpose of drawing the cables through.

From London to Watford four wires only were drawn in, but these had to be increased to eight, which number was continued on to Liverpool.

The work of constructing these different systems was finished by the beginning of 1855, and, after a very short life, in 1857–58 they were condemned, and wires on poles substituted. This applied to all the underground lines laid from London to the provinces in 1853.

When the greater portion of the wires were taken up in 1857 and 1858, a few sections were allowed to remain, especially in and near London. Portions of these lines have been recovered at different periods, in different localities, and under various circumstances. Some of the gutta-percha wires, that have been buried for more than thirty years, are now in first-class condition, but where this is the case they have been found wrapped in two layers of tarred yarn, and laid in iron casing or split pipes. The same cannot be said of that found in wood troughing, except under special surroundings. There is every reason to believe that the gutta-percha used to cover these wires was the real material, and was not subjected to anything akin to the so-called improvements in manufacture of late years.

Although the insulating material was good, yet there were many faults in the wire previous to its being buried. Probably owing to some fault in the machinery used for covering the wire, the copper wire got elongated and pressed in the form of a loop through the gum; many such places were discovered when the wires were recovered and examined.

The wire used by the Electric Telegraph Company on the London and North Western Railway, was covered with gutta-percha, and then each wire was served with tape. After this wire was delivered on the railway at Watford, it was passed through a bath of hot tar and sand; while the drums were moving at a regular pace, a serviceable jacket of tar and sand was given to the wire, but when anything happened to interrupt the continuity of this operation the portion left in the bath was exposed to a temperature sufficient to melt the gutta-percha, and the wire passed out covered with tape, tar, and sand only. Adequate care was not exercised in protecting the wire from the heat of the sun, it being allowed to remain lying on the banks of the railway uncovered for a considerable period, so that the copper wire got out of the centre, and in some cases became exposed altogether. After the cables had been put in place, the drawing-in holes at every fifty yards were left uncovered, and the ends of the wires left exposed, waiting for the jointers to come and make the permanent joints, and the split couplings to be put on.

The means adopted to preserve the wires were defective. Knowledge derived from a series of observations points to the fact that split pipes, whether of wood or iron, are not equal to the requirements of a subterranean line of telegraph wires. Wood troughing is subject to dry rot, and therefore various expedients have been resorted to with the view of preserving the timber; but some of these preservers act injuriously upon the wire, causing the insulation to be destroyed. When the line is placed near to trees, especially oak trees, the surrounding moisture is absorbed for a considerable distance; this applies to lines constructed of either wood or split iron pipes. Special circumstances may arise that would make it expedient to use wooden troughing, but where there is an absence of such special conditions solid cast-iron pipes are to be preferred. In London split pipes are a source of danger, for since the chief thoroughfares have been paved with wood or asphalt, the gas that escapes in considerable quantities from the gas companies' mains, accumulates under the surface and finds its way into these half-pipes, and thence into our junction boxes, causing much annoyance and inconvenience. I have known cases where the accumulation of gas, collected through split pipes, has been so great that it has been necessary to open the box some minutes before the jointer could light his lamp with safety.

Where earthenware pipes have been used instead of iron, it has been done for economical reasons only. Such a line was laid some years ago from opposite St George's Hospital, Knightsbridge, across Hyde Park, to Tyburn Gate, the joints being made with clay. Another section of the original line laid in 1851 between the site of the exhibition of that year and the Serpentine bridge was of earthenware. Some years ago the 16 wires that were drawn in when the line was laid, had to be drawn out to allow of the number being increased. Much difficulty was experienced in moving the old wires, and it became necessary to break one, and by laying it over the trench so to trace the locality of the obstacle; when this was done, and the ground opened, it was found that the root of a tree, about 10 feet long, had found its way through the clay with which the joints of the pipes were made, and had entwined itself round the cable in such a manner as to hold it fast. I need scarcely say that the gutta-percha had entirely perished at this point. Pipes of this description are always more liable to be damaged by the operations of the gas, water, or the hydraulic power companies' workmen when opening ground to get to their mains, than solid cast iron pipes.

Another, and I think the chief, cause of the rapid decay of the lines referred to, was the rapidity with which the work was carried out. All the companies were racing to get through to the provinces as soon as it was possible, and there is no doubt that this led to the work being done without the necessary supervision being given.

At the present time it is found necessary to place experienced men to watch the work as it proceeds, for where this has not been done the work has proved to have been unsatisfactorily carried out. When this is taken in connection with the fact that the majority of the men employed on these works were totally ignorant of the necessity of the greatest care being exercised, and the utter impossibility of the few able men to be everywhere along the works at the same time, it is not surprising that these early lines had to be so soon abandoned.

We now come to a very important epoch in connection with the telegraph systems of this country—the transfer of the telegraphs to the post office. This took place in the beginning of 1870, when all the different companies' lines were diverted to the central office of the Electric Telegraph Co. in Telegraph street, Moorgate street. This work was carried out under the direction of Mr. Henry Eaton, now the superintending engineer of the metropolitan district.

After the concentration had been effected it was soon discovered that nearly all the lines, with the exception of those in

Digitized by Google

solid cast iron socket pipes, were defective in insulation; and as the various methods of construction did not provide for renewals to be carried out without opening the ground, they were gradually abandoned, and the number of wires in the 3-inch cast iron socket pipes of the late Electric Telegraph Co. increased to meet the ever expanding requirements of the service.

Previous to the completion of the new post office in St. Martin's-le-grand, in 1874, the pipes and wires passing north, south, east, and west of the new building were led through the basement and up to the instrument gallery, where they were terminated upon a very extensive test-box, the terminals being numbered from 1 to 1,000.

The contemplated change from the office in Telegraph street having upset all the numbers in the joint-boxes in the streets, it was considered necessary to re-number the whole, and thus make the numbers in the boxes correspond with the new test-box. This was carried out so perfectly that the whole of the circuits were diverted to the new office in a very few hours on the night of January 17th, 1874, without the slightest interruption to the ordinary traffic.

At this date the length of pipes in the metropolitan district was about 100 miles, and the total quantity of wire in the pipes amounted to 3,000 miles. Shortly after this date an agitation was started against the over-house wires, and it was decided by the post office authorities that a new line of 3-inch cast-iron pipes should be laid down, and 100 miles of wire drawn into it, in substitution of 126 miles of over-house wire.

This was the first piece of work carried out in London with the view of reducing the over-house system belonging to the post office, and this was supplemented by many others, until the whole of the main lines of over-house wires had been removed.

The chief portion of this work was finished before the introduction of that marvellous little instrument the telephone, which must be held accountable for the dangers apprehended from the extraordinary network of wire suspended over the chief thoroughfares of the city, and, to a lesser extent, the suburbs of London. It has also had the effect of largely increasing the mileage of underground wire, for it was soon found that for a telephone to work satisfactorily underground, two wires must be used instead of one, and after may experiments it was found that much better results were obtained by the use of four-wire twisted cable covered with tape, two of the wires being used diagonally for the telephone circuit, thereby overcoming the effects of induction. Twenty of these four-wire cables, equal to 80 conductors, are now generally drawn into one 3-inch cast-iron pipe, some of which form part of the original lines laid down in 1847—40 years ago; and, judging from what I have seen when the wires have been drawn out for increasing, there is no reason to think they are likely to give any trouble for many years to come.

At the beginning of 1880 an experimental line of 1⅛ inch wrought-iron pipe and 30 No. 18 B. W. gauge copper wires, each covered with manilla, and the whole made up into a cable and covered with a braid of the same material, was laid for the post-master-general, under the direction of the patentee, Mr. David Brooks, of Philadelphia, the insulation being obtained by filling the pipe with oil after drawing in the cable.

After this line had been completed, the wires, with one or two exceptions, gave very good results as regards insulation, but from the first there was a very great loss of oil, and this continued more or less although every effort was made to trace and repair the leaks. Although the cost of construction and maintenance has been very heavy, it does appear to me that the system is worth a further trial under more favorable conditions—for instance, along a country road where it might form part of a through line, and where the pipes would not be subjected to such frequent disturbances as in the busy thoroughfares of London.

Several very large extensions to the boundary of the metropolitan district, and in some cases even beyond, as well as the enormous increase that has taken place in the supply of wires for private use, have increased the mileage since 1874 up to the present time from 100 miles of pipes and 3,000 miles of wire to 240 miles of pipes and 12,000 miles of wire, the latter being an average of 50 wires through the entire length of pipes. The total weight of copper buried in the metropolitan district amounts to over 200 tons, and that of gutta-percha to 250 tons.

It will be obvious that in the main thoroughfares near to the general post office the wires are very numerous. Through Little Britain there are two 3-inch pipes containing 109 wires; Aldersgate street, two pipes, 160 wires; Gresham street, two pipes, 150 wires; Cannon street, two pipes, 168 wires; Cheapside, two 3-inch, one 4-inch pipes, and 242 wires; Ludgate Hill, one 4-inch, three 3-inch pipes, 350 wires; and down Newgate street, two 4-inch, three 3-inch pipes, with over 400 wires. These numbers have been reached by gradual increments, the practice being to put into a new pipe as many wires as are actually required for the special service, with a small percentage of spare wires, and as soon as these have been appropriated for new circuits, to increase the number by drawing out the existing wires and replacing them by a cable with additional conductors. This class of work is continually being carried out in different parts of London to meet the great increase in telegraphic and telephonic business.

During the last fifteen years nearly every section of line has been disturbed, either for the purpose of removing faults which sometimes trouble us in or near the flush-boxes, through the necessarily frequent exposure of the gutta-percha to variations of temperature caused by the linemen getting new wires through, &c., or by the necessity of increasing the number of conductors as occasion may arise. So much of this work has been done that it would be difficult at the present time to point out any portion of line that has not been renewed during the above period.

The advantages of being able to replace the working wires by a greater number without seriously interrupting the communication must be evident to all; but this is easily accomplished where the lines are constructed of 3-inch cast-iron socket pipes with boxes either fixed flush with the pavement or buried beneath the surface at every fifty or one hundred yards, according to the size of the cable to be drawn in.

After many years' experience, and with a full knowledge of the many schemes that inventors have introduced from time to time, I do not know of any that can be compared with the present system for simplicity, utility and durability.

DISCUSSION.

Major-General Webber, R. E., pointed out that the practice of adulteration of gutta-percha was one result of the great demand for the material. The underground line between Lowestoft and the cable hut, which had now been down some 20 years, when last examined, was found to be in absolutely perfect condition—this being laid at a time when adulteration had not assumed the extent it had at present. In 1878 he went to Amsterdam to axamine some samples of gutta-percha; these, which were 15 in number, and varying in price from £10 to £20 per ton, were all found to be mixtures. He thought Mr. Fleetwood had hardly laid sufficient stress upon the fact that to the Electric and International Company was practically due the London system of underground work, this being laid under the direction of Mr. H. Eaton, Mr. R. S. Culley, and Mr. Ship. The secret of the success of the system was the power of drawing the wires in and out of the pipes. With regard to the aerial system of the United Telephone company, he thought that capitalists ought to recognize the fact that all the wires must eventually be placed underground, and that if they commenced at once to do this, doing a little each year, then eventually the whole system would be completed at an expense which would be little felt, and at a time when the use of aerial wires would be no longer tolerated.

Mr. A. J. S Adams thought that it would have been an advantage if Mr. Fleetwood had given a few more details concerning the durability of gutta-percha covered wires He considered that if the aerial trunk lines were properly built there would be no necessity for replacing them by underground work.

Mr. W. H. Preece thought that the object of the paper was not sufficiently appreciated. Mr. Fleetwood had given the result of his own personal experiences, and it was not to be expected, therefore, that he should have spoken of anything else. The underground work between Liverpool and Manchester, laid in 1870, had been spoken of; he would say with reference to this that it was still in use and was working properly, but the earthenware pipes, which had originally been used, had been mostly replaced by others of iron. One of the most promising systems of underground work was that being introduced by Mr. Eddison, of Messrs. Fowler & Co., Leeds; this consisted of cotton-covered wires bedded in a mixture of resin oil and other materials, and tightly enclosed in a lead pipe. Much had been said about the small amount of underground wire used in England as compared with that in other countries; but the facts were that in this country there were 25,000 miles of wire, which was 3,000 miles more than there were in Germany. There was now a proposal before Parliament to expend £2,000,000 in underground work, but it was doubtful if the amount would be authorized. It should not be forgotten that underground wires were four times as expensive as overhead wires and had only one-fourth the working capacity for fast-speed working. It was quite possible, however, that better and cheaper results might eventually be obtained. The use of secondary generators was likely to be very extensive, and the employment of these in connection with underground wires would have to be considered; such papers as that of Mr. Fleetwood went a considerable way towards assisting a solution of the question.

Mr. A. Siemens drew attention to the fact that in 1847 Dr. Siemens suggested the laying of an underground line insulated with gutta percha.

Mr. Eddison said that though the durability of lead had been questioned, he considered that this was groundless; he had a specimen of a lead-covered cable with him, which had been in a tunnel in Yorkshire for 32 years, and which was quite perfect in condition.

Mr. A. Bell said that one great fault in bitumen for insulation was its want of elasticity and the tendency to crack at low temperatures. In order to keep wires insulated with gutta-percha good the pipes ought to be thoroughly well jointed and to be deeply buried.

ELECTRIC LIGHTING FROM PRIMARY BATTERIES.

A NEW primary battery was exhibited this week by the New Electric Light Syndicate, limited, at 47 St. Mary Axe, London, E. C. The electrodes are zinc and iron or zinc and copper, the iron or copper electrode being covered with some depolarizing material. The exciting fluid is a caustic alkali. Originally this battery was made in the same shape as the well-known Lalande cell, the iron trough itself forming one of the electrodes. This was 18 inches by 10½ inches by 3 inches. The cell was tested by Dr. Walmsley, who reported favorably on it, and the following are some of the figures of this report: On an open circuit the E. M. F. was .75 volts. When the circuit was completed through a suitable resistance the E. M. F. fell to .69 volts, and the current was 3.45 amperes. After 50 hours' continuous run the current was still the same, but after 100 hours' continuous run it fell to 3.21 amperes, with a proportionate fall in the E. M. F., the external resistance having been kept constant all the time. After a total run of 150 hours the current was 2.27 amperes. The cells were not of the tray pattern, but ordinary cells in earthenware jars with vertical electrodes, which in this case were zinc and copper, the copper being coated with the depolarizer in the shape of an oxide of lead plate held in a bag of vegetable parchment. The solution is caustic soda. The inventor, Mr. Newton, claims that the vertical form gives better results as to constancy of current than the original pattern. Six of these cells were used to charge some E. P. S. accumulators, which in turn supplied the incandescent lamps fitted up to show that the battery is capable of being utilized for electric lighting. The crucial point in the system is the process by which the inventor hopes to recover all the zinc and about 95 per cent. of the caustic soda consumed. This process must for the present be kept secret, as the patent rights have not yet been fully secured. We are, therefore, unable to state its essential particulars, or to say whether it may reasonably be expected to prove successful in practice; but it must be evident that the inventor's claim of being able to light a house at a cost comparable with that of gas can only be substantiated if his process of recovering the materials is both easy and cheap. Until this has been publicly demonstrated it would be premature to form an opinion regarding the technical and commercial value of this battery.—*Industries.*

THE BURLINGTON BRAKE TESTS.

THE Brake Committee, of the Master Car Builders' Association, do not regard the recent brake tests at Burlington as conclusive enough to justify the recommendation of any particular brake for general adoption. They, however, regard two conclusions as indicated by the information derived from the recent tests.

1. That the best type of brake for long freight trains is one operated by air, and in which the valves are actuated by electricity.

2. That this type of brake possesses four distinct advantages.

(a). It stops the train in the shortest possible distance.

(b). It abolishes shocks and their attending damages to equipment.

(c). It releases instantaneously.

(d). It can be graduated perfectly.

The committee recommend further tests and investigation.

A HEAT BATTERY.

MR. J. A. KENDALL has devised a novel battery consisting essentially of two metal plates having a saline or vitrified substance called the "medium" between them. One plate is exposed to hydrogen, the other to heated air or oxygen. Platinum gives good results as the metal, but gold, palladium and iron may be used. Clay saturated with chloride of sodium or potassium, and firebrick permeated with vitreous matters, may be used for the medium. The cell is heated and the hydrogen traverses the medium, and is believed to combine with the oxygen or air. The electric current is drawn off by terminals connected to the plates as in an ordinary voltaic cell.—Glasgow *Engineer*.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Subway Litigation.—The Subway Commission Bill Signed by Gov. Hill.—Fire at the Works of the United States Electric Light Company at Newark.—Success of the Electric Bulb.

THE New York Electric Lines Company keeps to the front in its persistent efforts to get a foothold in the streets.

Judge O'Gorman, of the Superior Court, heard argument last month in its suit against the Electric Subway Commissioners, the American Consolidated Conduit Company, John D. Crimmins, contractor, and the Consolidated Telegraph Company, upon a demurrer by the defendants. The Eiectric Lines Company claims that its charter, granted by the Legislature, gives it the sole right to construct electric subways in the streets of New York, and asks the court to restrain the defendants from proceeding with their work. The demurrer sets up forfeiture of its legal existence by the plaintiff company through failure to begin work within the time specified in its charter.

The Electric Lines company claims that the filing of its plans constituted a beginning of the work as meant in the charter. Judge O'Gorman reserved decision.

Gov. Hill has signed the New York Subway Commission Bill and filed with it a long memorandum. The memorandum accompanying the bill is as follows:

It is of the utmost importance that the electric wires in the city of New York should be placed underground as soon as possible. Every good citizen, having the best interest of the city at heart, is desirous of seeing this done. But if this bill is not approved, the methods and machinery partially provided by existing statutes for the accomplishment of the work will prove of no avail, and the removal of such wires is indefinitely postponed. There is only one objection to the bill of any consequence, and that relates to the failure to add two additional city officials as commisioners. The Mayor is added, and it would have been preferable if the Commissioner of Public Works and the Comptroller had also been included. Upon the bill coming into my hands, I respectfully requested that it be recalled for the purpose of making such amendments. But the Legislature, by a decisive vote, refused to do so. This was a mistake which I very greatly regret. The question is presented, however, Should this objection be permitted to destroy the rest of the bill? Public sentiment seems to favor the measure, notwithstanding this objection. * * * The people want the wires placed underground, and care but little who does it, provided it is well, and promptly, and satisfactorily done. They have no interests in the squabbles and complaints of disappointed contractors or patentees who want to do the work or to have their own particular patents used by whoever does it. The interests of private individuals should not stand in the way of a great public improvement desired by every one.

It is true that the local authorities have expressed their disapproval of the measure, but solely on account of the single objection aforesaid. Two political organizations have announced their opposition to it for divers reasons. The measure, however, is in no sense a a political one. While I have much respect for the local authorities and for those political organizations, and greatly regret to differ with their judgment upon this or any other matter, I cannot resist the conclusion that the best interests of New York will be subserved by the approval of this bill.

The lamp factory of the United States Electric Light Company, at Newark, was destroyed by fire on Friday, June 17th. The fire broke out in the laboratory, and spread rapidly through the entire building. Most of the building was occupied by the manufacture of carbon filaments and glass globes for incandescent lights. Owing to the inflammable nature of the contents of the works and the delay in sending out an alarm the whole structure was in flames when the engines arrived.

A second and third alarm was sent out on the arrival of chief Kierstead, and the entire department of the city was soon at the scene. It required, however, the hardest work on the part of the firemen to save the new main buildings.

The entire building in which the fire started, occupying about 230 feet on Orange street and 100 feet on Plane street, and the engine house, which is situated in the centre of the block, together with their contents, were entirely destroyed, the walls falling in about two hours after the fire started. The loss is estimated at $150,000, which is covered by insurance. One hundred and fifty hands are thrown out of employment by the fire.

The factory will be rebuilt as soon as possible, as these are the only works of the United States company in the country, and a large number of orders are on hand.

The Electric Club of this city has developed into so large a company of good fellows, as to require more commodious quarters than the cozy rooms hitherto occupied at the Hotel Dam. A

Digitized by Google

movement started a few weeks ago towards securing adequate permanent accommodation, has resulted in the leasing of a roomy house in East 22d street, near Broadway, and a committee is engaged in having it properly fitted up for the use of the club.

The Electric Club offers a most agreeable outlet for the convivial and gregarious instincts of the now numerous class of men interested in one way or another in electrical arts. Its scheme of membership is elastic enough to include those whose interests are on the commercial side of electricity, among whom are to be found a large proportion of the active spirits of the club.

May the companionability and the good dinners never grow less.

NEW YORK, June 21, 1887.

PHILADELPHIA.

Explosion in an Underground Conduit.—More Underground Privileges asked from Councils.—Illumination of Girard College Grounds by Electricity.—The New Jersey Southern Telephone Co. Sued by the American Bell Telephone Co.—Camden Streets to be Lighted by Gas Another Year.—The Penn Electric Light Co. Going Ahead with Underground Work.

ABOUT 5.30 o'clock on the afternoon of May 30 an explosion occurred in the conduit of the Phfladelphia Sectional Electric Underground Company, under Chestnut street, between Seventh and Ninth streets. There were three loud reports following each other in quick succession. The reports were accompanied by a shower of gravel and dirt, and volumes of dense smoke pouring from five openings in the pavement. The large iron covers on the man-holes at Seventh, Eighth and Ninth streets were hurled into the air, and the granite blocks of the street pavement immediately over the conduit for three blocks were loosened from their places. Although the sidewalks were crowded with people, no one was injured; but one of the large plate glass windows in Porter and Coates's publishing house at the Southwest corner of Ninth and Chestnut streets, was shattered, and several of the windows on the Ninth street side of the Continental Hotel were broken by the concussion. One of the man-hole plates at Seventh street was thrown nearly thirty feet in the air, and was shattered by the fall.

The superintendent of the company said the explosion was caused by an accumulation of illuminating gas in the conduit becoming ignited by a spark from an electric light wire on which the insulating covering was defective. It seems likely that defective gas mains are responsible for these explosions, and perhaps when somebody is seriously in jured, and the city compelled to pay heavy damages in consequence, the authorities may think it about time to rectify the matter.

This is not the only explosion that has occurred in these conduits. A workman got pretty badly hurt sometime ago from the same cause.

"I think," said Mr. Hart at a meeting of the electrical committee of councils held in select council chamber, during the consideration of an ordinance granting the Keystone Light and Power Company rights to lay underground conduits on certain streets, "that the city should construct its own conduits, and then rent them out to the different companies asking for privilege."

Chairman Graham was opposed to granting the privileges to the Keystone company. He said that there were several facts which the committee should take into consideration before granting them any privileges. He said that there were several suits against the company, which might make it impossible for them to carry on the work. He claimed that an injunction was being sought against the system they intended to use, and contended that if councils favor the ordinance and the company dig up the streets and then be enjoined from continuing with the work, it would place councils in a bad light.

"I would like to know what company intends to bring these suits?" asked Mr. Abrams.

"The Edison company," responded the chairman.

Mr. Boyer was in favor of the ordinance, because similar privileges had been granted to another company to use the same streets.

"And that company," said Mr. Abrams, "was the Edison." Their ordinance came before councils some weeks later than that of the Keystone company. This is not fair play. The Keystone company came first, and yet because we delay it, and pass a later one first, we are about to throw this one aside because of that fact. I shall oppose both the Edison and Keystone companies ordinances in councils, but I believe both should go before the chamber on a fair footing. We have already granted one company exclusive privileges, with the power of leasing their conduits, and I think that is enough.

After some further discussion, the ordinance was acted on favorably.

The ordinance supplementary to the Penn Electric Company's ordinance, requiring five miles of conduits to be laid in one year, was also favorably acted upon.

On the anniversary of the birth of Stephen Girard a few days since, the college grounds, which cover a vast area, were brilliantly illuminated with electric lights. Seven iron towers 125 feet high, were erected in different parts of the inclosure, and from the tops of these towers clusters of lights, five on each tower, shed their brilliancy over the grounds and the neighboring streets. The towers are located so as to illuminate the sidewalk around the high wall.

The New Jersey Southern Telephone Company, a concern recently organized, has been cited to appear before Judge Nixon, in the United States District Court at Trenton, July 4, for an alleged infringement of the Bell telephone patent. The company has brought its service into general use.

The Camden Gas Light Company has been awarded the contract for the ensuing year for the lighting of the public lamps of that city at $25 per lamp, and the Wheeler Reflector Light Company, of New York, the oil lamps at $20 each. The proposition from the Camden Electric Light Company was rejected on account of the additional expense that it would entail.

The Penn Underground Electric Light Company has given out a contract for the laying of five miles of conduit under Chestnut, Market, Arch, South, Second, Eighth and other streets, the work to be completed by the first day of September.

The *Ledger* in a recent issue says, editorially:—

"As long as electric lights are maintained by an overhead system of electrical conductors the plant must be considered temporary, if not experimental, and it would be unsafe to abandon gas lamps and trust entirely to electricity for street lighting under these conditions."

PHILADELPHIA, June 16, 1887.

BOSTON.

Failure of Legislative Regulation of Telephone Charges in Massachusetts.—Rumors of the Supreme Court Decisions on the Telephone Cases.—Output of Telephones.—The Erie Telephone Co.—The Boston Electric Club.—The Electric Light Association.—Electric Signaling at Fires.—Electric Light Notes.—Electric Lights in the Hoosac Tunnel.—The Government Telephone Suit.

THE telephone people breathe easier for another year, as the bill regulating rates in Massachusetts was defeated, after passing the third reading. The electric light people will probably have something of this kind to resist next year, for undoubtedly a bill will be introduced to regulate their affairs.

That the Bell telephone cases before the Supreme Court, at Washington, were not passed upon this last term is well-known. There was much disappointment among brokers and adventuresome gentlemen who had invested on margins for a "flyer." There has been a ridiculous and persistent effort on the part of some of our local papers to impress the community with the idea that the court had decided the case (and one paper was kind enough to give the names of the justices and their votes), against the Bell company.

The Bell Telephone Company's output of telephones for the month ended May 20, and for the year to date is as follows:

May—	1887.	1886.	Increase.
Gross output	5,256	4,555	701
Instruments returned	2,320	1,359	961
Net output	2,936	3,196	*260
Dec. 21 to May 20—			
Gross output	21,692	17,054	4,638
Instruments returned	9,576	8,046	1,470
Net output	12,176	9,008	3,168

*Decrease.

The annual report of the treasurer of the Erie Telephone Co., for the year ended March 31, 1887, shows operations of the Erie Telegraph & Telephone Co., as follows:

Earnings—		
Agency	$ 14,640.39	
Exchange	460,471.78	
Extra territorial and toll	58,984.12	
Messenger	683.72	
Miscellaneous	5,085.49	
Telegraph commission	752.79	
Total		$540,618.29
Expenses—		
General expense	$ 11,579.40	
Instrument rental	110,149.41	
Insurance and taxes	8,615.02	
Miscellaneous	14,754.09	
Operating	151,024.95	
Rent	10,301.92	
Reconstruction, repair and maintenance	54,119.28	
Total		$360,544.07
Net earnings		$180,074.22
Construction (total disbursements for the year)		33,167.13
Net earnings above all disbursements		$146,907.09
Number of subscribers added during the year		798
Total connected March 31, 1887		9,722

The statement of assets and liabilities March 31, 1887, is as follows: *Assets*—Licenses $2,342,965.97; plant $2,350,000; treasury stock $200,000; supplies on hand $25,009.12; suspense account $29,447.39; accounts receivable $42,182.96; new construction $447,028.23; cash $7,157.80; total $5,442,791.47. *Liabilities*—

Digitized by Google

Capital stock $5,000,000; accounts payable $4,850.79; reserve for contingencies $914.48; profit and loss $384,563.88; surplus $52,962.32; total $5,442,791.47.

From the net earnings of $146,907.09, above shown, dividends aggregating 2½ per cent. on the stock, or $120,000, were paid, leaving the balance to surplus account for the year of $26,907.09. The report certainly is a very favorable one. The company paid regular quarterly dividends of one-half of one per cent., and an extra dividend in December of one-half of one per cent., making 2½ per cent. for the year on the $4,800,000 stock issued. The net earnings of $146,907.09 were equal to three per cent. on the stock, and a balance of $2,907.09. This result, in face of the opposition in the southwestern territory of the company, is particularly gratifying.

Erie is selling at higher prices. Perpetual contracts with the parent company have not been made for all of its territory yet. Mr. F. P. Fish, counsel for the Bell company has been through Texas and other southern and western states in which the Erie operate, and enjoined infringers in a lively manner, hence the improved tone of the Erie stock.

Sixty gentlemen representing the various electrical interests of this city, met at No. 70 Kilby street, Saturday afternoon, June 11th, and voted to form a club to be named the Boston Electric Club. A committee was appointed to consider and report a plan of organization at a meeting to be held on Tuesday, June 21. The meeting on Saturday was presided over by Mr. J. Frank Morrison, president of the National Electric Light Association, who was in the city attending meetings of the executive committee of the National Association, which convenes at the Parker House, August 9.

A meeting of the executive committee of the National Electric Light Association was held in this city June 10th, the following named gentlemen being present: F. A. Gilbert, A. V. Garratt and Frank Ridlon, of Boston, M. M. M. Slattery, of Woburn, and Thomas McCoubray, Frank R. Colvin, P. O. Kielholtz and J. Frank Morrison, of Baltimore. It was voted to hold a convention at the Parker House, August 9.

The board of fire commissioners is soon to test a new electric apparatus on the fire engines of the department, which, if it performs the work claimed for it by the inventor, Mr. E. H. Crosby, a Boston newspaper man, will effect a great saving of time and expense, as well as damage from water at fires. The invention is a system of electric signaling, applied to the hose in such a manner that wherever the linemen may be, they are in instantaneous communication with the engineer in charge of the engine. The wires are laid inside each length of hose and the brass couplings of each length are furnished with automatic electric couplings, so that if a piece of hose is damaged another may be quickly put in its place without deranging the electric circuit. The apparatus is to be placed immediately upon one of the down town engines, and in a few days a public exhibition will be given. This is an old notion, and a good one; patents were issued many years ago for this purpose, but like many others, were ahead of the times.

The Newton Electric Light Co., have been exhibiting lights at Watertown, and have made propositions to light the streets of the town.

The electric light companies, in this section show great enterprise in extending their systems. Whenever or wherever possible they run a wire from some established plant to a benighted gas or kerosene lighted town, put up poles and lights in prominent places, make a point of "seeing" the selectmen, and moving spirits in the place, and light up for the benefit of the natives. An order for lights or for "samples" follows naturally. The time may come, when a company will send out teams, loaded with steam engines, dynamos and a complete small plant, after the manner of the lightning rod man, and scoop in a half dozen small communities before sundown.

A corps of men from the Westinghouse Electric Co., of Pittsburg, Pa., is attempting to light the Hoosac tunnel by electricity. There is a little over four miles of space to be covered, and the power is obtained, for the present, from water power at the Glen pulp mill. The framework upon which the electric lights hang is supported by wedges of bar iron driven into holes drilled in the sides of the rock. Incandescent lights are used, as arc lights are impracticable because of the dripping water. It will require at least 400 lights.

The annual meeting of the stockholders of the Franklin Telegraph Co., was held June 1st, when the following-named officers were elected for the ensuing year: Directors, C. A. Tinker, A. R. Brewer, Norvin Green, T. T. Eckert, F. L Ames, John Van Horne, Jay Gould, Thomas Roche and Joseph F. Greenough; treasurer, R. H. Rochester; secretary, Thomas Roche.

June 13th, the United States Circuit Court room was crowded by lawyers and others to hear the arguments on the defendants' demurrer to the plaintiff's bill in the celebrated case of The United States *vs.* The Bell Telephone Co. Judges Colt and Nelson occupied the bench. The United States was represented by ex-Senator Allan G. Thurman, Solicitor-General Goode, Jeff Chandler, Grosvenor P. Lowrey, of New York, and William C. Strawbridge, of Philadelphia, and the Bell company by Chauncey Smith, J. J. Storrow, Charles S. Whitman, George L. Roberts and E. N. Dickerson. The defendants claimed that the plaintiff's bill is multifarious in that it joins allegations and prayers for relief, in respect to patents Nos. 174,465 and 86,787. Mr. Storrow opened the case for the defendants, and reviewed the case at considerable length, occupying some three hours in his address.

Mr. G. P. Lowrey, commenced his argument in the afternoon, for the Government, but owing to the closeness of the atmosphere requested postponement until the next day.

On the 14th, Mr. Lowrey resumed his argument. He said that it was the plain duty of the Government to bring the suit. Both patents must stand or fall together. He claimed that the assignee company did not stand in any better position than the assignor, Bell, in regard to the sixth item of the demurrer, that the bill did not set forth any fraud in the procuring of the patents; did not specifically set forth what acts the complainant relied upon; nor when, how, from whom, or by what means complainant first had knowledge of each alleged fact. Specific allegations of fraud were certainly made that it was not necessary to enumerate at this stage of the argument. Perjury was charged in the procuring of the first patent in 1876, and that specifically. For the second application in 1877, Mr. Bell was charged with surreptitiously procuring information of the items of another application, by Mr. Dolbear, in order to amend his own application. There was no lack of specification in that instance.

Mr. Goode then proceeded to argue the right and power of the Government to prosecute and maintain the suit. He read the several divisions of the bill separating the public and private rights in the premises. The United States claims its right to bring the suit. The demurrer admitted that misrepresentations had been made to government officials; that the patents had been procured through these representations; that the patents were of great value and public utility; that vast sums were being received for their use; that no private parties had a right to bring suit against the patents; and that the Government was in a similar position. "Who is to prosecute a fraud if not the Government?" asked the counsel. "Are the doors of the courts to be closed to the Government?" He held that the Government had a right to enter its own courts in equity to find cause to cancel a grant procured by fraud or made by inadvertance or mistake. When the king made a concession through false suggestion, he had the prerogative of cancelation on information. Several cases were cited in support of this view. In English common law suits of this description could be brought by any subject in the name of the sovereign with the approval of the law officers of the Crown. Where the public interest is at stake, the attorney-general can always sue. Every state of the Union recognized the principle. Where the interest is merely private, the principle did not hold.

In answer to Mr. Storrow that the Circuit Court had already settled the question at issue by a decision, Mr. Goode contended that the question then decided did not cover the ground sought to be covered here. There was no difference between patents for land and patents for inventions when fraud came in. That had been decided by the Supreme Court of the United States, and the principle was long recognized. Mr. Goode wanted the court to understand that it was entirely relieved of responsibility by the decisions already pronounced. The commissioner of patents could not revoke the issues of his predecessor. He was not a judicial officer. Such questions belonged to the courts. The cases upon which the defendant relies to maintain his demurrer were simply on private issues. The United States here attacks a grievous monopoly, of which the people were the victims from one end of the republic to the other, and it was charged that this monopoly was the result of patents obtained surreptitiously. The only congressional nullification of the power of courts to vacate patents was in 1836, when the courts were denied the prerogative when suits for cancelation were brought by private parties. The common-law remedy always prevailed, and was never interfered with by any remedy that existed before that act. Mr. Storrow's claim that the Government had no common-law rights Mr. Goode urgently combated. How is it, he asked, that the Government had successfully instituted suits against lands when there were no statutory provisions in regard to them? The Government, of course, had property in the land. It was claimed that the Government had no property in an inventor's brain; but it did have a right to prescribe the validity and lease of that brain's product. It was the same right that it had to limit a soldier's bounty, whether in land or money, the settler's preempted grant, etc. The consideration was the bottom of it all, and if the consideration was falsely alleged, the contract was void; it was prejudicial to the public interest. It was absurd for the defendant to deny the United States the right to the cancelation of a patent by a court of equity on the ground of fraud proved. Fraud vitiated everything. There had been no laches, no delay on the part of the Government, and its case should be admitted. The Government was not a professed detective, roaming up and down the land. It always presumed sincerity of purpose until the contrary was made manifest. The validity of the patent was not attacked on any single allegation—the case rested upon the allegations as a whole.

Digitized by Google

June 14th, Mr. Goode closed his argument for the Government as follows: The time has not arrived to consider the issue on its merits. Much has been said by Mr. Storrow about previous litigation and the fact that the patents have been sustained by the lower courts. Those cases are now pending in the Supreme Court, but the Government is a stranger to them. There is no charge of fraud in those cases, which is the principal ground of action in this case.

Mr. Chauncey Smith, of counsel for the Bell Telephone Co. next spoke. The bill, he said, is brought by one department of the Government to undo what had been done by another department of the Government. Something has been said about the inherent power of the Government to institute this proceeding. I don't understand what is meant by "inherent powers." The Executive must find its authorization for its acts in the constitution or laws made under the constitution. Now, if the Government, or any one, from the President down, can't find his authority in the constitution, then he must find it in the law of Congress, for there is no other authority. But the Government in this case seeks to find its authority in the law of Great Britain. I deny that any such power can be found even in the statutes of that country. The power of the Crown to revoke an act of Parliament does not exist. The power to bring an action of this sort is specially delegated to the officers of the Crown. It would not exist without such authorization, and it is not claimed that any such authorization has been made by Congress in this country. Mr. Smith argued further that no allegation was made by the Government which would not be an adequate defense for any infringer of the Bell patents, and therefore the extraordinary proceedings which had been resorted to was quite unnecessary. The Government sets up that it brings this complaint in order to reinstate the people of the United States in their rights. But an invalid patent deprives nobody of any rights. Such a patent may be infringed with impunity.

The court room was crowded when Judge Thurman rose from his sofa and approached the counsel table to address the court. He said—My associates have argued this case so soundly, and it seems to me so conclusively, that anything I may say must be, to a certain extent, a repetition of their words. I have been urged as the dean of the faculty—by reason of years and not of learning—to address you briefly. The first and main question to be considered is as to the power of the Government to bring and to maintain this suit. The general power of the Government to bring such a suit is not denied, but the point the other side make is this, they maintain that this power cannot be executed without legislation by Congress to specify the officer and the mode by which the proceeding shall be set in motion. In the absence of such legislation they hold that the power is dormant and that the Government cannot use it. I don't deny that ingenious arguments can be made on the other side, but I maintain that it is not an open question and that it cannot be considered as an open question. Mr. Storrow claims that out of hundreds of thousands of patents issued only one has been set aside by such a proceeding as this. But of millions of land patents that have been granted hundreds have been set aside. There are very good reasons, only the Government has not been forward in bringing such suits as this—much stronger reasons than in the case of public lands. In most cases the defences raised by infringers of invalid patents are protection enough of the public interests. The Supreme Court has decided in the case of Whitney *vs.* Mowry, that no individual can file a bill to set aside a patent; that only the Government could do that. Does any one suppose that in the case of the Bell telephone that such bills would not have been filed long ago if individuals had the power to file them?

It is the duty of the executive to enforce the law. Mr. Smith argues that in that case it is the duty of the executive to proceed against infringers. That is ingenious, but I think if Mr. Smith will sleep on that proposition he will abandon it.

Mr. Dickerson, of New York, for the company, followed, combating the idea of the competence of the attorney-general to bring the suit. A bill that had been prepared by the Bell Telephone lawyers giving him that power in certain cases had been defeated. This was intended to compel a patentee to try his case, and not continue a doubtful patent in force. Every court in America and Europe, where the patent has been considered, had decided that Prof. Bell was the original inventor, but he had been subjected to such a fire of billingsgate and vituperation as no man had ever sustained before. The whole matter with the complainants was the assertion that the American Executive was the successor here of the British King in a royal prerogative. They wanted just enough of English law entered into this case to suit them—no more. Where was the rest of it? Spilled over from the Mayflower? The fact was, the power lay only in Congress—the people—and Congress had refused to act. The theory that the President was heir-at-law to the king was rather a peculiar view for such a good democrat as Senator Thurman to take. The attorney-general, it was well known, had been turned out of the Circuit Court in a patent case, and was now in the Supreme Court on appeal. This patent had survived the most malignant litigation ever known throughout the length and breadth of the country, and now this court was asked to pursue it to its death. Mr. Dickerson contended that every allegation of fraud in the bill came under the criminal statute.

The court took the case for decision.

BOSTON, June 18, 1887.

CHICAGO.

Telegraph and Telephone Property Destroyed by Fire at Pittsburg.—Mr. F. R. Welles in Paris.—Mr. Henry Bentley and Dr. Samuel Plush of Philadelphia in Chicago.—Success of Mr. E. S. Babcock, Jr., on the Pacific Coast.—Trade Notes, the Western Electric Co. and the Vandepoele Electric Manufacturing Co.—Telephone Exchange Notes.—Arc Lighting in Chicago.—Promising Start of the Chicago Electric Club.—An Electrical Journal in Chicago.—Electric Lighting on the River Front.

THE fire in the First National Bank building, Pittsburg, on the morning of th 10th instant, destroyed all the instruments and battery of the Western Union Telegraph Co., in their operating rooms on the top floors, and damaged the switch boards and destroyed the cables of the Central District and Printing Telegraph Co., who occupied the third floor. It is not known to a certainty how the fire originated, but it was first discovered under the Western Union switch-board, and it is supposed that rats, or other vermin, had eaten off the paraffine and cotton covering, leaving the bare wires in contact with woodwork. An alarm was sent in from two boxes and the fire department responded promptly, but as the flames were in the upper floors, which were surrounded by a labyrinth of line wires, the firemen were much hindered by having to cut their way to the building. There were eight to nine thousand cells of battery on the top floor, and these played an important part. In Pittsburg the almost obsolete practice of filling up battery cells with signal oil was followed, about eight barrels of it being used in the room, This oil of course caused the fire to burn more fiercely and rapidly, while the fluids from the broken batteries poured down the inside and outside of the building, staining everything a dirty yellow. The telegraph company immediately transferred their business, so far as possible, into the eight circuits of the Mutual Union, and ordered a carload of supplies expressed from New York. In four days they had all their wires working. But with the telephone company such promptness in resuming business was impossible, because outfits for telephone exchanges are made to order and cannot be had on very short notice. One of the eight sections of 2,000-wire multiple boards was ruined, and the other seven had to be taken apart and sent to Chicago for repairs. The work of repairing what can be repaired, and of making the new apparatus and cables, is going ahead as fast as possible in the shops of the Western Electric Co., but manager Metzger does not expect to have the service in order before some time in the early part of July.

The exchange at Pittsburg is the third large telephone exchange, we believe, that has been destroyed by fire, the others being Montreal and Toronto. After the burning of the Toronto exchange it was suggested by Mr. Angus Hibbard, then superintendent of the Wisconsin Telephone Co., that, in view of the delay in getting large switch-boards in emergencies, it would be a wise thing in the way of insurance, if a number of telephone companies should jointly buy a complete central office outfit, to go to the first place burned out. The plan was considered favorably by those to whose attention it was brought, but no action has ever been taken. It seems as though it would be worth while for telephone people to insure in some such way for prompt resumption of business.

There are two points in the newspaper comments on this fire worth noting: First, wholesale denunciation of the system of overhead wires—they must go—because in this case, as in so many others, beyond dispute, the work of the fire department was delayed and rendered additionally hazardous by that obstruction. Second, appreciation of telephone service when it stops. The *Dispatch* comments on the "embarrassments expressed in the probably 100,000 oaths that must have been frequently uttered when no response came to the yet larger number of "hellos" that were shouted against the diaphragms of the transmitters. All this, more than the dollars in property destroyed, is indicative of the damage done by the fire."

Mr. Metzger states that, although the company cannot be made responsible for the loss of time in the use of the telephone, as the fire was no fault of theirs, still they will allow their subscribers a rebate in proportion to the time the telephones are compelled to remain idle.

The many friends of Mr. F. R. Welles, who was for a number of years manager of the Western Electric Co., and is now residing in Antwerp, Belgium, will join in our congratulations to him upon his escape from the scene of a terrible disaster. He and his family have been visiting in Paris, and he writes to friends in Chicago that upon the very night of the fire at the Opera Comique his party had planned to go to that place of amusement, but their steps were fortunately turned elsewhere. Mr. Welles advises us of the death of M. Barbier, the celebrated

Digitized by Google

manufacturer of Leclanche batteries, who got a bad fright while visiting the ruins of the theatre the day after the fire, and was stricken down with an illness which ended in blood poisoning.

Mr. Henry Bentley and Dr. Plush, of the Bell Telephone Co. of Philadelphia, spent a few days in Chicago last week. They enjoyed the cool lake breezes while attending to the special object of their visit, that of looking into cable matters.

Mr. E. S. Babcock, Jr., formerly of Nashville, is making a great success of his work in California. He is president of the Coronado Beach Co., who own and manage the finest hotel on the Pacific slope. Mr. Babcock has recently closed a contract with the Mather Electric Co., for an outfit of 1,600 incandescent lights for the hotel *El Coronado*.

The Western Electric Co. are still running their factory nights, but manager Brown says they cannot quite keep up with the demands of their customers. It has been definitely decided to build a large wing from the south end of the building on Clinton street. They have recent large orders for 7,000 feet of Patterson cable for Kansas City and 5,000 feet for Montreal, electric light outfits for St. Louis and Red Cloud, Neb., and a multiple board, with a capacity of 2,400, for Memphis.

Chattanooga, Tenn., with 500 subscribers, has abandoned the Law for the magneto system. The Nebraska Telephone Co. has also made a sweeping change at Omaha, putting in a complete new outfit of Western Electric multiple boards and magnets call bells.

The Vandepoele Electric Manufacturing Co. are doing a business that they are very proud of. Their mammoth 250 h. p. generator at Montgomery is doing good work, and they are completing two 100 h. p. generators for the Scranton Suburban Railway Co., increasing the equipment of that road. They have also recently equipped a street railway at Lima, Ohio, with their apparatus.

Lightning arresters were well tested by a violent storm that passed over Illinois on the 7th instant. At Decatur the Central Union company had 400 wires destroyed in their exchange tower.

The Chicago Arc Light and Power Co., have increased their plant by purchasing from the Western Electric Co. the large central plant on Monroe street. They also have leased a part of a large building fronting some 600 feet upon Market and Washington streets and the Chicago river, which they will use as a central station for supplying about 2,500 lights in the business part of the city. Their engineer, C. F. Moeller, was instantly killed yesterday by a shock that he got while fixing the carbon of a lamp. He was drenched to the skin at the time, having been working on the roof in a pouring rain.

Last month we noticed the incorporation of the Chicago Electric Club. Since then meetings have been held once a week, and all necessary steps have been taken for effecting a permanent organization. General A. K. Stiles, of the Vandepoele company, is president. The vice-presidents are, C. A. Brown, of the Western Electric Co., J. P. Barrett, city electrician, B. E. Sunny, of the Chicago Telephone Co., and F. G. Beach, of the Central Union Telephone Co. F. S. Terry is treasurer, and W. A. Kreidler, secretary. Eighty enthusiastic members are already enrolled, 50 of whom sat down at the opening banquet held at the Grand Pacific hotel last Saturday, The dinner was a most enjoyable one, the boys being in excellent humor, as is evident from the fact that 35 informal speeches were made. The club is undoubtedly a success, and a committee are looking for permanent quarters.

The first issue of a weekly periodical called the *Western Electrician* is announced for appearance on the 2d of July. Mr. W. A. Kreidler, who for some five years has been associated with the *Electrical World*, is the leader in the new enterprise, and he has associated with him Mr. Wayland Clark, a gentleman of large experience in the general newspaper field. They propose to publish an independent newsy paper devoted exclusively to western electrical interests.

Mayor Roche has taken an active interest this month in the project of lighting the river, and has submitted to the city council the estimates of cost made by city electrician Barrett, together with his suggestions. Briefly stated, he proposes to control the movements of vessels through the city so as to avoid as far as possible interruptions of travel on the principal streets during business hours. With electric lamps fringing the banks of the river, the bridges could be kept closed during most of the day and open most of the night, which would greatly benefit the public and cause but little damage, if any, to the shipping interests. The cost of the plant is estimated at $47,750, and of operating it, about $7,300 per annum, which is about 43 per cent. less than it now costs to light the bridges by gas. Prof. Barrett has also been figuring on general city lighting, and his estimates are commanding a good deal of attention, and are very favorably commented upon by the daily papers. He says that 15 plants, costing $45,000 each, would light the whole city, that they would pay for themselves in two years, as compared with the cost of gas lighting, after which the city could be lighted at about 45 per cent. of the present cost.

CHICAGO, June 21st, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.

CAN SPEECH BE TRANSMITTED WITH THE BORED-BLOCK TRANSMITTER OF PHILIPP REIS?

AN OPEN LETTER TO PROF. EDWIN J. HOUSTON, OF PHILADELPHIA.

[70.]—In the *Journal of the Franklin Institute*, for January, 1887 (vol. cxxiii., No. 733), Prof. Edwin J. Houston, of Philadelphia, criticises my early experiments with the original Reis telephone (illustrated below), and seems to doubt the correctness and loyalty of my statements in favor of the Bell Telephone Co. against which at present suit is pending in America. Especially erroneous are the remarks about my arranging the experiments. To show the unfounded character of his comments, I address this open letter to Prof. Houston.

FRANKFORT-ON-THE-MAIN, May 25, 1887.

To Prof. Edwin J. Houston, Philadelphia:

Having returned from a prolonged journey, I find to-day the January number of the *Journal of the Franklin Institute*, containing your answer to my letters of July 21 and October 21, last, also a note upon an article published by me in the *Electrotechnische Rundschau*, No. 11, page 126, in the year 1886.

Your explanations based upon the letter of Mr. J. R. Paddock, in reference to the question whether the *first* models of the Reis telephone could be used for transmission of long sentences, clearly imply, that during my negative experiments, 26 years ago, in conjunction with Philipp Reis, as well as alone later, I did not understand the use of the apparatus, and that solely through "unpardonable ignorance" I made assertions which were recently overthrown by your friend, Mr. J. R. Paddock.

To prove your assertion you refer to the statement in my letter of Oct. 23 last, that the *platina-contact* was in the experiment somewhat separated from the *membrane*. You make much of this sentence, and assert that I made my prior experiments with *an open circuit*. I never did that. Had that been done though, as you would have your readers believe, no *singing* sound could ever have been transmitted. Such a nonsensical arrangement is against all common sense. The sentence in my letter to you of Oct. 23, was intended to mean that through the vibration of the membrane, while speaking or singing in the wood-cube, the *platina point* was lifted from the membrane and thus a transmission of sound through an interrupted circuit was made. This fact Mr. Paddock admits in his letter (page 59, *Journal of the Franklin Institute*, No. 727), in the words printed in italics:—"articulate speech can be transmitted in the Reis instrument when used with the *so-called broken current.*" Even if the expressions of my letter might give you the right to charge me with absurdity, the article in No. 11, of the *Electrotechnische Rundschau*, mentioned and attacked by you, should have shown you that I experimented exactly in

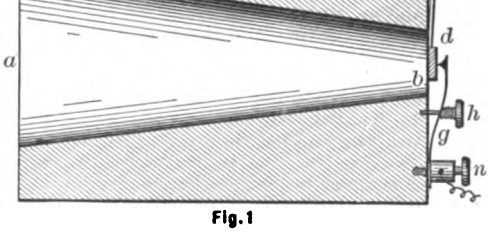

Fig. 1

the manner described by Mr. Paddock. In the article referred to (which was sent you Nov. 12, 1886); and in reference to the figure which you reproduce as figure 1 on "page 54, in your article in the *Journal of the Franklin Institute*, occurs the following sentence: "When speaking into the cube at *a*, broken currents are formed at *d*, through the vibrating of the membrane *b*, with very short intervals, and there is a small spark due to the perfectly broken currents. It is unnecessary to state that sound vibrations of the character required for the formation

Digitized by Google

of articulate speech cannot be produced by such broken currents, as the fact is sufficiently proven." My expression, "broken currents are formed" should prove to you that I did not attempt to work through a broken circuit, but used a closed circuit at the beginning of my experiments.

Your unkind attack upon me in the *Journal of the Franklin Institute* falls back upon yourself. From the above citation you must have seen, that like Reis himself I experimented with a closed circuit. Nevertheless neither Philipp Reis himself nor I, nor any other German experimenter, has ever been able to converse with a Reis bored-block transmitter and a Reis knitting-needle receiver as is claimed to have been done by Mr. Paddock. Properly, I should not permit myself to contend further with you, since with a model the same as the Reis instrument in your hands a long while before the publication of Mr. Paddock's letter, you held a perfectly uninterrupted and intelligible conversation of from five to six minutes, during which questions and answers were sent and received; but permit me the question, why you did not mention your *own grand success* in your letter of Oct. 1st, 1886, addressed to me (far different from an open publication) while now espousing the cause of Mr. Paddock and indirectly defending the Overland Telephone Co. From the sentence of your article—"Although the author has not personally repeated the experiments of Mr. Paddock with the original apparatus of Reis, yet he is disposed to give full credence to the statements of Mr. Paddock, because he (the author) had, prior to the publication of Mr. Paddock's letter, held an almost uninterrupted and quite intelligible conversation, continuing for some five or six minutes, in which questions and answers were given and received, by the use of a transmitter, which was an exact reproduction of the Reis bored-block transmitter, and employed the platinum contacts found on the Reis apparatus; and also because he does not see any essential structural differences between this form of transmitter and that in extensive commercial use to-day by the Bell Telephone Co." It is plain, assuming the correctness of the statements, that while using a Reis transmitter, you MUST have used a *Bell Telephone* RECEIVER. You can not well venture to deny this fact, although you ignore it in your article.—How is it, moreover, that in February, 1886, as he asserts, Mr. Paddock could plainly telephone with the simple Reis apparatus and with the broken current this long sentence, "William H. Vanderbilt died suddenly at his house on Fifth avenue yesterday. He is said to have been worth two hundred million of dollars," and that in November, 1886, he reached merely the carefully tabulated results given in your article under reply, page 55, and found that it was possible only to register "*examples* of words?" Why does the broken current suddenly change to a current "of undulations, interruption and breaks?" Very remarkable this; but more remarkable is the story of Mr. Paddock, which you, a scientific physicist, adopt, that he obtained the required tension of the membrane in the wood-cube telephone of Reis through the action of *sunlight*. What an imputation is involved in producing such scientific nonsense before the physicists of the whole world. Do not the two gentlemen know, that every animal membrane is very hygroscopic, and that in speaking against such a membrane the moisture of the breath is absorbed, and the membrane must loose its tension, even though Mr. Paddock let the sun shine in his mouth while using the apparatus. How is it that this contrivance was not necessary in the month of February, when the long sentence about Vanderbilt's death could be heard with a Reis knitting needle and a broken current? How is it, that in your criticism of my communication you suppressed the fact, that Mr. Paddock changed the Reis apparatus and did not experiment on the basis of the mode of the inventor, Ph. Reis,—as the only point was, to show that spoken words could be transmitted with the Reis bored-block transmitter *before* the invention of the Bell telephone?

I will in your favor and to your honor believe, that you had no knowledge of the changes which I made on the original bored-block telephone, which went to the United States through the agency of Prof. Silvanus P. Thompson, of London. In the printed documents which I have of the appeal in the Supreme Court of the United States, Oct. 1886, of the suit of the Overland Telephone Co., *et al*, against the American Bell Telephone Co., *et al*, Act. No. 1.—1. 1493,—there appears a confession of Mr. Paddock, made at his second hearing, Oct. 15th, 1885, that he had made fundamental changes of extraordinary importance in the original dispositions made by Philipp Reis, which he witheld in the first hearing although severely cross-examined. The assertion of Mr. Paddock, that it must always have been possible to speak with the Reis telephone, is not trustworthy, as may be seen from the circumstance, that he misstates in citing from the *Industrie-Zeitung*, which was published in 1863, in Chemnitz. In it was published the report of Mr. J. F. Quilling, of Frankfort-on-the-Main, in which he describes the construction of the Reis telephone:—"It was impossible with the apparatus as then constructed to transmit spoken words." This sentence which appears in the middle of Mr. Quilling's article, Mr. Paddock omitted (Overland Case 1—1. 1491).

It is therefore clearly proven, my dear Prof. Houston:—

1st. That I myself have experimented exactly in the same sense as my deceased friend, Philipp Reis, instead of working, as you *mala fide* impute, with an open circuit.

2d. That spoken words never could be transmitted by telephones of the kind under discussion.

3d. That Mr. Paddock, if it is true that he transmitted words with the above mentioned apparatus, changed the apparatus to conform with later telephone inventions.

At the close of your attack upon me, you express your *great surprise* that your statements and those of Mr. Paddock are doubted not only by the legitimate friends of Mr. Bell, but also in Germany. I answer to this that the first principle of German science is *truth*. We are satisfied that Philipp Reis was the first, who practically TRIED to transmit sounds and words to certain distances through a physical apparatus and the electrical current, but, that Bell alone has the undisputable right to assert that he invented the first *useful* apparatus for the practical far-speaking telephone; also, that the Bell Magneto Telephone is in *no way* identified with the construction of the Reis transmitter.

All this you have read in the *Electrotechnische Rundschau* (which is edited by myself), No. 11 1886, page 126 to 129. You admit in the paper under reply that you had read the article, but you ignore the contents entirely. You fail to mention even the number of the paper in which all the above assertions are stated and fortified; but that is certainly the easiest way to get rid of a scientific opponent. For us Germans it has long ago been proven, that the honor is due to the German electrician, Philipp Reis, of having first invented an apparatus which he called telephone for the purpose of transmitting sounds and words. However pleasing it may be to us, whatever the motives may be, that foreigners are so desirous of putting the merits of our Reis in the proper light, we are all the more in duty bound to save the memory of our friend from stain, and to treat exaggeration in the same manner as the deceased, who, if he were alive, would certainly repulse it.

May the scientific world of the United States learn through this letter, which I send as an *open* one, what is known in Germany of the capacities of the Reis apparatus, before the praiseworthy and magnificent invention of Prof. Graham Bell; and also in what manner Prof. Edwin J. Houston tried to use their scientific weapons.

DR. THEO. STEIN,
President Society of Electricians.

NOTE.

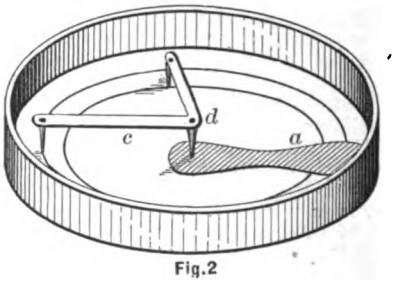

Fig.2

To prevent wrong impressions, I call attention to the fact, that my statement has reference exclusively to the first constructed telephone instrument invented by Philipp Reis. With the later the cube box transmitter, *single articulated words* could sometimes be transmitted. This happened when the speaking into the cube box was not too *loud*, in which case, sometimes, the needle lying on the metal peg, by the vibration of the membrane with the platina stripe *a*, figure 2, would not be entirely removed from the platina plate. If by the vibration of the membrane, there are no actual breaks in the circuit, the very feeble vibration of the membrane not lifting the contact entirely, there exist, as is known, undulating currents, which are essential for the transmission of articulate speech. Now and then this physical law comes into action through pressure of the peg *d* forwards, through which, but always accidentally, spoken words could be sometimes transmitted with this apparatus even 25 years ago. These facts were published in 1885, in the Paris publication *Lumiere Electrique*, vol. 16, page 583. T. S.

PATENT OFFICE EXAMINATIONS FROM AN AMERICAN POINT OF VIEW.

[71.]—Letter No. 69, page 235, of your June issue, certainly "strikes me like a clap of thunder in a clear sky." Such wholesale and ruthless condemnation is more often the result of prejudice than judgment, and if many people in this country think with the writer thereof, the sooner some intelligent missionary work is undertaken, the better.

The statement that actions of the Patent Office upon applications presented amount to nothing for the reason that they are

Digitized by Google

not conclusive upon the courts, is very insufficient proof that no patent is worth anything until it has at least been once considered by a United States court, and simply indicates that it would be absurd to set up the ministerial acts of the officers of a bureau of the government against the law of the land as judicially interpreted. It is an incontestible fact, nevertheless, that the actions, theories, and decisions of the Patent Office are very carefully considered in the decision by the courts of infringement suits, as also are the statements and admissions made by the inventor during the prosecution of his application.

A person used to European patent practice, and attempting to conduct applications before the United States Patent Office, would very soon get himself in a corner, and then naturally feel that the American system was all wrong. I do not really think that anybody but an Englishman, or a person familiar only with European patents, would contend that no United States patent is worth anything unless consecrated by a judicial decision.

Millions of dollars are to-day safely and profitably invested in patent property about the validity and merit of which there never has been, nor will there ever be, any contest or dispute. The instances of contest are the exceptions, not the rule.

Patent law more nearly approaches an exact science than any other department of the law, and it is not a matter of chance who wins a suit upon a good patent. It is too often the mistakes resulting from reckless and incompetent soliciting that cause trouble.

Many royalties are paid to-day as the result of searches made with a view to breaking down patents, but which only resulted in sustaining the action of the Patent Office. Would-be infringers, finding a profit in the manufacture of some patented article, and finding also, that the patent having been carefully prepared and no anticipation thereof having been found, there was no way in which they could overthrow or defeat the patent, have concluded they had better make terms with the owners and keep heir heads out of the lion's mouth, rather than risk the expense of a suit for infringement.

When would-be owners of patents actually "get it through their hair" that the Patent Office is not responsible for the results of its decisions, and that the value of a patent depends altogether upon the skill, honesty, and industry of the attorney *and* his client, they will then see that their own plain unmistakable duty is to ascertain the fighting strength of a patent before investing, when they will be less liable to incur future loss.

It is nonsense to say that none of the proceedings in the Patent Office are recognized in the courts. Has a patent ever been overthrown on the ground that it was granted to the wrong party as the victor in a contested interference proceeding? Then again, the suggestion of "money-bags, bribery, corruption, favoritism, and general rascality" is really carrying the joke a step too far. I have practiced before the Patent Office for seven years, and have prosecuted cases in every branch, and every division, and (never having been in the employ of the department) I take pleasure in saying that I do not believe a more honest, efficient, and faithful corps of public servants exists under any government. Is is *their* business to stand between the inventor who claims everything, and the public, which certainly has some rights; that is what they are there for, and it is the business of the *attorney* to mediate between the actions of the examiner and the claims of the inventor, and if he is competent and does his work properly, the chances are that 99 times out of 100 the patentee will secure claims covering all the ground to which he is really entitled.

The American patent system is superior to that of any other country in several particulars, for instance, it examines all applications; the result of which is that far more than is generally supposed to exist is shown, every word of which becomes a permanent record always accessible to the public. It insists upon a correspondence between the description and the drawings, and a precise use of language far in advance of the requirements of the patent laws of any other country. It refuses to tolerate or permit ambiguity of language of any kind whatever (a favorite trick under the English practice). It refuses to permit such alternative propositions as would involve more than can be gathered from the application as a whole. And last, it prescribes certain formulæ for claims, which, if carefully considered, will leave no doubt whatever in the mind of the person interested as to what the patent covers. The net result of all this is, that an intelligent and conscientious lawyer upon study of the claims can say, and with reasonable accuracy, what an American patent does or does not cover; whereas, with all European patents it is wholly a question for the courts, and no one can have any kind of certainty as to the result until after the expense and delay of an infringement suit has been incurred.

As nearly every inventor claims everything, if patents are granted for everything to every inventor one of two results happens; capitalists say, "we will have nothing to do with any of your patents until you have litigated the matter among yourselves for you all claim more than you are entitled to" (the effect of which is to shut out poor inventors); or innocent third persons reading the patent are imposed upon by their reverence for the great seal.

The claims of United States patents are restricted, so that when references have been produced, showing them to be too broad, any man with reasonable powers of comprehension who has the gumption to look into them can see what is not covered thereby. A patent comprising broad claims on a desirable improvement is always certain of attention, and in this country much more often means a paying interest in a good business than a hopeless struggle against wealthy infringers, as abroad.

From an American point of view our patent system has done more than any other one thing to develop the possibilities of this country, and is to be cordially recommended to the consideration and support of those most interested, as the best so far developed.

FRANKLAND JANNUS.

Washington, D. C., June 15th, 1887.

THE WIRE GAUGE PROPOSED BY THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

[72.] The adoption of metric measurement for wires and sheet metals may be desirable, but it is doubtful if the gauge suggested to the National Electric Light Association will prove to be the right thing. That gauge is open to the objection that it reverses the accustomed order of sequence from large to small sizes, and will thus be confusing to the mind—at least in its introduction. Then the differences between the successive numbers are too small in the large sizes, and too large in the small sizes.

For instance, No. 1 would be 10-100 of a millimeter, or 4 mils, No. 2 would be 20-100 (8 mils), and No. 3 30-100 (12 mils). The jump from 10 to 20 hundredths (4 to 8 mils), and from 20 to 30, (8 to 12 mils), is much too great. For these three numbers of the proposed gauge there are ten numbers of the B. & S. gauge, and they are all needed. The proposed gauge, therefore, could not be used for these small sizes, which must be designated by the numbers of some other gauge, or else by decimals of an inch or of a millimeter.

In the large sizes, on the other hand, there is no need for so many numbers. From 4 to 6 mm., for instance, the gauge offers 20 numbers, against 4 in the B. & S. gauge. From 6 to 8 mm. there are 20 numbers again, to only 3 of the B. & S. gauge, which may, perhaps, have too few numbers in those large sizes for some purposes; but so great an increase is certainly needless.

If we must have a gauge of some sort, it would seem that its principle of construction should be that of increasing differences between the successive sizes, in passing from small to large. A mere arithmetical progression leads to the defects noted above, and the making of a gauge without any apparent guiding principle at all, leads to the anomalies observed in the Birmingham, Old English, Standard British, and, in fact, in all the ordinary gauges except the B. & S.

In view of the failure of so many attempts at gauge-making, and in view of the general desire for something better than any known gauge, why not do like the rest of the world, and designate sizes *by sizes?*

A true word was said long ago by Miller, Metcalf & Parkin, (quoted in the "Memorandum on Gauges," in Brown & Sharp's small catalogue): "There is a very simple and easy way out of the whole snarl, and that is to abandon fixed gauges and numbers altogether." That is what other people do, or are coming to do. The English are more and more getting into the way of reckoning by mils, and the rest of the world, outside of the United States, has pretty generally adopted the metric system.

The gauge proposed to the Electric Light Association is the one adopted by the German manufacturers some years ago. (See letter from Felten & Guilleaume, *Electrical World*, Oct. 2, 1886.) So far as I can learn, however, this gauge is not in common use by the Germans at present. I have never seen it mentioned in any German book or catalogue or price list. Although I have been doing business with Germany for years, buying and selling, I have never seen the numbers of this gauge referred to in correspondence, nor heard them mentioned by Germans in conversation. They always talk and write millimeters, and buy and sell by millimeters, just the same as other Europeans.

Here you have, therefore, an attempt to introduce this identical gauge, the result being the adoption of millimeter measurement, pure and simple.

The name proposed for the gauge is also objectionable. "National Standard Electric Wire Gauge" is neither true nor appropriate nor convenient. It is inconvenient, because too long; inappropriate, because it conveys no idea of the system on which the gauge is based; and untrue, because the gauge is in no sense "national." It was German once, and is founded on a system French in origin but now international and world-wide. "Metric Gauge" is a name conveniently short, appropriate and true.

But as gauges have failed to meet the demand in America, and have been abandoned by the greater part of the world, would it not seem that their day is past, and that the thing to do is to adopt measurement by definite values?

Admitting this, the question is which to take, mils or millimeters. The mil has the advantage of being understood by everybody, and of being already in use to some extent. Beyond this,

Digitized by Google

all the advantage lies with the millimeter, for the following reasons:

1. It is the basis of all electrical units.
2. It is already in use by the whole scientific world.
3. It is used by the greater part of the world of business.
4. It is better and more convenient than the mil.

Reasons first and second are well-known facts, while the third seems not to have been fully appreciated, but is none the less true. Nearly all Continental Europe uses the metric system; so also the whole American Continent south of the United States boundary. In designating sizes of wire and sheet metals, however, the English system stubbornly disputed the ground, being in prior possession, and held its place in some countries for many years, but has now nearly disappeared from all countries whose language of trade is not English.

Metric measurement has thus made steady progress in the world at large, displacing local and inferior systems. It may be hopeless to try to bring the kilo and the meter into general use in the United States, but the adoption of the millimeter for measuring wires and sheet metals would have the advantage of bringing the country into line with modern progress in this one respect, and of assimilating American trade usage to that of the greater part of the business world.

As to the relative convenience of the inch and the millimeter, it is to be noted that the mil, or thousandth part of an inch, is not small enough for the thinnest wires and sheets, while it is too small for the thicker sizes. For very fine wires, such as No. 38, B. & S. gauge (4 mils, 10-100 mm.), the unit of measurement should be small enough not to require a sub-division to express any size required, and yet not so very small as to lead to a needless multiplicity of numbers. The mil does not fulfill this condition, for it must often be halved to express a required size. The hundredth of a millimeter, however, fills the bill perfectly. The successive sizes, 7, 8, 9, 10, 11 hundredths, etc., are all needed, and yet the differences are as minute as can well be measured for trade purposes; or at any rate if we can measure more closely we cannot draw wire more closely, and even for this degree of accuracy we must use diamond dies.

Passing to larger sizes we find the mil too small and leading to too many numbers, while the millimeter is about right. The near equivalents of the ordinary sizes of telegraph wire are as follows: No. 4, 6¼ mm.; No. 6, 5¼ mm.; No. 8, 4¼ mm.; No. 9, 3¾ mm.; No. 10, 3½ mm.; No. 12, 2¾ mm.; No. 14, 2¼ mm. The sizes vary at first by just 1 mm., and then by ½ mm. It would cause no inconvenience to change these current sizes to 6, 5, 4, 3½, 3, 2½ and 2 mm. (The standard size in Europe is 4 mm.)

Again, in the smaller copper wires (using now the B. & S. gauge), the current sizes and their near equivalents are: No. 12, 2 mm.; No. 14, 1½ mm.; No. 16, 1¼ mm.; No. 18, 1 mm.; No. 20, ¾ mm.; No. 22, ⅝ mm.; No. 24, ½ mm. The sizes differ generally by quarter millimeters, and there would be no inconvenience in going by quarters above 1 mm., and by tenths below 1 mm.

Let us compare these results with the mils representing the same sizes; Taking the telegraph wires we should have 243, 207, 169, 152, 138, 112 and 86 mils, and for the B. & S. gauge sizes mentioned, we should have 80, 64, 50, 40, 32 and 25 mils. Now if mils are adopted it will be impossible to hold purchasers to the standard sizes. Some one will order 250 instead of 243, or 200 instead of 207, or 80 instead of 64, or 30 instead of 32, and so on. Keeping stock of standard sizes will become very difficult.

All the arguments, therefore, favor the millimeter, except one—that of familiarity and habit—and yet this one may possibly outweigh all the rest. Unless you can bring into actual and general use the system chosen, all your resolutions of "adoption" might as well be thrown to the winds. (Witness the failure to introduce the new British gauge.)

The millimeter is infinitely preferable to the mil, as the kilo and gramme to pounds and ounces, the kilometer, meter, and centimeter to the mile, foot and inch, and the dollar to the pound sterling or rupee—or even to the franc, mark or florin.

But habit and custom—there's the trouble.

"Custom lies upon us with a weight
Heavy as lead and deep almost as fate."

Antwerp, June 10th, 1887. F. R. WELLES.

LITERATURE.

A PRIMER EXTRAORDINARY.

After Senhor Pedro Carolino's New Guide of the Conversation in Portuguese and English, we have seen nothing much funnier than the Electric Light Primer, of Charles L. Levéy, recently issued in New York, and to be had at 61 Broadway for half a dollar. Its sub-title is: "A Simple and Comprehensive Digest of of All the Most Important Facts Connected with the Running of the Dynamo and Electric Lights, with Precautions for Safety, etc. For the Use of Persons whose Duty it is to Look After the Plant."

A few selections from its pages will illustrate our meaning and justify our amusement better than any description.

In the preface the author says:—"In the hope of giving, in the most concise form, an insight into the workings of electric lights, both arc and incandescent, the author proposes to write a species of *Primer on Electricity*, divested of all complicated mathematical calculations, without touching on technical terms (save in explanation).

"The object of this work is to instruct those whose duty it is to attend to the running of dynamos, and to guard against some of the mishaps that are liable to arise. These few hints may be of considerable benefit, as this duty usually falls to the lot of the engineer (and being a man of good common sense), to such this work will, I hope, prove most valuable."

The following extracts are from the body of the work.

ELECTRO-MOTIVE FORCE.

"Electro-motive force expresses in electricity what steam in a boiler does to an engine, but as no circuit or work can be obtained without resistance, then we conclude that much E. M. F. is wasted in overcoming this resistance.

DYNAMO FIELD MAGNETS.

"Field magnets are made of soft cast or wrought iron, on which is wound a quantity of insulated copper wire. These fields become highly magnetized by the rotating of the armature, which is so connected to them as to generate a great current in the neighborhood of these magnets.

ARMATURE.

"Armature is that part of the dynamo machine which is attached to the spindle, but perfectly insulated therefrom. It is of suitable discs, made up in parts, surrounded with copper wire, and rotates in close proximity to the fields or pole pieces.

COMMUTATOR.

"Commutator is that part of the machine which is also attached to the spindle, but perfectly insulated therefrom. It is a copper ring made up in as many pieces as are bobbins on the armature, and each section is thoroughly insulated from the other.

BOBBIN.

"A coil of wire, or a number of coils, mounted so as they can be rapidly revolved.

INSULATION.

"Any substance, non-metallic, can be used for insulation, from paper up. It is the fact that no metal contact exists, and the various substances must be judged according to the work to be done.

AMMETER.

"Ampere meter is an instrument for measuring the current in amperes. By its use (if in circuit) it will instantly show the condition of the current.

VOLTMETER.

"Voltmeter is about the same, but gives the measurement in volts or E. M. F. Every installation should have these two instruments. Without them the party in charge is in the dark, however brilliant the light may be. If a breakdown occurs he is often unable to detect the cause.

EARTH.

"The return of any telegraph circuit: but in electric lighting a second or return wire is used, which is often called earth.

SHORT CIRCUIT.

"Short circuit means that the current takes the shortest path, and having no work to do causes fire. Moisture will cause a S. C. This will generally burn up the dynamo.

The necessity of good joints and entire absence of moisture is strongly urged. Moisture leads to loss of current, and to the destruction of the conductor, and the injudicious use of earth.

SPEED INDICATORS.

"Of these there are various makes, but the best are those that will denote the exact speed that the dynamo is rotating at."

Perhaps we can make no better comment on this remarkable manual than by quoting the following from Mr. Levéy's general directions.

"The difficulties that beset the engineer are chiefly internal and invisible, and they can only be effectually guarded against by testing or probing."

CATALOGUES AND PAMPHLETS RECEIVED.

Messrs. James W. Queen & Co., Philadelphia, send us a new catalogue of Specialties for Physicians, Physiological Apparatus for Original Research, &c. In addition to important electrical apparatus the circular contains lists of a great variety of optical and chemical appliances. Messrs. Queen & Co. make a specialty of fine electro-metrical apparatus.

Messrs. I. W. Colburn & Co., Fitchburg, Mass., manufacturers of arc and incandescent dynamos and lamps, have issued a Vest Pocket Edition of their Price List and Hand Book, containing illustrations of their machines and lamps, and many tables useful to electricians. They have also included a large amount of miscellaneous information, largely in tabular form, embracing interesting topics of physical science and useful arts. The exceedingly small type detracts somewhat from the usefulness of the little volume.

The pamphlet on Vulcanite Emery Wheels, issued by the New York Belting and Packing Co., has much interest for manufacturers and others interested in mechanical processes. Emery wheels are a relatively recent addition to the resources of mechanical work; and in the short treatise prepared by the New York Belting and Packing Co., they aim to show the essential points of the manufacture and use of emery wheels, and under what conditions their service is most effective and economical. These conditions include the mode of manufacture, the speed at which they should be run, and different purposes for which they are best adapted.

ELECTRICAL NEWS AND NOTES.

THE JUBILEE DINNER OF BRITISH ELECTRICIANS IN NEW YORK.

The dinner arranged by resident British electricians in celebration of the jubilee of Queen Victoria's accession and of Wheatstone's telegraph in England, was given with great success on the evening of June 20th, at Martinelli's restaurant on Fifth avenue. At 7.30 P. M. 50 gentlemen, including a considerable number of American electricians fortunate enough to be invited, sat down to dinner in a room gaily decorated with flags, and about 9 o'clock the speech making began, all the toasts being received with musical honors. Mr. George C. Ward gracefully presided, and gave, as the first toast, the health of the Queen in a happy speech, which was drunk standing, with hearty and prolonged cheers, following with that of the President and Mrs. Cleveland, responded to by Dr. Otto A. Moses. In reply to the toast, "The Jubilee of the Telegraph in England," Mr. James D. Reid made one of his characteristic speeches, full of humor and pathos. To the toast, "The Land we Live In," Mr. Erastus Wiman replied in a manner that aroused an enthusiasm only equalled by that attending the toast, "The Land we Were Born In," given by Mr. W. M. Callender, and replied to by Mr. Wm. Maver, Jr. "Our Profession," proposed by Mr. T. C. Martin, was replied to for the telegraph by Mr. F. W. Jones, who said: "It is very interesting to know that at the present time the ideas of the old and new world are crossing the Atlantic over a Wheatstone bridge, which is supported by 10 cables, anchored in both countries; and the American ideas and English ideas pass over this bridge in opposite directions at the same time and never quarrel, nor jostle one another on their way." Answering to the same general toast, Mr. Frank Fisk spoke for the telephone, Mr. Thomas Whiteside Rae for the electric motor, Mr. Callender for the electrical manufacturer, and Mr. G. M. Phelps, Jr., for the electrical press. The toast of "Absent Friends" had Mr. J. B. Taltavall as responder. In giving the toast of "Our American Friends," Chairman Ward said:

"I confess I had an inward desire to offer the toast myself, because I wanted to have the opportunity of telling our American friends how welcome they were and what pleasure their presence gives us to-night, but I have not words at my command to say what I want to. Like Sir William Thomson in his message that has been read this evening, I never have looked, and never can look, upon this grand United States as a foreign nation. From the day I stepped on its hospitable shore I felt I was at home. I have worked and lived with people of many nationalities, from the lethargic Arab of the east to the enlightened and wide-awake American of the west, and I know that in no country in the world is there such freedom, such opportunity, such energy, such enterprise, such push, as in this great country. I owe much to its people. In fact I will take the responsibility of saying we all owe much to its people, and we have much to learn from them. Why do we Englishmen prosper here? I say because the Americans give us the opportunity, and without this opportunity where should we be?—Not assembled here to-night. Speaking for myself personally, I have received the greatest kindness and assistance at their hands, I have many warm friends among them, and I consider it a privilege to be associated with them. We extend our friends a cordial welcome to-night; we hope this may be the beginning of many similar gatherings, and we trust we may continue to be brothers in thought and feeling." The toast was admirably responded to by Gen. E. B. Fowler. The last toast was that of "The Chairman."

Music added much to the festival character of the evening. Mr. E. Gould sang the song "England is where Britons be,"—verses written for the occasion by Mr. T. C. Martin—accompanied by Mr. G. H. Guy, who composed the music; and "The Skippers of St. Ives." Mr. A. E. Braddell sang "Dear Old Pals" and "Sailing"; Mr. W. Forman Collins sang "They all Love Jack," and Mr. J. Wetzler and Mr. G. H. Guy played a piano duet, "Valse Brillante," by Schuloff. The company sang "God Save the Queen," "The Star Spangled Banner," "Hail Columbia," "Yankee Doodle," and "Auld Lang Syne," accompanied on the piano by Mr. G. M. Phelps, Jr.

During the evening letters and telegrams from distant points were read. Sir William Thomson cabled from Glasgow as follows:

"Please convey to the committee my cordial thanks for their kind invitation for the 20th, and my regret that time and space alike forbid my accepting it. Kindly give this message to the company assembled. I am very glad indeed to have this opportunity of expressing hearty sympathy with the native-born British subjects connected with the electrical profession assembled to commemorate our beloved Queen's jubilee, and that of the electric telegraph in England; and with all friends of the United States of America or of foreign nations who may be joining with you. I never can regard the United States of America as a foreign nation, and with the Atlantic cables connecting us, the natural bond is strengthened and rendered practical in a thoroughly beneficent manner. It would have given me much pleasure to be with you all this evening, and as the next best to that, I gladly seized the opportunity afforded me by our good friend Mr. Ward, in thus speaking to you by cable my hearty congratulations, and the pleasure it gives me to join with you in the loyal commemoration of the double jubilee."

A cable message from Mr. W. H. Preece, was read as follows:

I regret I cannot be with you in body as I am in spirit. Britons all over the world rejoice this week in our sovereign's long life and happy reign; but we telegraphers duplex this jubilee, for while it excites our love and loyalty, it also enables us to celebrate the fiftieth anniversary of the birth in England of the means whereby we live. The jubilee of the connecting link of the great Anglo-Saxon race is one of the most important events of the Victorian era. May this never be broken. God bless our Queen."

Mr. Thomas D. Lockwood sent the subjoined telegram from Boston:

"Regret that previous engagement prevents my presence with you. In faith, I am like to greet. May continued advance attend the science, which founded by Gilbert in the reign of Elizabeth and extended by Hawksbee in the reign of Ann, has achieved the chiefest victories in the work of Faraday, Henry and your noble selves, during the fifty years of Victoria's reign."

Mr. J. R. Beard read the following from South America:

"The officers and staff of the C. & S. A. Tel. Co., the West Coast of America Co., and the Transandine Tel. Co., in Central and South America, cordially join me in wishing success to the commemoration of the fiftieth anniversary of the inauguration of the telegraph in England which you celebrate this evening in New York.

"We salute the fraternity. May our cables and our friendship never be interrupted.—Pescod Chorillos."

Letters of regret for absence were received from Mr. Leo Daft, Mr. Edward Weston, and others.

The celebration did not close till the small hours of the morning, and was most heartily enjoyed, not only by the Britons who gave it, but by their American guests.

THE U. S. ILLUMINATING CO.

At the annual meeting of the shareholders of the United States Illuminating Co., held June 21st, the following gentlemen were elected directors for the ensuing year:—Henry S. Marquand, George Montague, Richard Irvin, Jr., James Stokes, Duncan D. Parmly, George W. Hebard, Eugene T. Lynch.

ELECTRIC LIGHTING CONDUCTORS AT THE ROYAL JUBILEE EXHIBITION, MANCHESTER.

The distance of the Fine Art Galleries, and of Old Manchester and Salford, being very great from the dynamo room—in the former case about a fifth of a mile, and in the latter a quarter of a mile—and the very large number of lamps required, have necessitated the employment of exceptionally heavy conducting wires formed into cables for the incandescent lighting of the sections. These cables have been made in various sizes according to the requirements of the several sections, but they represent a total length of cable exceeding nine miles, whilst the bare weight of the copper alone required for the conductors of these cables is calculated to be very nearly ten tons. The whole of the conducting wires, including mains, branches, and leads for the incandescent lighting, and also the major portion for the arc lighting of the exhibition, have been manufactured and supplied by Messrs. Walter T. Glover & Co., of Salford, Manchester.

TELEPHONE BETWEEN HAMBURG AND KIEL.

A telephone connection between Hamburg and Kiel has been decided upon, and the preparatory works have been recently commenced. For part of the distance the telegraph wires will be used, but between Hamburg and Altona a separate line will be constructed.

THE UNIVERSITY OF KANSAS.—COURSE IN ELECTRICAL ENGINEERING.

Nothing is more significant of the rapidly increasing prominence of electricity as a science and in the useful arts, than the marked attention given to electrical engineering in many colleges and technical schools.

The University of Kansas, has just issued an announcement of a four years' course in electrical engineering. The scheme presented in its circular treats electrical engineering worthily and upon an equality with civil engineering. The prescribed qualifications for entrance and the course of study laid out, evince a thorough appreciation on the part of the faculty of the nature and scope of the training required to develop capable electrical engineers. Requirements for admission are similar to those of other first-class engineering and technical schools. The four years course includes Mathematics (Algebra and Geometry completed, Descriptive Geometry, Trigonometry, Analytical Geometry, Analytical Mechanics, Differential and Integral Calculus, Mathematical Theory of Electricity and Magnetism), Draughting, Chemistry (General Chemistry, Qualitative and Quantitative Analysis), Physics (Mechanics, Sound, Static Electricity, Electricity and Magnetism, Heat and Light), Surveying, Properties of Metals, Electrical and Magnetic Measurements, Resistance of Materials, Electro-dynamic Machinery, Photometry, Special Applications of Electricity, The Steam Engine, Astronomy, Botany, German, French, Latin, Specifications and Contracts.

The course will be inaugurated at the beginning of the next college year in September.

The circular concludes with the following announcements.

PROVISIONS FOR LABORATORY INSTRUCTION.

During Freshmen and Sophomore years, students in electrical engineering will find excellent facilities for practical work in general physics and chemistry, in the very completely equipped laboratories of the University. To meet the requirements of the more advanced courses of the Junior and Senior years, a large number of instruments for electrical and magnetic measurements are now in process of construction for the University by the best makers in this country and Europe. A steam engine of 15 h. p., with dynamo machines and motors of different types, and complete installations for arc and incandescent lighting and the electric transmission of power, will be in operation by the opening of the college year in September.

SPECIAL STUDENTS.

In placing the course in Electrical Engineering upon an equality with the course in Civil Engineering, already in existence in the University, both in the requirements for admission and in the number of years necessary to its proper completion, the University has in view the needs of students who intend to follow this branch of applied science as a profession, and who desire as complete preparation for their life-work as can be obtained within the limits of a college course. Persons desiring to pursue shorter courses in applied electricity will, however, be given every opportunity for the study of such subjects as they are qualified by their previous training to carry on successfully. Such students must be able in all cases to pass examination in the subjects required for entrance to the University, and in such other branches as are deemed essential to the courses they wish to pursue.

For further information, address

THE CHANCELLOR OF THE UNIVERSITY,
or
EDWARD L. NICHOLS, *Professor of Physics*,
Lawrence, Kansas.

ROSE POLYTECHNIC INSTITUTE.

The Rose Polytechnic Institute, is one of the very few schools in the United States, which are especially devoted to the education of civil and mechanical engineers. It owes its existence to the generosity of the late Chauncey Rose, of Terre Haute, Ind., who bequeathed something more than a half million of dollars for its establishment and support. It is one of the youngest technological schools of the country, having been opened for instruction in the year 1883. One of the peculiar features of the Institute is the thorough and extensive "shop practice" of the students in mechanical engineering. Not only are machines designed and working drawings made, but actual construction is required and is made possible in extensive workshops, the equipment of which has cost over forty thousand dollars.

Another valuable feature, and one which is somewhat unusual, is that the number of students admitted is not allowed to exceed a fixed number.

The plan of the Institute is to restrict the attendance to such an extent as to realize the benefits arising from small classes.

The course in Physics includes "general principles of electrical measurement, of testing instruments, of dynamos, of primary and secondary batteries, of the telegraph and telephone, and of transmission of power to a distance." The President, Prof. Mendenhall, is well known among electricians, and his interest and attainments in electricity will ensure adequate attention to that branch of physics.

ELECTRIC LIGHT AND POWER.

An electric light plant will be erected at Bar Harbor, Me. Judge Nathan Cleaves, of Portland, is interested.

The Pittsfield Electric Illuminating Co., of Pittsfield, Mass., are changing their plant from the old direct current system to the Westinghouse alternating system. Their first installment is for 1,300 lights, and they have received the contract for the city lighting for the ensuing year. 25 c. p. lamps will be used. They are also preparing to run a line to Lenox, Mass., a distance of six miles, for the purpose of lighting the summer residences in that town.

The Plainfield Electric Light Co, Plainfield, N. J., has nearly completed the enlargement of its station to a capacity of 3,000 lights on the Westinghouse alternating system. This is said to be the handsomest finished station in the country. The light is exceedingly popular, both for commercial and domestic use, and the financial results to the company are said to be very satisfactory.

Owego, N. Y., will be lighted by electricity. Address Henry Billings.

The Pueblo Gas and Electric Light Co., Pueblo, Col., will make extensive improvements to its electric light plant.

An electric plant will be put in at Monmouth, Ill. Address, W. B. Young.

The Brookline (Mass.) Gas Co., has bought the Local Electric Lighting Co., of Brookline, operating the Thomson-Houston system, and will operate it in connection with its gas business.

The Edison Illuminating Co., of Harrisburg, Pa., has purchased an arc plant from the Thomson-Houston Co., of Boston, to use in connection with their present incandescent plant.

The Pennsylvania Gas Co., will establish an electric light plant at Jamestown, N. Y.

The electric light excites rather more enthusiasm in the prairie state than in eastern localities. We quote below from a late issue of the *Evening Eye*, Roodhouse, Ill., a notice of an arc light installation in that town.

FIAT LUX.

THE ELECTRIC BLAZES OUT IN ALL ITS DAZZLING GRANDEUR.

* * * * *

When everything was ready for the test, and steam was let in to cylinders of the "little giant" Westinghouse engine, as many as could crowd in and around at the doors and windows were anxiously watching. Four lamps were connected with the circuit, and as with the quickness of lightning, the dazzling arcs of flame burst forth between the carbon points, as if the genius of electricity, angry to find his course opposed, had leaped the barrier, white with rage.

From the first the light was a perfect success. The room was illuminated with a brilliancy that cannot be described. It was a perfect glare of light. The only comparison we can think of is the fierce white flame of a molten mass of iron in a blast furnace. Except for the shadows, such an appearance did the room present.

Finding that everything was working to a charm, and that the light was all that could be desired, Mr. McIver and Mr. Shockley, representatives of the Western Electric Company, decided, in order to get the full effect of the light, to test one suspended from the Armstrong building to the bank at the northwest corner of the square.

The lamp was placed in position and hoisted away. A few moments of breathless expectation, and a great cheer goes up as the carbons break into flame. The effect was wonderful and far exceeded the expectations of all. It was well calculated to arouse enthusiasm.

* * * * *

To "drop into poetry" was natural after such a burst of light and enthusiasm, and in the same paper we find :—

PANSY'S PIECE.

No more in darkness will we grope
Along the gloomy street,
And on a narrow walk collide
With every one we meet.

The wonderful electric light,
Our highways will illume,
While all the towns for miles around,
Are talking of our boom.

Behold it gleaming in the sky,
With scintillations bright,
Like some resplendent jewel in
The shirt front of the night.

The pale moon shines with sickly hue,
And hides her yellow face,
The spark electric rules the night,
And has usurped her place.

And burning Phoebus, lord of day,
When this new sun he sees,
Withdraws himself to other parts,
And shines on the Chinese.

The Burlington (Vt.) Gas Light Co., started a Brush plant 10 months ago, with 50 street arcs and 11 commercials. To-day it has 70 street lights and 25 commercials, and expects further increase. It is extremely pleased with the working of the plant, and advises other gas companies to follow its example. It says, moreover, that the use of the electric light has unquestionably stimulated the demand for gas.

The Portland Electric Light Co., Portland, Or., having made a success of arc lighting, has decided to go largely into incandescent lighting. It has contracted for four 60 h. p. Westinghouse engines, making seven in all.

The City Council of Atlanta, Ga., has authorized the Metropolitan Street Railway Co., of that city, to operate its road by electricity.

An electric street railway is projected for Muncie, Ind.

Digitized by Google

Prof. Thomson is quoted as predicting that when the means of utilizing the power of creating quick heating by electricity is better understood it will be used in every workshop for welding, forging and other purposes. It would be well for our manufacturers to watch the progress of the adaptation of electricity to manufacturing purposes.

Foreign.

Austria.—The central railway station in Buda-Pesth is lighted by 70 arc lamps of 600 c. p., 430 glow lamps of 20 c. p., and 461 glow lamps of 10 c. p. The engineer in charge, Herr Kovacs, has just handed to the board of directors a report on the working expenses of this installation. The whole of the arc lights are nightly in use; but of the incandescent lamps 279 are not in regular use, these being fitted in state rooms, board rooms, etc., and only lighted on special occasions. The total annual 10-candle lamp-hours were 2,770,775, in which figure are included the 20-candle lamps, as equivalent each to two 10-candle lamps. The total annual arc lamp-hours were 211,390. The annual working expenses are given in Austrian money, of which, for the convenience of our readers, we give here the approximate equivalents in United States money, calculated at the current rate of exchange: Glow lamps burned out, $1,265; carbons for arc lamps, $2,167; fuel, $2,289; lubricants, $535; petty material, $876; personal expenses and wages, $3,530; engine repairs, $477; electrical repairs, $268; total, $11,407. Since the installation is mixed, it is desirable to obtain a common basis on which to estimate the working expenses per unit of light, and for this purpose, Herr Kovacs estimates 15.8 10-candle glow lamps to be equivalent in energy to one of the arcs, and on this assumption the total annual 10-candle lamp-hours result as 6,284,030, the expenses being at the rate of, say, 18 cent. per 10-candle lamp-hour. This is found much lower than the cost of the same amount of light from gas at Vienna prices, about 1.25 per thousand feet.

Belgium.—The *Bulletin International de L'Electricité* states that five cars have been actually fitted up on M. Julien's system, and the inauguration of the service is announced for the end of this month. This date may be a little too soon, but we may reckon on the cars being in operation by May 15th, notwithstanding the difficulties which M. Julien has to deal with at present, one being that the representative of Messrs. Siemens at Brussels threatens the tramway company with an action for infringement in connection with the armature of the machine employed by M. Julien. This matter, which is to be submitted to examination by experts, will cause some excitement in Brussels.

Belgium.—The inauguration of electric traction on the Brussels lines has been arranged to take place this month, and five cars have already been supplied by the Societe l'Electrique. The installation in the Rue Bronier, where the accumulators are to be charged, is almost finished. It consists of DeNayer boilers, a 150 h. p. Walschaerts engine, and four dynamos each for a current of 30 amperes, but varying voltage from 200 to 500. The engine and boilers, the dynamos and the batteries, are all in different rooms. The battery room has been arranged so as to facilitate quick charging, and special arrangements are being made for the easy and rapid replacement of the batteries in the cars when these enter the station.

France.—The ironclad *Le Furieux*, which is now being constructed at Cherbourg, has recently been fitted with two projectors of 15,000 c. p. each, and 150 16 c. p. incandescent lamps. Gramme dynamos, driven by Brotherhood engines, are used. In the Mediterranean, experiments have been made for the protection of harbors against torpedo attack. The search light is placed on a revolving platform, about 33 feet above the level of the sea, and by changing the position of the arc in the lantern, it is possible to either illuminate a considerable area, or to concentrate all the light on one point. During these experiments, it was found that the approach of a torpedo can be detected, even at a considerable distance.

Germany.—The Khotinsky glow lamp has met with considerable success in Germany, and has, up to the present mainly been supplied by a Rotterdam company, which has also works at Cologne. The German Edison company now claim that the right of manufacturing this kind of lamp is covered by certain of their patents, and an action has been instituted against the Dutch company to restrain them from making such lamps. M. Khotinsky is said to have succeeded in manufacturing reliable 150-volt lamps.

Hungary—A project has been set on foot for the introduction of the electric light in the town of Fiume, the most important seaport of the Hungarian empire. It is proposed to utilize the water power of the river Fiumera, which comes from the Karst Mountains, and has a magnificent fall a few miles from the town. Since the town contains the large torpedo works of Whitehead, an important tobacco factory, and several large paper mills, the promoters are confident of obtaining sufficient custom to justify their commencing with an installation of 3,000 lights, which, however, will be arranged with a view to future extensions. It is proposed to employ transformers.

Russia.—The Czar of Russia, at his winter palace on the banks of the Neva, possesses what is probably the largest permanent installation of electric light ever placed in a single building. The palace itself is illuminated by 12,000 incandescent lamps, while 56 powerful arcs light up the front and the various court-yards. The machine room contains eight engines, capable of developing 2,500 h. p.; the dynamos, including reserve machines, are 26 in number. The work was planned and carried out by the engineers of the palace, in conjunction with the St. Petersburgh house of Siemens & Halske, and the installation has been at work since the commencement of last winter.

NEW INCORPORATIONS.

The Chicago Arc Light and Power Co., Chicago, Ill. Capital stock, $1,000,000. Sidney A. Kent, and others, incorporators.

The Improved Light, Heat, Power and Manufacturing Co., Saco, Me. Capital stock, $500,000. President, Frank A. Dearborn, Newton, Mass.

The Home Electric Light Co., Roanoke, Va. President, J. M. Gambill.

The Hiawatha Electric Light Co., Hiawatha, Kas. Capital stock, $20,000. John Schilling, and others, incorporators.

The St. Louis Investment Co., St. Louis, Mo. Capital stock, $30,000. David B. Gould, and others, incorporators.

The Thomson-Houston Electric Light, Heat and Power Co., Woodbury, N. J. Capital stock, $25,000. Charles O. Baird, and others, incorporators.

The Clinton Electric Co., Clinton, Mo. Capital stock, $18,000. George Hormeyer, and others, incorporators.

The Hamilton Electric Light Co., Hamilton, Ohio. Capital stock, $50,000. Thomas Millikin, and others, incorporators.

The Manhattan Electric Co., Manhattan, Kas. Capital stock, $25,000. George Higinbotham, and others, incorporators.

The United Electric Light Co., Springfield, Mass. Capital stock, $100,000. Gideon Wells, and others, incorporators.

The Millbury Electric Co., Millbury, Mass. Capital stock, $10,000. C. D. Morse, and others, incorporators.

The Charleston Electric Light Co., Charleston, Ill. Capital stock, $15,000. J. W. X. Neal, and others, incorporators.

The Ashtabula Electric Power and Light Co., Ashtabula, Ohio. Capital stock, $5,000. W. J. Morrison, and others, incorporators.

The C W. Harvey Electric Light Co., Waterloo, Iowa. Capital stock, $40,000. C. W. Harvey, and others, incorporators.

The Battery Light and Power Co., Buffalo, N. Y. Capital stock, $1,000,000. Charles H. Gibson, and others, incorporators.

The American Electric Light Co., limited, of Carthage, N. Y. Capital stock, $7,500. Vergil K. Kellogg, and others, incorporators.

The Napoleon Electric Light Co., Napoleon, Ohio. Capital stock, $15,000. Alfred Beard, and others, incorporators.

The Eickemeyer Dynamo Machine Co. Capital stock, $60,000. Rudolph Eickemeyer, and others, incorporators.

The Warsaw Electric Light Co., Warsaw, Ill. Capital stock, $3,000. George P. Walker, and others, incorporators.

The Mutual Electric Illuminating Co., New York, N. Y. Capital stock, $25,000. John G. H. Meyers, and others, incorporators.

The Citizens Freeman Electric Light Co., New York, N. Y. Capital stock, $30,000. Thomas O'Brien, and others, incorporators.

The Dexter Electric Light and Power Co., Dexter, Wis. Capital stock, $10,000. Samuel S. Ireland, president.

PERSONAL MENTION.

Mr. Robert H. Read, for six years an examiner in the patent office, in the chemical and electrical divisions, has begun business on his own account as solicitor of patents and mechanical and electrical expert. Mr. Read's experience in the patent office, where his services were very valuable and highly appreciated by the commissioners, well qualify him for success in his new field.

MANUFACTURING AND TRADE NOTES.

The Phosphor-Bronze Smelting Co. (Limited), Philadelphia, are finding a wide market for their products. Their metal proves applicable to a great variety of uses. They have recently issued a circular, giving, with other information, a table of prices for machine castings, with a convenient classification of qualities and uses, the prices varying somewhat for different grades of metal.

Digitized by Google

The Stratton Separator Co., recently received by telegraph an order from the Pennsylvania Railroad, for three of their steam separators, for use on high-speed engines at Philadelphia, Altoona, and Harrisburg. They are now placing an apparatus on the 17" steam pipe of the U. S. Steamer *Boston*, at the Brooklyn Navy Yard, which is a duplicate of the one previously placed on the U. S. Steamer *Atlanta*, with such very satisfactory results in the development of both power and speed.

The Billings & Spencer Co., who were the first to make drop-forged commutators for dynamos, have been pushed even beyond their utmost possible capacity to keep in sight of orders. They are making about a dozen sizes of these copper pieces for the Edison Electric Co., and a similarly large number for the Westinghouse Electric Co.

The demand for their products has compelled the New York Carbon Works to fit up a new factory at Newark. New ovens and additional machinery are being provided for the manufacture of their special battery carbons. The office of the works is at 39 Dey street, New York.

The Westinghouse Electric Co. are meeting with an enormous demand for their alternating system for central station work. The shops employ about 1,200 men, and are working a night gang. Their lamp factory is already the largest in the United States. They have now over 40 stations under construction or in operation. Recent contracts have been made in Pittsfield and Springfield, Mass.; Hartford, Conn.; Denver, Colorado Springs and Ouray, Colorado; St. Louis, Mo.; Cornwall, Canada; Littleton, N. H.; Portland, Me.; Morristown, N. J.; Staten Island, N. Y.; Galveston, Texas, and Charleston, W. Va.

The self-winding clocks, made under patents of Mr. Chester H. Pond, are manufactured and sold by the American Mfg. and Supply Co., 10 and 12 Dey street, New York. These clocks are electric only in the sense that the winding mechanism is actuated electrically. Each clock is supplied with a small battery, which is usually concealed within the case, or it may be placed in any other location if desired. The clocks are entirely automatic, self-winding at regular intervals by electricity, thus obviating all the care and attention required in the use of key-winding clocks. Experts in horology have expressed very favorable opinions of the advantages of these self-winding clocks.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From May 17th to June 14th, 1887 (inclusive).

Alarms and Signals:—*Electro-Magnetic Thermoscope*, H. J. Haight, 362,957. *Recording Compass and Marine Indicator*, R. W. F. Abbe, 363,039. *Electrical Device for Operating Steam Whistles*, W. M. Pease, 363,079. *Electrical Matting*, A. H. Freeman, 363,290. *Thermostat for Incubators*, C. L. Wells, 363,307, May 17. *Mail-Box Indicator*, C. M. Ball and T. J. McTighe, 363,574, May 24. *Signal Box*, H. A. Chase, 363,948, May 31. *Annunciator System*, P. Seiler, 364,444, June 7. *Thermostatic Circuit-Closer*, W. S. Johnson, 364,518, June 7. *Electric Burglar-Alarm*, G. R. Lehy, 364,764. *Low-Water Alarm for Steam-Boilers*, W. J. Kassler, 364,940, June, 14.

Clocks:—*Electric Striking Device for Clocks*, S. C. Dickinson, 363,215, May 17. *Secondary Electric-Clock Movement*, C. D. Warner, 363,440. *Primary Electric Pendulum Clock*, J. Zeiner, 363,498, May 24. *Electric Clock*, J. E. Mejer, 364,429, June 7. *Electric Synchronizing Apparatus for Clocks*, A. Ramel and W. W. Dean, 365,023, June 14.

Conductors, Insulators, Supports and Systems:—*Covering Insulated Electric Conductors*, J. Tatham, 363,182, May 17. *Machine for Making Seamless Lead-Covered Electrical Conductors*, G. L. Kitson, 364,177. *Lead-Covered Electric Conductor or Cable*, same, 364,178, May 31. *Terminal or Distributing Box*, F. E. Degenhardt, 364,994, June 14.

Distribution:—*System of Electrical Distribution for Railways*, W. J. McElroy and J. D. Nicholson, 363,250. *Indicator for Electric-Lighting Systems*, W. J. Hammer, 363,333, May 17. *System of Conversion of Electrical Energy into Mechanical Force*, H. M. Paine, 363,669, May 24.

Dynamos and Motors:—*Dynamo-Electric Machine*, J. W. Easton, 363,128. *Method of and Apparatus for Detecting Short-Circuits in Dynamo-Electric Machines*, same, 363,129. *Self-Exciting Alternate-Current Electric Generator*, same, 363,126. *Safety-Contact Brush for Dynamo-Electric Machines*, same, 363,127. *Automatic Commutator-Adjuster*, E. Thomson, 363,184. *Alternating Current Electric Motor*, same, 363,185. *Alternating Current Motor Device*, same, 363,186, May 17. *Electric Motor and Dynamo-Electric Machine*, R. M. Hunter, 363,466, May 24. *Electric Motor*, G. F. Card, 364,086, May 31. *Method of and Apparatus for Forming Armature Cores*, F. Wynne, 363,106, May 17.

Galvanic Batteries:—*Pocket-Battery*, L. T. Stanley, 363,304, May 17. *Electrolyte* A. C. Tichenor, 363,562, May 24. *Device for Preventing the Escape of Noxious Fumes from Batteries*, M. Bailey and J. Warner, 363,880, May 31. *Galvanic Battery Cell*, J. R. Hard, 364,344, June 7. *Galvanic Battery*, V. Francken and E. Bender, 364,639. *Battery Solution*, W. P. Kokogey, 364,656. *Battery Cell*, A. V. Meserole, 364,660, June 14.

Ignition:—*Electric Gas-Lighting Apparatus*, I. Fisher, 364,235, June 7. *Electric Gas Lighter*, C. W. Holtzer, 364,760, June 14.

Lamps and Appurtenances:—*Electric Arc Lamp*, J. F. Denison, 363,611. *Incandescent Electric Lamp*, C. G. Anderson, 363,500; W. Stanley, Jr., 363,559, May 24. *Device for Attaching and Detaching Electric Lamps*, W. J. Hammer, 363,332, May 17. *Incandescent-Lamp Fixture*, M. J. Wightman and H. NEW YORK, AUGUST, 1887.

THE FUTURE OF ELECTRICAL TRANSPORTATION.

THE application of electricity as a motive power for railway trains, the earliest conception of which appears to be due to that eccentric genius, Henry Pinkus, "late of Pennsylvania, in the United States of America, gentleman," who flourished in London *circa* 1840, has apparently passed through its preliminary experimental period, as exemplified by the work of Siemens at Berlin, Edison at Menlo Park, Finney at Pittsburgh, and Field at Chicago, and has now reached the stage of a somewhat extended practical development. This era in the progress of the art may be said to have commenced with the Lichterfelde line of Siemens, opened May 16, 1881, which was followed by the Portrush line, September 30, 1882, and these two by many others, as given in Mr. Martin's table, published on page 228 of our current volume. At the present moment a glance at the technical journals is sufficient to show that electric railway enterprises are springing up like mushrooms in every direction, both in this country and abroad.

It may not be uninteresting at the present juncture to attempt to forecast some of the probabilities of the future development of electric transportation, in the light of what has already been accomplished.

In one field, that of surface street railroads, the universal employment of the electric motor is without doubt only a question of time, and not a very long time either. The practical success which has everywhere attended the introduction even of the comparatively crude methods and apparatus at present in use are a sufficient evidence of the ultimate fulfilment of the prophecy. Even the ingenious and efficient, though expensive, cable system is certainly destined to follow the patient plodding horse into the limbo of superseded and obsolete street-car motors.

The next field to be occupied is that of the elevated and other city and suburban rapid transit passenger lines. This undertaking is a far more difficult one, but its accomplishment may, in our opinion, be looked for at no distant day. The conditions of the problem have been thoroughly mastered, the obstacles to be met with are sufficiently well appreciated and understood, and meanwhile several of the ablest practical electricians of the day are devoting their best energies to the subject. No less than four electric locomotives designed for this class of service are under construction by different parties at the present time, and we shall be much disappointed if one or more of them does not upon trial give sufficiently favorable results to render the future success of electric traction on railways of this class an assured success. The relief to the public in being freed from the annoyance of steam, smoke and cinders, and in great measure of noise as well, will be incalculable, while the probable resulting economy in operating expenses, although in our opinion considerably overestimated by sanguine inventors, will nevertheless be sufficient to render the change a profitable one to the owners of the roads.

Another field, and one in which the electro-locomotive of the future may be expected to achieve its greatest triumphs, is that of rapid passenger traffic between our chief commercial centres. Steam locomotion, so far as speed is concerned, has practically reached its limit. The unavoidable restrictions of bulk and weight forbid any material increase in the power of the express locomotive of to-day. No such restrictions apply to the electric engine. The amount of power which by this means it is possible to apply to the axles of an ordinary train without materially increasing its weight, may, without exaggeration, be said to be almost limitless. We believe that the rapid transit railway of the future will have its trains propelled by electricity; it will be straight, as the crow flies; it will follow the topographical undulations of the country almost regardless of grades, and its trains will attain a speed of more than one hundred miles per hour with safety. Without doubt, this may be looked forward to as the next great step in the progressive improvement of the art of transportation.

It remains to speak of another development of electric transport, which for some occult reason has failed, at least in this country, to attract the attention that its importance deserves—the telpher system.

This ingenious invention, although apparently perfectly successful at Glynde, England, where it has been for quite a long time in practical operation, can be expected to have but a limited field of usefulness in the land of its nativity, compared with that which awaits it in the rugged and mountainous regions of our western mining states, to say nothing of the vast undeveloped territories of Mexico, and Central and South America.

We have thus briefly indicated some of the probable future lines of development of electric transportation. Doubtless many others will discover themselves from time

Digitized by Google

to time, as the ceaseless march of improvement goes on; but what the ultimate outcome will be is scarcely less difficult of prediction at the present moment than it was in the days of "Henry Pinkus, of Pennsylvania," now almost half a century ago.

ELECTRICAL DISTRIBUTION BY INDUCTION.

According to a report published in the newspapers at the time, Mr. Edison said in the summer of 1883: "About six weeks ago I closed my laboratory, and I have now got the system worked down to the minutest detail. There is nothing more in electric lighting to be invented or required." If Mr. Edison really did make the statement thus attributed to him he must have been laboring under a temporary misapprehension. At least one thing more was very urgently "required" in 1883 and for sometime afterwards, and that was a system whereby electricity could be distributed at a cost which would permit of the payment of reasonable dividends to the stockholders of the illuminating companies operating incandescent lamps from central stations.

It was perhaps well for the progress of the art that other inventors were in the field who were not quite so certain that the *ultima thule* had been reached in electric lighting. At the very time that Mr. Edison closed his laboratory for the alleged reason that there remained "nothing more in electric lighting to be invented," an apparatus was being for the first time publicly exhibited in London, which, as it now appears, was destined to produce a revolution in the art of electrical distribution for incandescent lighting. The claim then put forth by the inventors, Messrs. Gaulard & Gibbs, namely, that they presented their method as a solution of the problem "of the further industrial development of absolute distribution, that is to say, a system of distribution limited neither by the distance of the central factory from the point of consumption, nor by the number of consumers to be supplied," was received in some professional circles with mild and in others with energetic incredulity. They persevered, however, in spite of ridicule and opposition, and in the autumn of 1883 seven miles of the underground railway in London were fitted up by them, this being the first industrial plant ever put in service for lighting by alternating main line currents and local induction coils. In commenting upon this installation, soon after its completion, *Engineering*, a high authority, urged as a prominent consideration in its favor that "the cost of a conductor to carry the current directly for lighting by incandescence on a circuit of fifteen miles would be perfectly prohibitory to any scheme."

In September, 1884, another plant was set up at the Turin exhibition, on which occasion a group of 24 Swan lamps was lighted at a geographical distance of 25 miles from the generator. This demonstration was followed by the installation of a commercial plant in London of nearly 1,500 lamps. The difficulties of regulation in the Gaulard & Gibbs system, which were from the first of a quite serious character, were soon traced to their true cause by Kennedy, of Glasgow, who in a communication published in June, 1883, pointed out that the irregularities observed were due to the series arrangement of the inductive primaries then in vogue, but that by placing the latter in parallel arc these would be obviated, and the system would become, as he expressed it, "beautifully self-regulating." The importance of Kennedy's suggestion was but little appreciated until long afterwards. In fact the entire system, in the words of Kennedy, was "criticised by some, scoffed at by many, and altogether ignored by the majority of electricians." By way of exception to the general rule, it may be noted that the Hopkinson brothers, with their usual sagacity, designed in 1884 important improvements in the construction of the induction apparatus, which they patented, and then quietly awaited the progress of events. In 1885 Zipernowski and Deri, of Hungary, announced a new and greatly improved system of electrical distribution by induction which for a time attracted much attention, but which turned out after all to be little more than a reinvention of the improvements which Kennedy and the Hopkinsons had made upon the original Gaulard & Gibbs invention.

In the following year, 1885, Westinghouse established the first commercial plant of the kind in this country, embodying the inventions of Gaulard & Gibbs, Kennedy and Hopkinson, together with many improvements in detail originating in his own establishment. The sudden popularity and gratifying success which has attended the introduction of this admirable system in this country is due to its economy in first cost, as well as in maintenance and operation, its perfect adaptation to all conditions of service, and last but not least, to the simplicity and excellence of the construction of the apparatus.

From present indications it would certainly seem that the incandescent lighting system of the future will be operated by inductive apparatus and alternating currents.

The reorganization of the New York Subway Commission, as the Board of Electrical Control, with Mayor Hewitt added to its membership, is less satisfactory than it would be if the Commissioner of Public Works and the Comptroller had also been added to the commission as proposed in the interest of the city. But, while the mayor is a minority of one-fourth for voting purposes he has already shown himself a majority of three-fourths or more in knowledge, common sense, and appreciation of the nature and scope of the work of the board. Gratification and amusement for the public were provided in about equal quantities by the proceedings at recent meetings of the board. Mr. Hewitt's incisive questions and determined action routed the old members of the commission, horse, foot, and dragoons. He administered some elementary instruction on the rusting of iron pipes; asked the chief engineer a few questions about electric light wires under which Mr. Kearney collapsed, and finished a good afternoon's work by preventing the appointment as chief inspector, at a salary of $3,000—of one Cornell, a city politician. The mayor's questions concerning the qualifications of Cornell as an electrical engineer brought out the fact that he possessed no knowledge or experience of electrical work, together with the comical suggestion, offered with much seriousness, that he was teachable and would be instructed by the chief engineer. The commissioners were deeply grieved that their nominee, backed by the recom-

Digitized by Google

mendation of chief-engineer Kearney, should be so closely scrutinized by the mayor. Their emotion was too much for them, for just as they were about to vote Mr. Cornell in as chief inspector they lost their heads or their courage and permitted the passage of a sudden motion to adjourn, offered by the mayor.

Whether or no Mr. Hewitt succeed in forcing the Board of Electrical Control to adopt a policy and methods solely in the interest of the city, and to place the execution of their work under the guidance and supervision of competent electrical engineers, he has rendered and doubtless will continue invaluable service as a check upon the commission.

Not much has been expected in the way of promoting the legitimate objects of the commission from politicians like Mr. Jacob Hess, but better things have been expected of Mr. Gibbens than his advocacy of so conspicuously unfit an appointment as the one attacked so promptly and effectively by Mayor Hewitt.

Mr. Rankin Kennedy, of Glasgow, in the current installment of his very interesting series of papers on Electrical Distribution by Alternate Currents and Transformers, remarks in reference to the United States patent of Gaulard and Gibbs, that he understands these parties to claim to be the only true inventors of the *parallel* system of working transformers at constant potential. A more careful study of the claims of the patent will, we think, convince Mr. Kennedy that he is in error in this particular. It is only just to Mr. Kennedy to say that the importance of his own work in this field is well understood in this country, and so far as we are aware, the fact that he was the first, not only to point out the advantages of the parallel system, but to clearly explain the reasons therefor, has never been questioned. It is, however, true, as he states, that the series system has never been tried in America,—at all events for practical work, while on the other hand we may mention that many successful plants are at work on the parallel system, making use of a converter differing but little in principle from Mr. Kennedy's ring converter of 1883.

Prof. Tyndall's retirement from the Chair of Natural Philosophy in the Royal Institution was signalized by a banquet in London, June 29th, in his honor and in recognition of his distinguished service in the cause of science. A notable company of men of learning and achievement attended. We reproduce elsewhere an extract from Prof. Tyndall's address in response to the toast to his health, for which we are indebted to the columns of the *Electrician* of London.

The sentiments of regard and appreciation bestowed upon Prof. Tyndall by his countrymen will be largely shared in America. His memorable visit here fourteen years ago, during which he delighted as well as instructed all who were privileged to enjoy his lucid and beautiful lectures, made a lasting impression, and had much influence in stimulating interest and effort in the cause of scientific research.

The practical every day use of telegraphing to and from moving railroad trains on the Lehigh Valley railroad, described in a notice reprinted from the *Railroad Gazette*, in another column, though promising a useful and important addition to the resources of railway management and a convenience to the traveling public, will scarcely be deemed an unmixed benefit. One can count no longer on an express train as a refuge offering complete immunity for a few hours from missives of any kind; his reading, musing or sleeping will be at the mercy of the telegraph, his temporary refreshing isolation gone. Perhaps a steamer at sea may not much longer keep out of reach of the dots and dashes of the telegraph; if Mr. Edison can telegraph through seven miles of sea water why not through seven thousand?

One of the stock assertions of the oratorical and newspaper mouth-pieces of that highly disinterested group of citizens, who for the last few years, in season and out of season, have vociferously demanded the instantaneous inhumation of the electric wires, has been that such wires are all underground in London, *ergo*, the same thing can be done here. But now comes the annual report of the United Telephone Company of London, from which it appears that the cost of repairing the damages to overhead wires caused by the great Christmas storm of 1886, was over $75,000, a very tidy little sum, and one which indicates that all the overhead wires are not in New York after all.

The Semi-annual Convention of the National Electric Light Association, to be held at the Parker House, Boston, August 9th, 10th and 11th, will doubtless be largely attended. Several matters of importance were partially considered at the February meeting, and left over for further action, among them the proper insulation of conductors and the wire gauge question.

The rapid development of improved methods of distribution is attracting general attention among electric light people. Interesting reports and discussion on this subject should be forthcoming at the Convention.

The *Western Electrician*, of which four weekly numbers have now been issued, has fully justified the favorable anticipations felt and expressed in many quarters. Its columns exhibit a judicious combination of electrical news and technical articles. It is well illustrated, and in general appearance is a very handsome journal; typography and press-work are extremely good. Chicago is to be congratulated upon the establishment of so creditable an electrical journal.

The success of the Electrical Exhibition undertaken by the New York Electrical Society in connection with the autumn exhibition of the American Institute, is already assured by the number and character of the applications for space now in hand. Apparently the electrical exhibits will be the predominant feature of the general industrial fair. Elsewhere we print the lists of committees and the rules adopted for the management of the Electrical Exhibition.

ARTICLES.

EXPLORATIONS OF THE MAGNETIC FIELDS SURROUNDING DYNAMOS.

BY CARL HERING.

During the Electrical Exhibition at Philadelphia, in 1884, the writer had occasion to examine the large Edison dynamo, commonly known as "Jumbo," with a view to find what disturbing effect, if any, the iron of the direct coupled steam engine had upon the distribution of the magnetism of the two pole pieces, it being attached to one of them. The examination was directed to finding the position, polarity, and approximately the intensity, of magnetic poles on different parts of the engine and pole pieces. By the somewhat strange behavior of the exploring needle, the writer's attention was called to the peculiar distribution of the magnetism around the yoke piece and parts of the coils of the dynamo itself where it was apparently not affected by the engine. The peculiar results obtained in some parts led to a similar examination of other machines at the exhibition with a view to making diagrams of the magnetic fields surrounding the dynamos by plotting the direction of the external lines of force. The resulting diagrams were not only interesting but may also prove to be instructive to designers and builders of dynamos, as they show clearly and conclusively the nature of the invisible field surrounding the different parts of the magnets; and as a large part of this field is leakage or wasted magnetism, they show how frames should and how they should not be constructed with reference to magnetic distribution.

The tests were made as follows. The exploring needle, which may be termed a "magnetoscope" or indicator of magnetism, as distinguished from a "magnetometer" which measures the quantity, was an ordinary short, light, compass needle, strongly magnetized and loosely supported on a pivot. While the dynamos were running and the magnets fully excited, this needle was moved about in the space surrounding different parts of the magnets and the machine frame. If the case containing the needle be turned so that the needle is always perpendicular to its pivot, thus allowing it to turn as if on a ball and socket joint, the needle will take the direction of the lines of force in this space. By moving it systematically all around the different parts of the machine, and by plotting the direction of the needle on outline drawings of the machine, the directions of the lines of force may be readily indicated. To explore the curved paths of the lines of force the needle may be held near to any particular part of the frame and then moved continually in the direction in which the farther end points, that is as the direction of the needle changes the direction in which it is moved must be changed so as always to conform with that to which the needle points. The path which it describes will then be that of the particular line of force. In this way the curvature and the two terminals of an external line of force can readily be determined and plotted with all due accuracy, as the needle is always a tangent or short cord to that curve, and where the needle points directly to the iron when held closely to it, it indicates the point where the line enters or leaves the iron. By shaking the needle to cause it to oscillate, a rough approximation can be obtained of the intensity of the field or the number of lines of force at different places. Great care should be taken not to move the needle too fast, as the lines of force in some machines make such short curves that the needle is demagnetized and even reversed in polarity before it has time to turn on its pivot. It is necessary, on account of this possible reversal of the magnetism, to test frequently its polarity at one of the machine poles, otherwise very queer and conflicting curves may be obtained.

The polarity of a magnet being usually represented by the signs + and —, the former indicating the north or north seeking pole, and the latter the south or south seeking pole, the direction which the external lines of force are conventionally assumed to have, is from + to —, that is, as if they emanated from the north pole of a magnet. If the compass needle or magnetoscope has an arrow head on its north end, the direction of this arrow will always show the direction of the lines of force of the field which is being explored.

It will greatly facilitate the examination and plotting of these curves to remember that every line of force appears to make a closed curve which encircles the wire through which the exciting current flows. This will also enable one to interpolate the probable return paths of the lines in the iron where their presence cannot be ascertained by means of a needle otherwise than by their external manifestations. All lines which do not pass from the pole pieces to the armature core and are therefore not cut by the armature coils, are wasted and represent leakage.

In the accompanying diagrams the probable return paths of a few of the lines of force in the iron parts have been indicated, and it is believed they are correct. The drawings may not in all cases represent the exact proportions of the frame, as they are copied from mere rough note-book sketches.

The first machine examined was the large Edison "Jumbo." Figure 1 shows the results obtained, copied from the

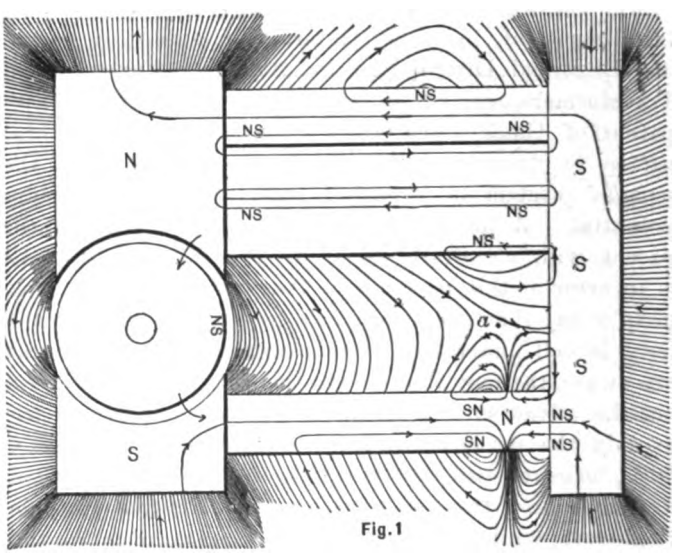

Fig. 1

rough sketches. As is well known, the frame of this machine is unsymmetrical, consisting of two horizontal sets of cylindrical, parallel magnets in the upper part, and one set in the lower. Each set consisting of four magnets, there were altogether eight magnets in the upper part and four in the lower. From this unequal distribution alone, it might have been supposed that either there would be considerable leakage of the excess of magnetism of the upper sets of magnets, the lower ones presenting only half the cross-section of iron, or that if the upper ones were only half saturated in order not to over-saturate the lower, there were more magnets in the upper part than required to produce the needed magnetism. The coil of each lower magnet was found to be connected in series with the two above it, thus forming a series of three coils; these series groups were then connected in multiple arc with one another, forming a series-multiple group of three in series and four in multiple. If, therefore, the number of turns of wire was the same in each of the upper and lower coils, the upper half of the machine must have received twice the amount of magnetism that the lower had. From the external lines of force this appears in a measure to have been the case. The exploration of this field showed a somewhat peculiar distribution of magnetism which it was at first thought might be due partly to reversals of polarity of the exploring needle, but repeated examinations during which the needle was frequently tested for

Digitized by Google

polarity, showed that the results were quite correct, as might have been shown *á priori*, had it been known that the total ampere-turns in the upper part were much greater than those in the lower.

Beginning first with the upper pole-piece marked N, the usual intense leakage was observed on the surfaces and at the corners, and especially at the pole-piece projections, magnetically shunting the armature. Passing next along the upper magnet the first neutral point marked N S was found beyond the middle, the lines of force on the other side of it, entering instead of emanating from the cores, as before. Passing next to the upper end of the yoke-piece a strong south pole was found. The lower one of the upper magnets was found to be similar on its lower side, to the upper side of the upper magnet, only that the neutral point was nearer the yoke-piece than before,—neutral point being understood to mean a point where the two poles are exactly equal in intensity and where, therefore, the external lines of force are parallel to the cores. In a normal, straight bar magnet, the neutral point will always be in the middle, and might be termed the magnetic middle of a magnet, which in a normally proportioned bar magnet should coincide with its linear, axial middle.

In the space between these two upper parallel magnets, it was found that the lines of force were quite straight along their whole length, and parallel to the magnets, but in the opposite direction to their course in the cores. In other words, these two like magnets were neutral along their whole length on the sides facing each other. This might be considered as another proof that in two such parallel like coils ending in the same pole-piece, those parts of the coils which are nearest each other neutralize one another as far as the useful magnetism of the pole-piece is concerned; it will be noticed that these parallel lines of force when continued, as shown, through the cores, encircle those portions of the coils.

Passing next down the yoke-piece it was found that instead of being neutral in the middle, as usual, with poles at each end, it was a strong south pole along its whole length with no signs of a neutral point at any place. This is no doubt accounted for by the great excess of magnetism of the upper magnets over that in the lower.

The south or lower pole-piece was quite similar to the north, showing the usual intense leakage on all sides and corners and especially at the pole-piece projections.

Passing finally to the lowest magnet a very peculiar result was obtained, which was at first discredited, but upon repeated and careful exploring it was found to be verified. A short distance from the right hand end there was a very intense north pole, the lines of force being at that point quite perpendicular to the coil for a short distance, as shown, and afterwards branching out to the right and left, finally entering the iron again. Between this point and the yoke-piece, there was, of course, a neutral point, marked N S, and on the left hand side, also quite near to it, another neutral point of opposite polarity, marked S N. These two neutral points situated so very near a strong pole, created a very curious field, the most interesting part of which is that lying above them where the lines come together with those of the magnet above it. At this point, *a*, marked by a dot, it will be noticed that the lines which come together make four sharp turns as though there was something at this point which did not permit the lines to pass through but which reflected them somewhat as rays of light are reflected from a mirror. A needle held at this point acts as though it were uncertain in which direction to point, and if moved about this point even for very short distances, it will have very decided but quite different directions, as will be seen from the arrows which show the direction of the needle when in the respective lines of force. If a very short needle could be placed exactly at this point it would act similarly to a body balanced in unstable equilibrium, the slightest movement from this position causing the needle to deflect in a certain definite direction. Such points might therefore be termed "points of unstable magnetism," or "points of magnetic deflection having four poles," as there are four general directions of the lines of force in the vicinity of this point. Their characteristic peculiarity is that the needle is very apt to have its polarity reversed when moved through them, the explanation of which is, no doubt, that the lines of force make such abrupt curves that their direction through the needle is reversed before it has time to turn on its pivot.

In a few places the probable courses of the lines of force through the iron itself, have been indicated. It is not possible to determine this definitely with the aid of a needle only, but from the nature of the field surrounding the iron and from the general laws of lines of force, it is very likely that the courses indicated are correct.

From the results obtained in the exploration of the field of this dynamo, the following conclusions may be drawn: Two similar parallel magnets, like those in the upper part, ending in the same pole and yoke-piece, are not to be recommended as there is considerable leakage between them. When the general form of the magnets for a dynamo is that of a simple U magnet, it should if possible be symmetrical magnetically as in an ordinary horse-shoe magnet. The magnetism of that part of the lower magnet between the letter *n* and the yoke-piece, is in the opposite direction to that generated by the ampere-turns on this part, from which it appears that the magnetism from a certain number of ampere-turns on other parts of the magnet is consumed in first neutralizing that in this part and then reversing it; it appears from the strong north pole on the lower magnet that the economy in the magnetism from the ampere-turns is poor, the reason being apparently in the unsymmetrical distribution of the iron and coils. As most of the lines of force shown in the figure do not pass through the armature, they represent leakage or wasted magnetism.

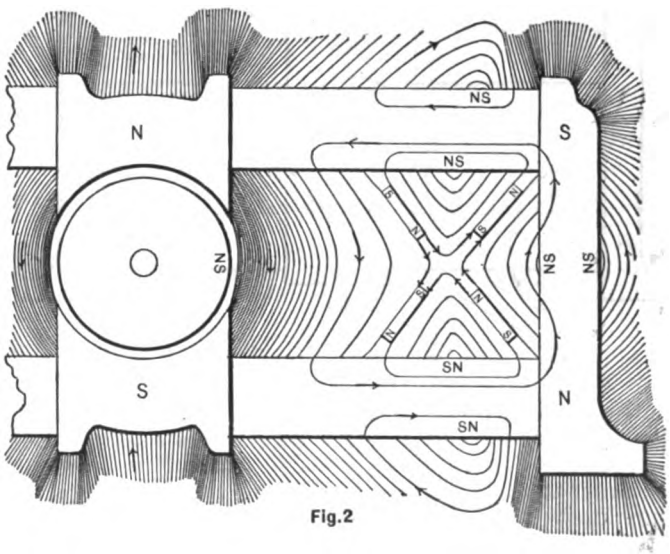

Fig.2

Figure 2 shows one-half of a normally proportioned Weston machine, the general type of frame being used also by numerous other makers. The field surrounding this frame appears to be quite symmetrical above and below, which in fact would naturally follow from the symmetrical distribution of the iron and the magnetizing coils. The two neutral points on the upper and lower surfaces of the same magnet were not directly above each other, that on the outside surface being nearer the yoke-piece. Both the upper and lower coils showed strong poles at each end. The yoke-piece has strong poles at its ends and neutral points in the middle. No portions of the coils have reversed magnetism in them, which is no doubt due to the symmetrical distribution of the magnetism. A point of "unstable magnetism" or of "magnetic deflection" was found in this machine also, differing from the one observed

Digitized by Google

in the Edison machine in the fact that the lines of force around it were symmetrically distributed. The general character of the field at such a point is more clearly shown in this machine. The upper and lower lines of force having opposite directions or opposite polarity, will, according to the laws of lines of force, attract each other, forming sharp curves at their nearest point; the same is true of the lines on the right and left hand sides of this point thus forming the four curves shown. The field at this point is similar to that produced by four bar magnets placed in the position shown, the opposite ones having like poles toward each other. It will be noticed that this point is bounded by four neutral points (one of which is in the armature) alternating with four poles, the successive neutral points and poles being alternately of opposite polarity, a neutral point being considered to be a point in the magnetic circuit around which the external lines of force are parallel to the axis, as described before. This is also true of that point in the Edison machine, only that the distribution is not as regular as in the Weston. In both these machines, and probably in all others having such U magnets with two coils, the complete iron circuit of the useful lines of force, beginning at one pole-piece thence successively through one magnet, the yoke-piece, the other magnet, the other pole-piece, and finally returning through the armature, includes four alternately opposite poles, separated by four neutral points of alternately opposite polarity, the polarity of the neutral points being indicated by N S or S N respectively. If the entire U magnet were made in the form of a circle wound over its whole length with coils, like a Faraday induction coil, and cut at one point for inserting the armature as in the Sir Wm. Thomson and the Mather machines, it is possible that this succession of poles and, therefore, also the point of magnetic deflection, would disappear.

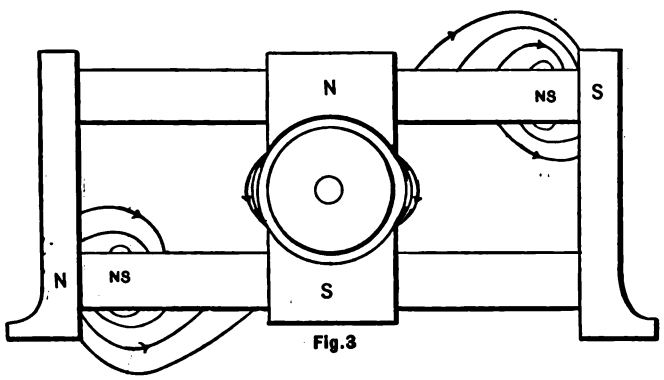

Fig.3

Figure 3 shows a Sprague motor in which two neutral points were found near the far ends of two alternate coils, while none appeared to exist on the other coils. Unfavorable circumstances prevented the further examination of this machine, but it is quite probable that it would prove to be similar to the Edison machine in figure 1, as there appeared to be two series-wound coils on two alternate magnets, and two shunt coils on the other two, which, unless the ampere-turns were equal in both, would cause unequal distribution of magnetism; the location of the two neutral points, as shown, indicates that this may have been the case with this particular machine while it was being examined. The unsymmetrical distribution is probably intentional in this machine, to accomplish certain results.

Figure 4 shows the results obtained from a Van Depoele machine, the frame of which is of an entirely different class from those already shown. Only one-half is shown here; the coils surround the large massive cores which terminate each in one pole-piece. On the upper and lower side of the frame are two flat pieces which were presumably intended for yoke pieces to magnetically connect the south pole at the right hand end of the one core with the north pole at the other end of the other core. The exploration of the field, however, indicates that it performs the entirely different and very objectionable function of magnetically shunting the armature by inducing the otherwise useful lines of force to leave the edge of the north pole-piece and return through this intended yoke-piece to the south or right hand end of the magnet, thus acting as a superfluous and objectionable yoke-piece to the two ends of the same magnet; the lines of force which should pass through the armature are therefore shunted off to one side. Furthermore, that portion of this flat piece which lies directly above the two pole-piece projections marked S and N, appears to short circuit, magnetically, these two pole pieces, or in other words, it magnetically shunts the armature, as a portion of the lines of force which should pass through the armature are led off around it and are, therefore, wasted. If this is as it appears to be, it might be better to omit these pieces altogether or to make them of some diamagnetic material.

The strongest leakage appears at the two pole-piece projections, the leakage being into the intended yoke-piece. This leakage extends along the side of the coil, nearly to the neutral point N S, which is near the farther end. The yoke-piece also exhibits a neutral point nearly above the one in the magnet and of the same polarity. As might be supposed, there is very intense leakage from the ends of the machine, the right hand end in the figure being a very strong south pole. But the leakage at this place does not

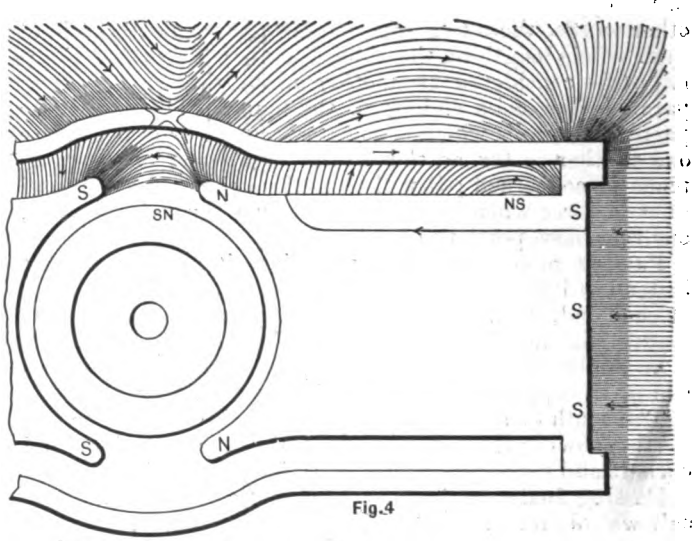

Fig.4

necessarily represent wasted magnetism, as most of the lines of force which escape here no doubt pass through the armature after passing through the core of the magnet, and are therefore not wasted; their return course, however, is to a great extent through the air, thus making open circuit magnets as distinguished from closed circuit or iron-clad magnets in which the lines pass through iron along their whole course, and as the magnetic resistance of air is much greater than that of iron (according to Kapp 720 times that of iron) the magnetism must be weakened considerably in passing through so much air in its return circuit.

A peculiar field was noticed outside of the yoke-piece almost directly above the middle of the machine. In moving the exploring needle horizontally at this place it suddenly made an abrupt turn of about 90° and over, indicating a sharp turn of the lines of force at this point. Further examinations indicated that the lines of force had the direction as shown at this point, which can readily be explained on the assumption that there exists in the iron of the yoke-piece directly below these sharp curves, a point of deflection of magnetism or point of unstable magnetism as it was termed above, which has been indicated in the figure by four short curves. Not only do the lines of force all around this point indicate its presence, but in a very similar machine (figure 7) the same point was shown

Digitized by Google

to exist in nearly the same relative position, being in this case in the air instead of in the iron, and its existence could therefore be determined definitely. If lines of force form closed circuits in themselves it is probable that those which are deflected downward to this point without entering the iron, are the return circuits of those which leak out at the two ends of the machine.

The field around the Thomson-Houston machine, shown in figures 5, 6 and 7, proved to be one of the most interesting, some of the curves being of a very peculiar nature. The magnetism was so intense in several places and the lines made such sharp turns that the exploring needle was repeatedly reversed in polarity during the examination, thus giving absurd results. It was not until the needle was repeatedly tested for polarity, and all results obtained with a reversed needle discarded, that any conclusive results could be obtained. The test was furthermore rendered difficult at first by the fact that the direction of the lines of force could not be tested in one plane only as in the other machines, as they curved around in different planes in such a way as to make it difficult to represent their courses on the plane of the drawing. In order to be sure that the results were correct the writer recently repeated the tests very carefully on a new 30-light arc machine, and obtained the results shown in the figures, which are believed to be substantially correct.

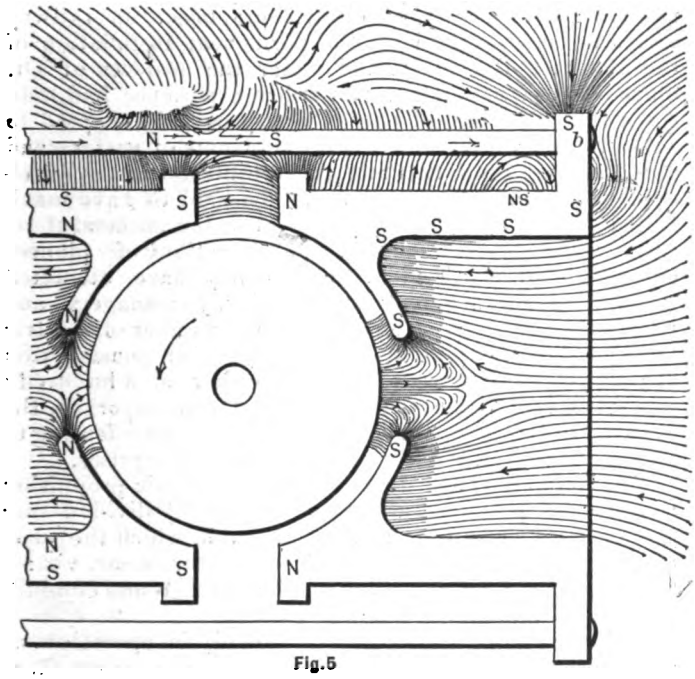

Fig.5

Figure 5 shows more than half of the vertical cross-section through the centre, taken perpendicularly to the shaft. The coils are wound around the large, hollow cast-iron cores which terminate at the armature and at the ends of the machine, one of which is shown complete. There is a round opening in the thin shell which embraces the right and left hand sides of the armature. The intended yoke-piece consists of a series of horizontal, round, wrought-iron bars, two of which are shown, one above and the other below the armature. It is, therefore, similar in general outline to the Van Depoele machine in figure 4, and the results should therefore agree to a certain extent with those shown in figure 4, which was found to be the case. As in the Van Depoele, there was a very strong leakage from the magnets to the yoke-piece, especially at and near the ends of the pole pieces, showing that many lines of force were magnetically shunted around the armature, and were therefore wasted. A neutral point was found near the right hand end of the core as shown. Immediately above the bars of the yoke-piece a strong field existed which showed the same polarity as that between the yoke and pole-piece, as indicated by the arrows, showing that these yoke-pieces had two strong poles one above each of the pole pieces, but of opposite polarity to the latter. Immediately above this field and represented by an open space, the needle exhibited that peculiar state of unstability, indicating a point of deflection, while above this space it again had a definite and decided direction. In this space, left blank on the figure, the lines were found to be perpendicular to the plane of the drawing, as is shown more clearly in figure 6, which is

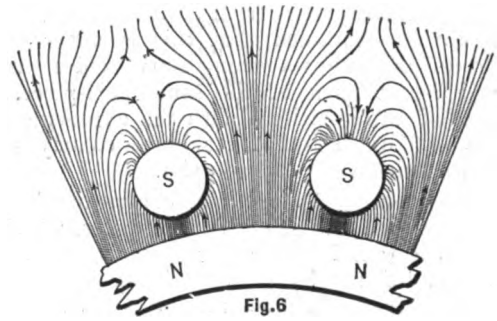

Fig.6

an enlarged vertical cross-section taken through the north pole-piece perpendicular to the bars of the yoke-piece. As shown in this figure the lines passed from the pole-piece into the yoke-piece on all sides, while the others from the pole-piece pass out into the air between the bars, thus forming above the bars at about the relative distance shown, a point of deflection having four poles, similar to that in the Edison and Weston machines.

Referring again to figure 5 a peculiar deflection of the lines was noticed almost directly above the south pole-piece, which was somewhat similar to that observed in the Van Depoele machine. It is possible that this was due to another point of deflection existing in the iron, as indicated in figure 5, with four or possibly six poles, but these curves in the iron itself are probable conjectures only. A similar deflection was noticed a few inches to the left of this point.

In moving the exploring needle vertically above the north pole-piece, it was found to turn abruptly through almost 180° a few inches above the yoke-piece, as shown by the arrows, while nearly above this there was a deflection similar to that in figure 4. This was found to be due to a point of deflection existing between the bars but above them, and is shown more clearly in figure 7, which

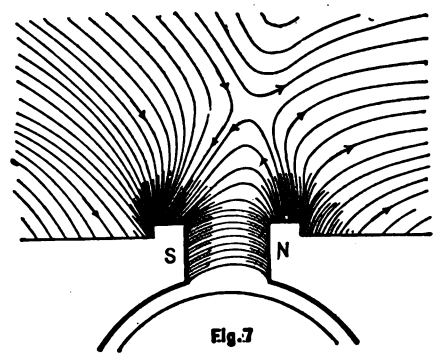

Fig.7

represents a portion of a section like figure 5, but between the bars. This point was clearly indicated by the needle, and assists in connection with figures 5 and 6, in explaining some of the peculiar curves noticed above that part of the yoke-piece which lies above the pole pieces in figure 5.

At the right hand end of the core the usual strong pole was found. A peculiar curving of the lines was noticed at *b*, where the rounded projections of the wrought-iron bars passed through the flanges. A possible explanation of this is, that the cast-iron flange is over-saturated to a greater extent than this projection of the wrought-iron bar, which, therefore, attracts the lines.

Following the surface of the core to the inside or hollow

Digitized by Google

portion, a weak south pole was found to exist on the cylindrical surface, while on the interior flange embracing the armature, the south pole was found to be very strong, the lines from it passing out through the open end. By placing a small needle very near the revolving armature and in the opening in the iron, it was found that many of the lines from this south pole entered the armature. From the general principles underlying all other dynamos, it would be supposed that the polarity of the pole-piece embracing the right hand half of the armature, was the same in all parts, but it appears from the external lines of force which could be examined, that this is not the case with this machine as there is a strong north and a strong south pole on different parts of the same pole-piece. Careful and repeated examinations with the exploring needle on the same and on different machines clearly shows this peculiar disposition of poles to exist.

Near the opening through the centre of the core, was another point of deflection with four poles, which in some machines was found to be very near the armature, as shown on the left hand side, while in others it was located several inches from the armature as shown on the right hand side. The lines of force at this point were very intense, and their curved directions were very decided, for this reason it was found that a very short needle had to be used and that it had to be moved about very slowly to prevent it from having its polarity reversed before it could respond to the change of direction. By moving the needle rapidly from the armature through this point of deflection, its polarity can readily be reversed, and it will then point in the same direction as it did before passing the point, thus making it appear as if there was no point of deflection. Moving the needle toward the armature will not reverse it so readily as these curves are less abrupt.

The lines of force at this point appear to oscillate very rapidly, which is probably due to the pulsating character of the magnetizing current. If, therefore, a small induction coil in the form of a simple coil of copper wire, be held concentric with this opening in the core and near to it, an alternating current would no doubt be induced in it. A telephone in series with this coil will indicate the presence of such alternating currents by a buzzing sound, the note emitted being apparently dependent on the speed and number of coils of the armature.

It is quite probable that the curves shown in all these figures would change very much with different degrees of saturation. A careful study of the curves of each machine at regularly increasing degrees of saturation, might lead to a determination of the best proportions and shapes of the iron parts.

Figures 4 and 5 are good illustrations of how not to proportion the parts when the best economy of magnetization is desired. At the same time it must not be forgotten that the energy used to excite the magnetism is for the best machines only a few per cent. of the whole output, and that, therefore, any improvements in the frame that would economize magnetism would only lessen this already small fraction, and possibly in some cases economize material. Other conditions may be of so much more importance as to make an increase in the economy of magnetism of little significance in comparison. The fact that the Thomson-Houston machines are used in such large numbers, shows that great economy of magnetism is not one of the most important points about a machine.

It is often represented as a good feature of a machine that its magnets are very powerful and will hold very heavy weights; a little consideration, however, will show that such external magnetism, especially when at the pole pieces, represents leakage and waste, and, therefore, is an objectionable feature. It would be much more creditable to a designer of a machine to be able to show that when running with its full load the magnets will not even attract a small bunch of keys, all the magnetism being diverted into the armature where it is wanted.

From the nature of the fields surrounding a dynamo, as shown in the figures, the following general deductions may be made. That machines exhibit the following magnetic properties: Free north and south poles, neutral points of two different polarities, and points of deflection; the latter exist in the external fields but may possibly exist also in the iron itself; they generally appear as four curvatures of the lines of force towards and receding from one point, and are in that case enclosed by four free poles and four neutral points of alternately opposite polarity. That the lines of force in and around a magnet appear to have the following properties: Like lines repel, unlike lines attract each other; they never intersect; they appear to form circuits or paths closed in themselves and surrounding the current generating them; when not prevented by other forces they take the shortest distance between the iron parts. The illustrations of these statements in the special cases shown, is not offered as a proof of their correctness in all cases, they are given here only as general guides in exploring and plotting such fields.

OVERHEAD CONDUCTORS FOR ELECTRIC RAILWAYS.

Although some five years have elapsed since the commercial practicability of electric propulsion for railway cars was demonstrated by the permanent installation of the Portrush line in Ireland under the auspices of Dr. Siemens, yet it was not until further experience had indicated that this form of energy was peculiarly adapted to fulfill the somewhat exacting requirements of surface and street railway lines, that any general interest in the development of electric locomotion can be said to have manifested itself. More recently, however, the successful results which have attended the operation of pioneer enterprises of the kind in this country have attracted general attention among street railway managers and projectors; so much so indeed that the number of electric lines projected, chartered or actually under construction at the present time can fall but little short of a hundred; in fact a late issue of our esteemed contemporary, the *Street Railway Journal*, contained news items referring to no less than 50 different electric railway enterprises.

The methods or so-called systems of electric propulsion thus far in practical use, may be roughly divided into three classes, according to the manner in which the electric current is supplied to the electro motor or car, viz.:—the overhead or aerial conductor, the underground conduit, and the accumulator or storage battery.

Of the electric street railways already in operation, as well as those under construction, by far the larger share appear from the published statements to derive the electric power from an overhead conductor, erected and supported in much the same manner as an ordinary telegraph or electric light line. Each locomotor is provided with a contact device, called a "trolley" or "traveler," supported and running freely upon the overhead wire, and connected with the vehicle by means of a flexible conductor, which serves the two-fold purpose of conveying the electric current from the constantly charged conductor to the motor, and of pulling the trolley along the conductor as the vehicle moves forward upon the railway. This simple and effective device is quite inexpensive in first cost, and has been found to operate admirably, at least in all cases where the maximum rate of travel does not exceed 15 to 18 miles per hour, a speed which is quite sufficient to meet the requirements of ordinary suburban and street railway traffic.

The original conception of this method of supplying electricity to moving vehicles appears to date back at least as far as 1878, in which year Dr. Joseph R. Finney, a dentist then residing in Pittsburg, Pa., who had occupied

Digitized by Google

himself considerably with electrical investigations, invented a system of telegraphy designed to place moving railway trains in communication with the stations along the line, a problem which has since been worked out with great success, although in an entirely different way, by L. J. Phelps and others. Dr. Finney's railway telegraph of 1879 is illustrated in figure 1, in which A represents a car running upon a track, B; C is an electric conductor supported at the necessary intervals by posts, of which one is shown at D, provided with a horizontal arm, *d*. A yielding spring arm or bracket, C, which is curved as shown, grasps and sustains the conductor at its outer end, and is secured at its inner end, by means of insulators, *c'*, to the horizontal arm *d*.

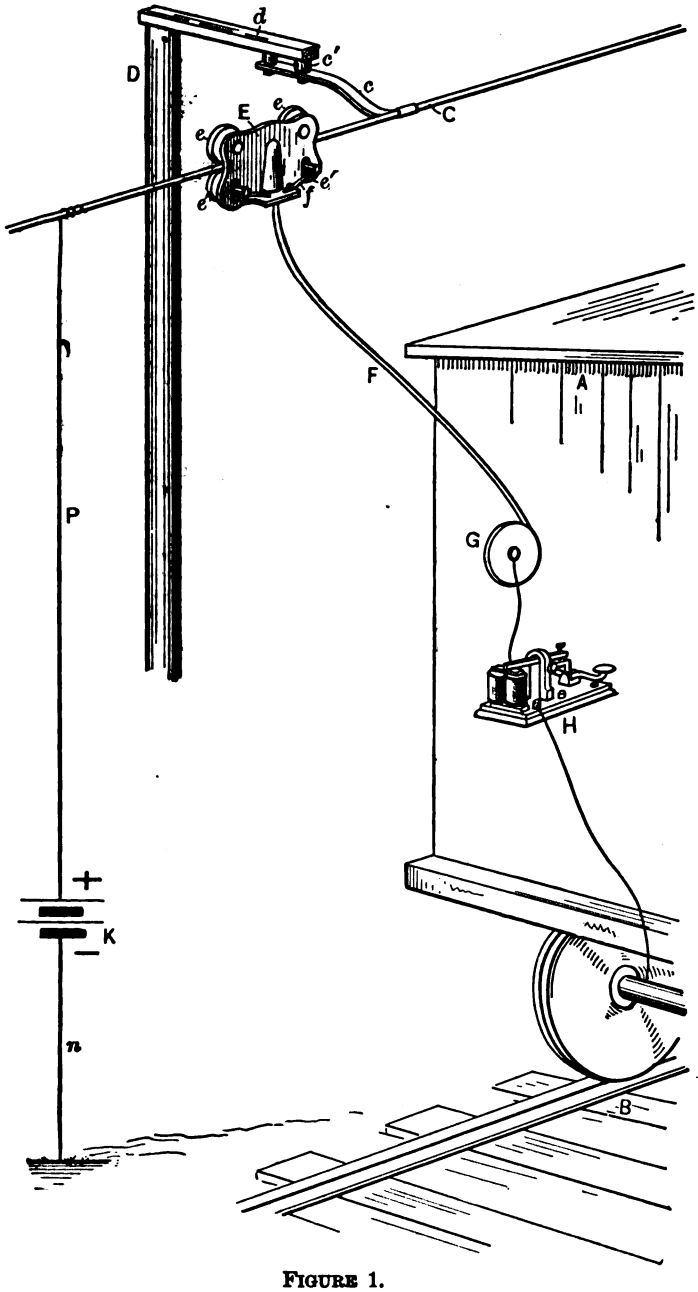

FIGURE 1.

The trolley or traveler consists of a metal frame, E, in the upper part of which are mounted two grooved or flanged wheels, *e*, *e*, adapted to run on the upper surface of the conductor C. In the same frame, directly underneath these, are two more similar grooved wheels, *e'*, *e'*, mounted in yielding or spring bearings, *f*, *f*. The effect of this arrangement is to cause the conductor C to be grasped firmly between the upper and lower sets of wheels, while at the same time the whole arrangement is left entirely free to move horizontally along the conductor, and to yield sufficiently to pass without difficulty the enlargements of the conductor C at its points of support. A generator of electricity, K, is connected to one terminal of the conductor C, in the manner diagramatically shown in the figure; that is to say the wire *p* connects the positive pole of the generator with the line conductor C, and the wire *n* connects the other pole with the earth. F is a flexible conductor, one end of which is attached mechanically and electrically by a pivot joint to the frame E of the trolley, while its other extremity is in electrical connection with an ordinary telegraphic apparatus, H, on board the car, and thence with the earth through the wheels and axles of the car and the rails of the track, B.

As in many cases it would not be practicable to carry the suspended conductor C at a uniform distance from the track, Dr. Finney provided a take-up device, G, consisting of a hollow spool having a coiled spring within it, upon which is wound a considerable length of the flexible conductor F. The spring keeps the connecting wire taut, but permits it, when required, to be drawn out to provide for any increase in distance between the track and the suspended conductor. The operation of receiving and sending telegraphic messages needs no detailed explanation, the novelty of the apparatus consisting for the most part in the devices whereby a continuous electric connection is maintained between the moving vehicle and a conducting wire extending approximately parallel to the track. This invention is of especial interest for the reason that it contains the essential principles of the most successful devices which have been employed for a similar purpose in the electric railway service, that is to say, the line wire, the trolley running thereupon, in such manner as to be *held in contact therewith by the pull of the car*, the electrical apparatus on board the car, and the take-up device for varying the length of the connecting conductor.[1]

The adaptation of this organization to the propulsion of street cars and like vehicles was but a short step in advance. Dr. Finney at once turned his attention in that direction; and, subsequently, having procured the necessary facilities, he filed an application for a patent on Feb. 15th, 1882.[2] In order to demonstrate to the public the feasibility of his invention, he fitted up an ordinary street car which was placed upon a track in Pittsburg, Pa., and successfully operated for some time early in the summer of 1882, in an experimental way. The general plan of the apparatus employed by Dr. Finney in this demonstration was similar to that of his railway telegraph, the essential difference consisting in the substitution for the telegraphic apparatus of an electric motor, properly geared to the axle of the car. He also introduced a number of subsidiary devices of more or less importance, among which may be mentioned an adjustable resistance, for decreasing the strength of current when the motor is running slowly, and a device for enabling one overhead conductor to cross another at an angle without interfering with the proper operation of the trollies. In his specification he describes the method of lighting the car by the same current that is employed to propel it, now in quite general use. He also sets forth the application of an independent motor to each car of a train, all of which are supplied with current from a single trolley and connecting conductor.

The following contemporary account of the above-mentioned experiment is extracted from the *Pittsburg Post* of August 21, 1882:

"The days of the street car horse are numbered."

This was a remark of a prominent iron manufacturer as he sat in a car propelled by an electric motor over a roughly built track in the yard adjoining the Union Line stable on Saturday evening last. What is more, his remark was apparently fully justified by what he saw and experienced. By a slight pressure on the contact lever the insignificant looking dynamo machine began to sparkle, and in an instant the little fly wheel was spin-

1. *Vide* Finney's U. S. patent, No. 281,552, of Aug. 24, 1880; and re-issue of same No. 10,232, Nov. 9, 1882.

2. U. S. patent No. 285,353, of Sept. 18, 1883.

Digitized by Google

ning around at the rate of 1,500 revolutions per minute. A gentle pull on the lever attached to the clutches set in motion the gearing connecting the motor with the car tracks, and away it went as steadily as though drawn by a pair of strong horses. To stop it required but the touch of a lever, and to reverse its motion it was only necessary to move the same lever to the opposite side of the short rack. Back and forth it went over the track until all were satisfied that the gentleman was about right when he said: "The days of the street car horse are numbered."

Dr. J. R. Finney, of Sixth avenue, the inventor of a number of very useful attachments to electric motors, some of which are of the most vital importance to the successful application of electric power to railways, had charge of the experiments. Some time since a similar machine was tried at the stables of the Citizen's Line, but the engine used to drive the dynamo machine, or generator, was not strong enough, yet the results were such as to convince those present that a fair trial was all that was necessary to sustain the inventor in all his claims.

An old style Citizen's Line car, weighing 6,000 pounds, which is nearly a ton heavier than the ones now in use, was fitted up for the experiment. This fitting up consisted mainly in tearing up enough of the floor to expose both axles of the trucks. The electro-motor is suspended below the level of the floor by a truss attachment to the truck. The only machinery in addition to a simple dynamo machine, rated at one and one-half h. p., is a series of gear wheels by which the car wheels are made to revolve once to 30 revolutions of the motor, which propels the car at the rate of 10 miles an hour.

The motor used is one of the Weston electric light machines manufactured at Newark, N. J., and is rated at one and one-half h. p. The machine was designed and built for the purpose of generating electricity, but in this case it is used to transform the electrical power into motion, and instead of sending out a current one is sent into it. Thus one machine is made to convert motion into electrical power which may be conveyed on conductors for miles and converted back into motion by another machine which is a perfect duplicate of the machine which produced the power. In this case the electricity is produced by a dynamo-electrical machine located in the Pittsburg Locomotive Works, and is conveyed on a wire suspended a short distance above the car on brackets attached to arms extending from posts set at the side of the track.

The current is led from this conductor to the motor by a contact traveler, consisting of a grooved pulley held loosely on the conductor by another pulley on the under side. The current is grounded through the wheels and rails, the latter having a continuous connection in order to make a more perfect ground. The traveler is drawn along the wire conductor by the car, and the pulleys are so adjusted that they pass over the brackets without breaking the contact, furnishing a constant and steady supply of electric power to the machine which it transforms into motion just as the old fashioned mill wheel converts the weight of water into motion and transmits it through the proper gearing to the burrs, which in turn converts wheat and corn into flour and meal. The entire machine could be placed in a medium sized shoe box, and does not exceed 300 pounds in weight.

While Dr. Finney had been prosecuting his experiments in this country, Dr. Siemens had evolved a similar system in Germany, the first published description of which is found in a German patent, October 13th, 1880;[3] it is also vaguely alluded to in one of his British patents,[4] and was crudely illustrated in various technical publications in the summer of 1881.[5] During the electrical exhibition of the same year in Paris, an electric railway embodying the principle was successfully installed and operated by Siemens, which transported a large number of passengers. Full descriptions of this railway were published in the technical periodicals of the time, but as we have seen, the essential principles of the Siemens plan of construction had already been anticipated in Finney's patent of August 24, 1880, and in the subsequent experiments of the same inventor.

In the meantime, however, another American inventor had appeared in the field, Eugene H. Cowles, of Cleveland, Ohio, who received a patent upon an application filed June 27th, 1881, for a system of electric propulsion,[6] essentially the same in its principle as that of Dr. Finney. Cowles' invention embraced the overhead suspended line wire, and a trolley consisting of two grooved wheels set in a frame, running on the upper surface of the line wire, and connected with the car by a flexible and longitudinally extensible conductor.

The records of the patent office show that an interference was subsequently declared, under the rules, between the application of Dr. Finney above referred to and the previously issued patent of Cowles, which ultimately resulted in a decision by the Examiner, June 25th, 1883, adjudging Finney to be the first and original inventor, and accordingly the fundamental patent was issued to him.[7]

Meanwhile Dr. Finney had succeeded in procuring sufficient pecuniary assistance to enable him to work out more completely some of the details of the invention. In 1882 he made some important improvements in the construction of the trolley, one of which consisted in constructing the wheels with broad radial flanges forming a deep groove as shown in figure 2, thus dispensing with the necessity of another wheel below the conductor. In connection with this change in the form of the wheel, the supporting bracket was made of a U-shape so as to support the conductor from beneath without interfering with the passage of the wheels. At the same time a modified form of take-up mechanism was devised, consisting of a spiral spring coiled around a rigid rod, as shown in the figure, a device not only more simple and cheap than the spool and coiled spring, but equally effective in cases where too great a variation in the length of the connecting conductor is not required.[8] These improvements, although matters of detail, were nevertheless quite important in a practical sense, as the proper movement of the trolley, as well as its constant and uninterrupted contact with the conductor, are essential to the satisfactory performance of the apparatus in actual service.

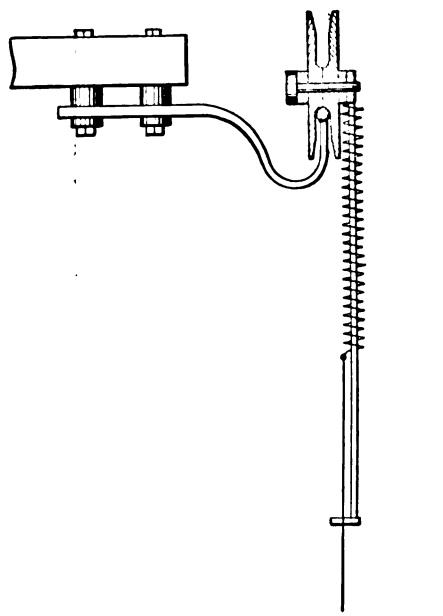

FIGURE 2.

Having thus worked out the application of this system to street railway service, Dr. Finney conceived that it might be applied with equal advantage to ordinary vehicles, running upon such pavements or roadways as are ordinarily found in the streets of cities and towns. In order to do this, it becomes necessary to employ two independent overhead conductors, placed at a uniform distance apart upon the same set of supports. Upon this double line, as upon an aerial railway, runs a four-wheeled trolley with deeply grooved wheels, the two wheels running on one line being properly insulated from the two running on the other line, the whole being united by means

of a flexible double conductor with an electric motor geared to the rear wheels of the carriage. The front wheels are provided with a steering mechanism, resembling in principle the well-known device employed upon hook-and-ladder trucks. Dr. Finney proposed to extend a pair of conductors along each side of a street or thoroughfare, so that the driver of a vehicle, desiring to proceed in one direction or the other, would only need to connect his vehicle to the wire of the trolley upon the appropriate pair of conductors, and then by means of a switch on the carriage admit the electric current to the motor.[9]

Although this application of electric traction may appear at first sight to be a somewhat visionary one, yet a careful consideration of the matter will tend to show that such is by no means the case. Nothing is more probable than that the general use of electricity for the propulsion of street cars will be followed at no distant day by its application to the movement of ordinary vehicles upon much traveled roads or streets.

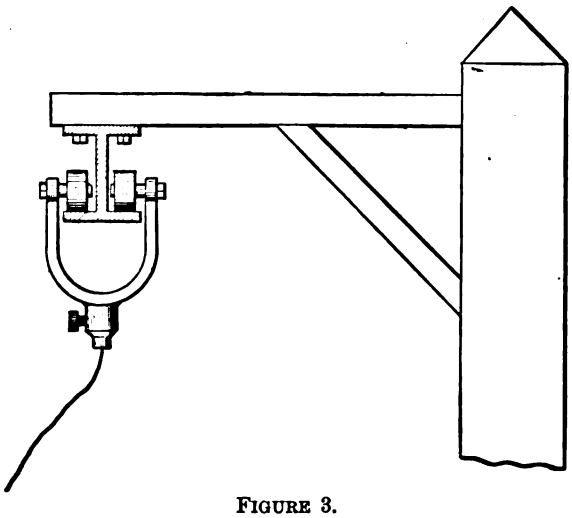

FIGURE 3.

Another modification in the arrangement of the overhead conductor, invented in 1882, is illustrated in figures 3 and 4. This is adapted for a more permanent structure, or for a line on which a very heavy traffic is to be provided for. It is also well adapted for use in mines, tunnels and similar situations. The conducting bar or strip of I-form, is bolted by its upper flange to suitable supports. The traveling contact runs on the lower flanges of the bar. The conductor may if preferred be made in two parts separated by an insulating strip, as shown in figure 4, in which case the earth need not be employed as a conductor.[10] One advantage of this construction is that the cars may be run at very high rate of speed without danger of derailing the trolley.

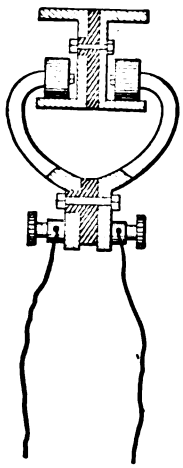

FIGURE 4.

An experimental electric railway was put up in Chicago, in February, 1883, by Charles J. Van Depoele, in which the conductor was laid between the rails and underneath the cars, the object being more particularly to test the efficiency of electric transmission from the stationary dynamo to the motor on the car, and so far as it went the demonstration appears to have been a very satisfactory one. At the Chicago Inter-State Fair in September, 1883, Van Depoele had a full-sized electric railway plant in operation, and carrying passengers, in which the positive and negative conductors were placed above the car, the latter being provided with brass contact-rollers so mounted as to press upwards against the under side of the conductors. In July, 1884, the same inventor exhibited an electric railway at Toronto, Ontario, 3,000 feet in length, making use of a conduit system below the track. The following year, 1885, a line one mile in length was fitted up by him in connection with the Toronto Industrial Exhibition, connecting the city street-car line with the exposition grounds. In this plant an overhead wire was employed, and the car was provided with a contact wheel carried on the end of a pivoted beam above the roof, which was fitted with a spring for pressing the wheel against the under side of the conductor. This car commenced running regularly on the 5th of September, and continued to do so during the period of the exposition, carrying a very large number of passengers. It is not necessary in the present case, to describe the details of this apparatus, which can be learned by those interested by consulting Mr. Van Depoele's patents.[11] One of these patents contains some novel and important details which deserves attention in connection with the suspension of overhead conductors at curves and angles, as for instance, in passing round the corner of a city block.[12] In the electric railways which have been successfully installed by the Van Depoele Electric Manufacturing Company at Montgomery, Ala.; Detroit and Port Huron, Mich.; Appleton, Wis., and Scranton, Penn., a trolley is employed running upon the top of the conductor and held in contact therewith by the pull of an extensible connecting cord, as in Finney's railway telegraph of 1878. The same system is used in the electric freight railway at East Boston, Mass., constructed by the Sprague Electric Railway and Motor Company, and in the Los Angeles, Cal., electric railway, and other lines constructed by the Daft Electric Light Company of New York.

The general adoption by the successful electric lines of the Finney apparatus, would seem to indicate that it has been found better adapted than most others to the conditions which are to be met with in actual work. The unrivaled economy, both in construction and operation, of the overhead conductor system, and its perfect adaptation to all the requirements of surface traction at a moderate rate of speed, are considerations which will more and more recommend it for that particular service, as its advantages are developed by experience.

ELECTRICAL DISTRIBUTION BY ALTERNATING CURRENTS AND TRANSFORMERS.[1]

BY RANKIN KENNEDY.

(Concluded from page 262.)

TRANSFORMERS.—(CONTINUED.)

A VERY simple and most convenient form of transformer employed by me in some experiments in 1885, consists of a laminated Siemens shuttle-wound armature, s, in figure 15, half size. On this was wound 40 turns of No. 12 wire as a secondary, *c*, *d*, and over this 800 turns No. 24 silk covered wire as a primary, *a*, *b*, the length of the armature being about six inches. This form gives very good results for self-regulation and economy, and I use it generally for distribution purposes for small installations, say up to one or one and one-half horse power.

The outer sheathing may be of iron wire or of iron discs, and should be made so that the armature may be withdrawn for repairs.

Figure 16 shows the construction of the large transformers employed by me to raise the pressure of the electric energy at the generating station; it is built up entirely of hoop iron and bound together by bolts as shown. The primary coils and the secondary coils are wound on a

1. From the *Electrical Review* (London).

Digitized by Google

mould and then slipped on; the thick wire, which is in this case the primary, being first put on, and the secondary or fine wire slipped over it; finally, the strips of iron are

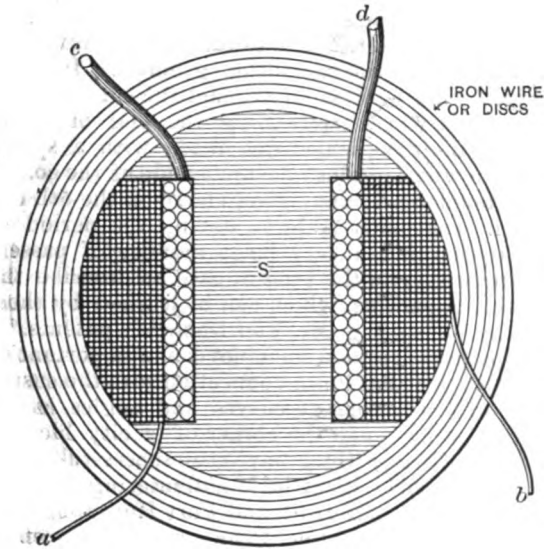

Fig. 15

placed on the ends and this closes the magnetic circuit. The lamination and ventilation in this form are very perfect.

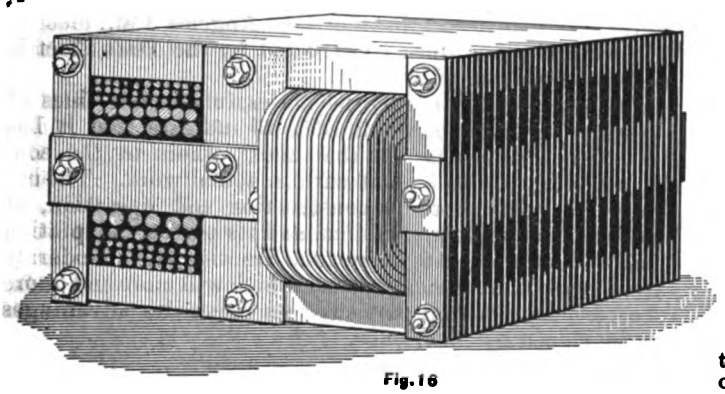

Fig. 16

The Ferranti transformers, figure 17, end view, and figure 18, side elevation partly in section, are also built entirely of hoop iron. The hoops are laid out in four bundles,

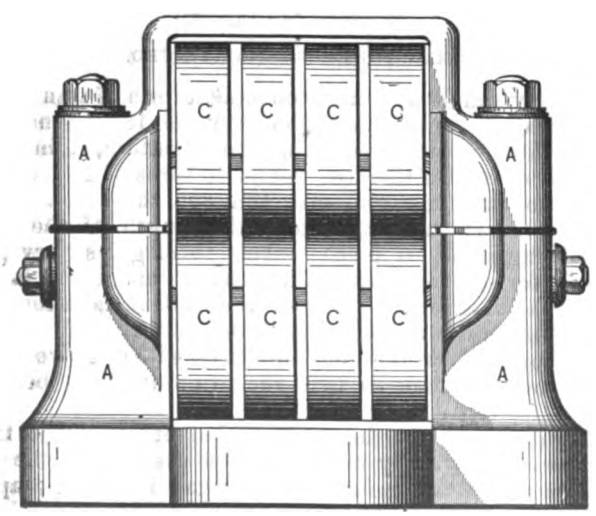

Fig. 17

C, C, C, C, figure 17, straight and close together; the thick secondary wire, D, D, figure 18, is wound on over the middle portion of the bundles of hoop iron, and over this thick wire the fine primary wire is slipped in sections which have been previously wound on a mould. The hoop iron bundles are then divided at X, X, figure 18, into halves, one-half bending up over the top and the other bending down under the bottom, thus closing the magnetic circuit; finally, the whole is enclosed in a cast iron shell A, A. The lamination in this construction is hardly perfect as the flat side of the iron is presented to the penetration of the lines of force, but altogether it is a very practicable construction.

There are many other forms of transformers, but as they are all similar in principle and are merely simple modifications of the leading types herein described, they are not of sufficient interest to occupy space here.

In America, the parallel system and the closed magnetic circuit transformer have been introduced by the Sun Elec-

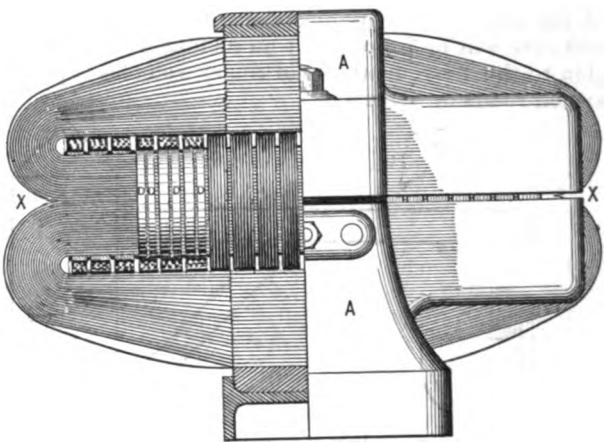

Fig. 18

tric Co., of Woburn, Mass., under the name of "Mr. Slattery's system," and also by the Westinghouse company, of Pittsburg.

Slattery's system embraces a simple ring converter the same as my 1883 converter.

The Westinghouse company have obtained the patent of Gaulard and Gibbs in America, the claims in which I give here complete.

1. The hereinbefore-described art or method of electrical distribution and conversion, which consists in establishing in a closed electric circuit, a current of alternate and equal positive and negative potential, producing by the influence of such current an inductive field of alternate polarity, and thereby inducing in translating devices situated in an independent closed circuit traversing such field, a similar alternating secondary current of greater quantity and less potential than the originating or producing current.

2. In a system of electrical distribution, an inductorium or converter in which the length of that portion of the conductor traversed by the primary current within the magnetic field created by itself, exceeds the length within the same field of the conductor traversed by the secondary current, in combination with a dynamo-electric generator producing alternating electric currents or pulsations of equal potential and duration, and translating devices actuated by said secondary current.

3. In a system of electrical distribution, an inductorium or converter, in which the resistance of that portion of the conductor traversed by the primary current within the magnetic field created by itself, exceeds the resistance of that portion of the conductor traversed by the secondary current which lies within said field, in combination with a dynamo-electric generator producing alternating currents or pulsations of equal potential and duration, and translating devices actuated by said secondary current.

4. In a system of electrical distribution, a dynamo-electric machine, organized for the production of alternate positive and negative currents, equal to each other in potential and duration, in combination with the primary circuit of an inductorium or converter organized to induce in its secondary circuit alternating currents of lower potential and greater quantity than those of the primary circuit, and one or more translating devices actuated by said secondary currents.

5. In a system of electrical distribution, the combination of an inductorium or converter, having its primary and secondary circuits constantly closed, a dynamo-electric generator for producing alternating currents of equal potential and duration included in said primary circuit, and one or more translating de-

Digitized by Google

vices included in said closed secondary circuit, substantially as set forth.

These claims construed into simple language mean simply that Gaulard and Gibbs claim to be the only true inventors of the parallel system of working potential transformers at constant E. M. F. in the mains. The patent is dated October, 1886.[2]

Judging from recent utterances in America, where the introduction of this system has created a somewhat amusing flutter among the electrical fraternity, the distinctions existing between the two systems, series and parallel, are not yet recognized, for the simple reason that the parallel system with the potential transformer has been bodily imported by them from Britain, in a complete and perfect form. The series system has never been tried in America, and therefore they have none of the failures attending attempts to work that system. The parallel system has been a great success, but it was just as great a success in Europe two years ago.

I shall not take up the consideration of the actions in the transformer. From a magnetic point of view they are exceedingly interesting, in fact the consideration of the magnetic effects and actions give us an entirely new and wider view of magnetism than can be obtained from the consideration of any other electro-magnetic instrument or machine. We shall also take note of the rapidly increasing practical applications of the transformer to purposes other than the distribution of electric lighting.

The numbers of modifications of the closed magnetic circuit is very great, in fact any form of dynamo armature makes a good transformer; thus, besides the forms already described, we can use a laminated drum armature of Siemens type with an outer iron sheathing, or better still, an armature of the same type with projecting teeth, such as the Weston armature, with an outer iron wire, or plate, sheathing, and thus form a subdivided transformer. Pole armatures of the old Lontin type may be also used with success when properly laminated with an outer sheathing, as in figure 19. The two conductors are wound on the

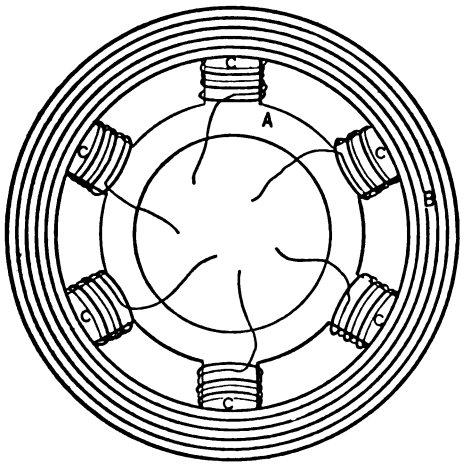

Fig. 19

poles as shown; A is an end view of the laminated iron core with C, C, C, C, and B is the iron sheathing. All these modifications are equally efficient and perfect self-regulators, and the only question to be decided by the maker is which form is the cheapest to manufacture; the question for the intending buyer of transformers is which form is the easiest to keep in repair and cheapest in first cost.

Enough has been said about the construction of transformers to show that it is one of the simplest pieces of electro-magnetic apparatus imaginable. Simply, it consists of two insulated electric conductors combined with an iron magnetic conductor. The only room for improvement lay in this iron conductor, and the experience gained in dynamo building is all applicable in this direction.

We may now enquire into the practical rules for the construction of transformers. Hitherto no definite numerical rules have been published. Transformers have received most elaborate treatment in the hands of mathematicians, and a vast array of formulæ could be here introduced with a view to elucidate the theory of the construction, but I don't think that would be of any use to practical electrical engineers. In this place I am persuaded that a few simple rules within the capacity of any intelligent workman will be much more useful.

In making a transformer the first question is, of course, what form of iron magnetic circuit is it to have? The choice lies between the Zipernowski type or the subdivided type, as these have by far the lowest magnetic resistance and can be perfectly laminated, being equally efficient and self-regulating. The choice must be decided on the score of practical convenience for repairs and ease of manufacture. After deciding upon the best form of iron organ for the transformer, the most important question next, is what length of wire shall be required for primary and secondary conductors? Upon these lengths depend the most important function of self-regulation and economy in the transformer.

The length must be found for self-regulation according to the laws—

1. When no work is being done in the secondary circuit there should be no current in the primary circuit—that is, the counter pressure in the primary must be equal to the primary pressure, or very nearly equal thereto.

2. As the current increases in the secondary circuit the current in the primary should increase proportionally in the ratio of the transformer—that is, the counter pressure in the primary should fall as work is increased in the secondary.

Here I may observe that there is an impression abroad that the mere employment of the fine wire as primary and the thick as secondary in an induction coil was a great invention made only recently, I am certain that this has been tried by innumerable experimenters during the past 20 years.

To be of any use the wires must be wound to satisfy the laws, irrespective of their thickness or thinness, and then they must be employed in combination with main conductors at constant pressure, and if more than one is to be operated at one time they must be connected in parallel order, and they must be constructed accurately with a fixed ratio. All these imperative requirements are not stated, described or claimed in any one patent yet issued, and yet none of them can be neglected in a system of distribution by alternating currents and transformers.

As the rules for finding the correct lengths, and the reasons for them are obvious enough to those who could follow, I will simply state them as:—

Rule 1.—To find the lengths of the primary and secondary conductors in a transformer for reducing from a high to a low pressure, divide the primary pressure by the coefficient of induction in the primary circuit (that is, by the induction in volts per foot of wire), this will give the length in feet of wire for primary.

Rule 2.—Divide the secondary pressure by the coefficient of induction in volts per foot, this will give length in feet of wire for secondary.

In the best transformers working with about 200 alternations per second this coefficient is very high and averages about two volts per foot, and that may be taken as the figure for use in the above rules; for example:—

Given a primary pressure of 1,200 volts, and the required secondary pressure given as 80 volts, what lengths of primary and secondary wire should be employed? Answer, $\frac{1,200}{2} = 600$ feet for primary, $\frac{80}{2} = 40$ feet for secondary.

2. The specification and claims of Messrs. Gaulard and Gibbs's U. S. patent afford no basis for this statement. So far as we are aware, no claim has ever been put forth either by or in behalf of Gaulard and Gibbs, to the method of working in parallel at constant potential.—[Editor.]

Digitized by Google

These lengths do not include wire not under induction.

If the alternations are not so rapid this coefficient becomes less. It might be argued from this fact that as it is perfectly easy to make the alternations very much more rapid than 200 per second, that, say 500 or 1,000 alternations should be adopted. There is a limit to that; as the alternations increase in number per minute the losses in the transformer increase, and that fact often accounts for different efficiencies being found for the same transformer by different experimenters—the one, perhaps, has employed the alternations for which the transformer was calculated, the other has employed slower alternations, and therefore, no agreement could be come to. It is, therefore, necessary to ascertain by experiment the coefficient of induction for each type of transformer at a given alternation rate. In transformers with long magnetic circuits, common to all the coils of wire, the coefficient will not be higher than 1.5, and often falls as low as one foot per volt.

Practically this coefficient may be found by taking the given alternating pressure having the given rate of alternations through an approximately correct length of primary wire on the transformer, say a length calculated at two volts per foot (the secondary circuit being open or not yet wound on), and measuring the current produced through this length. If no measurable current is observable then that is the correct length; there should be some current, of course, say, perhaps, two per cent. of the maximum current. If the coefficient of induction is less than that calculated upon, a considerable current passes in the primary when no secondary current is flowing. The primary wire must, in that case, be increased in length until this initial current disappears, or becomes so small that it is of no account, and then the length of secondary can be calculated by the rule.

Rule 3.—The ratio of a transformer is found by dividing the primary pressure by the secondary pressure, thus in my previous example—

$$\frac{1,200}{80} = 15.$$

15 would be said to be the ratio of that transformer, and thus

	Primary.		Secondary.
The pressures are to each other as	15	to	1
The lengths of conductors to each other as	15	"	1
The cross-section of conductors to each other as	1	"	15
The currents to each other as	1	"	15

The iron conductor of magnetic force should not at any time be anywhere near half saturation; it should therefore have large cross sections, and data for calculating its size may be obtained from dynamo builders.

The application of these rules to transformers for *raising* the pressure is obvious, only I may point out that in this case the short thick wire is the primary, and the coefficient of induction must be found for it, and the lengths calculated from this coefficient. Of course the initial current allowable in the primary circuit may be comparatively large (the initial current is the current flowing in primary with no current in the secondary circuit), thus we may have in the transformer primary circuit, with full load on the secondary, 100 amperes at 100 volts pressure; while with no load in the secondary we may have only five amperes, or only five per cent. of initial current; of course, by increasing the length of the wire, we lower this initial current, but we also lower the coefficient of induction per foot of wire.

Those who wish to study the exact science of the subject should study Mascart and Joubert's work, Hopkinson and Ewing's publication, and the articles by Kapp, now appearing in *Industries*.

Its high efficiency, combined with great simplicity of construction, is bound to recommend the transformer for many applications not yet thought of; it must prove a powerful machine in the hands of electricians when they become better acquainted with it practically. The application of the transformer to electric welding is an example in point. I have recently employed a small transformer for multiplying or dividing the readings of an alternating voltmeter, and by this means I can employ any ordinary alternating current voltmeter, reading between, say, 10 volts and 120 volts, to measure alternating E. M. F. up to any pressure, say 5,000 volts.

A Cardew voltmeter combined with a transformer whose ratio is say 20 to 1 may be connected to the secondary conductor, or, more properly speaking, to the low pressure conductor; the pressure to be measured is connected to the high pressure conductors, then the readings of the voltmeter have only to be multiplied by the ratio 20 to give the exact pressure in the primary; if the voltmeter indicates 100, then the pressure is 2,000, and so on for any pressure. If we use a transformer having a ratio of 50 to 1, we can just as easily measure 5,000 volts. By this means it is possible to multiply extremely low E. M. F.'s and measure them on ordinary voltmeters. The ratio is constant enough for all practical measurements of alternating E. M. F.'s.

In conclusion, I may say that these notes on this interesting subject have not been very carefully arranged, and might have been extended to some advantage on some of the points, but the subject is already a large one, and requires the expenditure of valuable time in writing up even without any polishing.

I hope, however, to return to the subject, with the kind permission of the editors of the *Electrical Review*.

Something might be said about the dynamos, but there is really no new feature to notice about the later alternating dynamos; they are all old types built with the experience and knowledge obtained from continuous current dynamo evolution.

The rule being to make the magnetic field as powerful as possible and to shorten the length of wire in the armature as much as possible; as the field gets stronger and the armature wire shorter, so the dynamo improves.

PRACTICAL NOTES CONCERNING THE CONSTRUCTION, USE AND MANAGEMENT OF STORAGE BATTERIES.[1]

BY A. RECKENZAUN.

(Continued from page 266.)

ANALOGY BETWEEN HYDRAULIC AND ELECTRIC ACCUMULATORS.

Some 40 years ago the first hydraulic crane was erected on a quay at Newcastle, and this crane had to work with a constant head of water 200 feet high in order to produce a pressure of about 90 pounds per square inch upon the rams which moved the chains. To keep this pressure up, the water had to be pumped into a tank at the height indicated. It was some time after this, when Sir. W. Armstrong discovered that if water be pumped into a pipe or cylinder fitted with a movable plunger, and if that plunger be loaded with weights, the enclosed water was in exactly the same mechanical condition as if it were in communication with a reservoir many feet above it. In either case the water is under pressure, whether that condition is caused by a load of metal or a load of water. The vessel which stored the water has been called an accumulator, because it actually accumulated the power of the steam engine, and it returned that power at a constant rate whenever requisite. The pumps worked by the steam engine supply the accumulator with water as fast, or nearly as fast, as the same is consumed by the hydraulic rams. So long as there is any water at all within such a

1. From the *Electrical Review* (London).

Digitized by Google

cylinder containing a weighted plunger, there will be a constant pressure maintained. The stroke of the plunger, or the diameter of the cylinder, or, more correctly, the *capacity* of this hydraulic accumulator, had to be arranged in accordance with the supply and demand of water under pressure. If the demand is regular and the supply somewhat irregular, then this capacity must be large in proportion.

In the case of electric accumulators we have also to proportion the *capacity* according to the irregularity of the dynamo, or electric "pump," but that irregularity must be kept within very narrow limits; whereas the number of strokes of the water pump may for a few moments be reduced to an exceedingly low number; so long as the smallest quantity of fluid remains in the accumulator there will be a constant pressure due to the weight, whilst in the case of the storage battery a comparatively small reduction of speed on the part of the charging apparatus will cause a discharge of electricity from the accumulator into the generator. It is this great sensitiveness of the dynamo which renders the secondary battery statically unlike the hydraulic accumulator. When the supply ceases, the pressure of the hydraulic accumulator is practically constant until the last drop of water is squeezed out; with the battery, on the other hand, the pressure decreases considerably before the cells are entirely discharged.

CONSTRUCTIVE DETAILS.—THE FAURE BATTERY.

We come now to the most difficult, and at the same time, the most important part of our subject. The success or failure of a secondary battery depends upon minute and apparently unimportant details of construction. One could scarcely imagine a simpler apparatus than, for instance, an original "Faure" battery, which consisted of sheets of lead, the surfaces of which were covered with a thin paste of red lead and the whole rolled up with some cloth or felt to keep them apart. This thing worked admirably for a short time, and the invention was hailed with enthusiasm even by the highest scientific authorities when first introduced into this country. Hundreds of tons of this crude form of storage battery were manufactured when it was still in that immature, untried condition. Instead of commencing careful experiments and gradually developing the invention of M. Faure, people at once began to manufacture these cells wholesale, and it was only after thousands of pounds were spent, and after many months' fruitless endeavors, that the great defects in this form of storage battery were discovered. Its utility was found to be great, but it was far from perfect. We agreed with Dr. Lodge when he wrote a few years ago that some day it may perhaps be recognized, that because it can be shown that a thing will be extremely useful when perfect, it does not follow that it has already attained that perfection, that, indeed, probabilities based on historical developments are enormously against such abnormal and instantaneous maturity, and that the careful nursing and rearing necessary to healthy maturity are better given in the seclusion of laboratory and study than in the excited and heated atmosphere of the stock exchange.

It is doubtless recognized already that all preliminary operations are better conducted on a scale smaller than the wholesale manufacturing one. In developing a new industry there are scientific difficulties to overcome, and there are manufacturing difficulties. By scientific difficulties, we mean such as the determination of weak points, the best way of strengthening them, and generally the discovery of theoretically the best modes of effecting the object in view; the manufacturing difficulties begin with questions of expediency and economy—how most cheaply and satisfactorily to carry out the indications of theory, to obtain this or that material—and includes the organization of a system of manufacture, of division of labor, of machine tools, which shall enable the work to be done with economy, security and despatch. Over-haste in the preliminary stages caused both these sets of difficulties to be tackled together, and thereby threw a grievous burden on all concerned. All these untoward conditions have storage batteries experienced; and to say that they have not fulfilled the hopes of their early promoters, is no more than to say that those hopes were untimely and unreasonable.

The main difficulties which were found with the Faure battery were firstly, that the red lead paste would not adhere to the smooth sheet lead; it became detached in flakes; secondly, the wrappings of cloth or felt became corroded with the acid; and thirdly, the separating material, being comparatively dense, prevented the circulation of the electrolyte; the acid was in consequence exhausted in some parts and concentrated in others, altogether there was too little of it in the immediate vicinity of the plates. There was greater activity consequently in some parts of a plate than in others.

The detachment of the oxide coating was not entirely due to a want of cohesion between it and the smooth lead plate. Sheets with roughened surfaces were tried with no better results. The peeling off is partly due to the fact that the acid penetrates through the pores of the coating and creeps up between it and the sheet lead when sulphate is produced, and patches of the substance are by this means rendered inactive owing to the insulating properties of lead sulphate. The main evil, however, lies in a different direction, and this has probably never been explained; it is this, the paste expands during oxidation and also when sulphating; the minute particles must then travel along upon the surface of the metallic support, which does not expand, and thereby diminish the adhesion of the paste which was originally smeared upon the lead plate and dried before placing it into the box with acid.

EXPANSION OF OXIDES AND BUCKLING.

We have already stated, in the last paragraph, that the paste of red lead expands during oxidation and also while sulphating. We have mentioned that this increase of volume was the main cause of the detachment of the oxide from its flat lead support. It is this expansion of the active material that has been the cause of most of the trouble experienced with lead storage batteries. Whether the paste is packed into holes, grooves, corrugations, slots or reticulations, the process of enlargement in positive plates goes on, and buckling, falling out of oxide, and other deteriorations follow. The cause is known, but it is somewhat difficult to find a remedy. We cannot prevent expansion or do away with the natural properties of oxides, but we must aim at the production of plates in which an increase of volume can occur without distorting the shape of the electrodes. The materials, active and conducting, must be distributed in such a manner that any growth shall take place equally all over the surface. Until this can be accomplished, *buckling* and bending is sure to take place with the disastrous results well known to makers and users of secondary batteries. Oxidation of the positive plates must occur when the cells are being charged, and sulphating takes place whilst they are discharged. In the case of perforated plates the paste expands and with it the lead support during oxidation. The lead support has practically no elasticity, therefore the paste would become loose during the discharge were it not for the compensating effects brought about by the sulphate which is formed simultaneously. If the active material did return to its original volume, then the contact between it and the metallic support would be almost destroyed. Positive plates grow slowly but continually; their volume increases gradually; and since the paste does not return to its original shape, old and well used plates must be more porous than new ones. This greater porosity may account for the increased capacity of positive plates which have been in use for a long time.

The volume of oxides relatively to their metals has

Digitized by Google

been calculated by chemists. When 207 grammes or 18.44 cubic centimeters of lead unite with 16 grammes of oxygen to form Pb O, the increment of volume is found to be 2.6 cubic centimeters. In the oxidation of 112 grammes of iron to $Fe_2 O_3$, the increment of volume is 8.1 or 3×2.7 *c. c.*; thus 16 grammes of oxygen in chemical union with heavy metals occupy 2.6 to 2.7 cubic centimeters.

In practice, with battery plates, only a portion of the active material becomes oxidized, therefore the above proportions, which refer to atomic volumes, cannot be applied unless we know how many molecules there are exposed to the action of oxygen. If every atom of the lead could be utilized, then the increase of volume from Pb to Pb O in the first stage of oxidation would alone amount to $\frac{2.6}{18.44} = 14$ per cent.; this increment, if Pb = 1, to Pb O, would be 1.14; to $Pb O_2 = 1.28$, and so on. We have found that a positive plate which had a surface of $9 \times 10 = 90$ square inches when new, grew to 94.76 square inches after one year's daily use; we only measured the expansion in the direction of length and width; older plates of the same description showed an increase of from 90 square inches when new, to 97 square inches when almost worn out. A positive plate is considered to be worn out when its lead support or grid is broken or cracked to a considerable extent. Metallic lead becomes very brittle in course of time when exposed to the electrolytic action of oxygen, and a period arrives when the grid refuses to extend itself with the increasing volume of the paste. The bars of the grid crack, and these cracks gradually open out, and then the whole plate becomes unserviceable.

We endeavored to strengthen the plates by providing stout ribs, diagonally, parallel to the sides, and in various other ways, but we found that this only aggravated the evil. The portions of the grid which were surrounded by strong ribs, expanded and buckled, in any direction that offered the least mechanical resistance, whilst the ribs themselves did not elongate in the same ratio.

This method of stiffening grids had to be abandoned, and, finally, we came to the conclusion that any attempt to strengthen positive plates by mechanical means was fruitless. We must allow the paste free scope for expansion in every direction, and this can be done by making the grid or supporting frame of equal strength throughout, and the softer the conducting material the better for the plates. It was suggested, some five years ago, to strengthen the lead grid by providing an alloy of antimony and lead, whereby a much stiffer plate could be obtained. This plan was tried by the Electrical Power Storage Company in the year 1882, but the results were not entirely satisfactory, and the reason for this partial failure will be explained hereafter.

When the cells are partially or wholly discharged, and then left to stand idle, sulphate is being formed, and buckling sets in at a comparatively rapid rate, even with well-constructed plates. To counteract this tendency, secondary batteries should always be kept well charged. If one face of a plate is slightly more active than the other, it is natural that the most active side will expand first, and thus become convex, and when buckling has once begun it continues very easily, and eventually the paste, for want of elasticity, will break and tumble out.

All sorts of devices have been tried to prevent buckling, and consequent contact between neighboring plates. Wooden frames were tried, grids of ebonite, India rubber, and other insulating materials have been used; bands were stretched round the plates, and, finally, rubber plugs, spaced at short distances all over the plates, have been adopted to keep them flat. All these and other kinds of separators, however, do not remove the *tendency* to buckling or unequal expansion; such supports are merely a rude remedy, but they do not do away with the cause. There is only one rational cure, and that is to make the grids of equal strength all over, apply the paste with care, so that it should not be more dense in one part than another, and then leave the plates as free and unconstrained as possible by giving them room for expansion. These are manufacturing details. As regards maintenance, we have already stated that excessive sulphating can be prevented by never allowing discharged cells to stand idle in acid for any length of time.

(*To be continued.*)

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Continued from page 253.)

CHAPTER VIII.—FIELD MAGNET COILS.—(CONTINUED.)

RECURRING to the formula for calculating the smallest allowable diameter of the wire directly from the required number of ampere-turns, namely:

$$d = \sqrt{\frac{.875\ (a\ W)\ l_m}{v}}$$

it is evident that its application is not limited to the particular case before stated, but that in general, it may be used in any case if only the ampere-turns, mean length of one winding, and the potential at the ends of the coils, are known; as the formula does not contain the current as one of its factors, it is not necessary to know this current to calculate the diameter of the wire. For instance, if only the potential of the exciter, and not its current, is fixed, or if a number of machines are to be excited in common by one exciter, the fields being all in multiple arc with one another, the diameter of the wire can be calculated without first knowing the current. After determining the diameter of the wire any suitable current may then be chosen, and when divided into the number of ampere-turns required, will give the number of windings of this wire. But this current is not only limited by other considerations to a certain range of values, which range may sometimes be quite great, but in most cases there will be one particular current which will, considering everything, be the most desirable in each particular case.

The principal considerations which limit the choice of this current, are the following. Suppose a very great current is used, and, therefore, a correspondingly small number of windings, then, as the potential remains the same, the energy in the coils will increase with the current and may exceed the heating limit, as the radiating surface is fixed by the known dimensions of the coil. The greatest allowable current should, therefore, be based on the heating limit and may be calculated from the surface of the coil and the potential, by one of the heating formulæ before given. But besides this heating limit, it may be restricted to a still smaller value by the desired efficiency of the machine, for it is evident that if the energy lost in the magnet coils be relatively great the efficiency of the machine will be poor. To calculate the current from this limitation, determine how much energy in watts may be allotted to the coils and divide this by the known potential, thus giving the current. The amount of energy to be used in the coils will vary greatly with different machines; in large well built machines it may be made as low as 1.5 to 2% of the whole output, while in small, cheap machines it often is as high as 10 to 20%. In large well proportioned machines this is the most important limitation for the current, provided, of course, that it does not exceed the heating limit as before described. As an increase of the current is accompanied by a nearly proportionate decrease in the quantity of wire, and therefore, also in its cost, it is evident that when cheapness of construction is of more importance than efficiency, the current should be taken as great as the heating limit will allow in order to economize wire, while if efficiency is the

Digitized by Google

chief consideration the current should be as small as practicable. The smallest value which the current may have depends on the greatest amount of space which the coil may occupy and on the cost of the wire. If the current be taken too small the number of turns required to give the necessary ampere-turns, may be so great as to occupy more space than is allowed for the coil; furthermore, the depth of winding may then be so great that the mean length of one winding will become much greater than what was assumed, and consequently the resistance of the coil will be too great to take its required current at the given potential. This minimum value of the current can readily be ascertained by calculating how may turns of the wire determined from the formula may be wound in the space allotted for the coil, and dividing this number of turns into the required ampere-turns, thus giving the current. It may be preferable in some cases not to decrease the current to this smallest value on account of the expense of the wire. As the formula for calculating the diameter of the wire gives that value which the wire must have to enable at least the required number of ampere-turns to be generated, it follows that this is the smallest diameter which the wire may have; any larger size than this may be used without fear of increasing the resistance by the increased mean length of one winding due to the greater depth of winding.

From these considerations it will be seen that there is no fixed rule for determining the winding of the coils, but that there are certain limiting conditions differing in their relative importance in different machines, which give the designer some latitude in selecting the winding. As all these limitations can be readily calculated as described, from the known data, the most direct method of determining the winding of the coils appears to be, to calculate the limiting values for the current, the number of windings and the diameter of the wire, and then to choose such values within these limitations as will best meet the desired requirements of cheapness in first cost on the one hand, and good efficiency on the other. For instance, from the formula determine the smallest diameter which the wire can have; from the heating limit, the surface of the coil and the potential, determine the greatest current; from the desired efficiency determine again the greatest current; from the coil space and least diameter of wire determine the greatest number of windings permissible; from these, the best proportions will, in most cases, become self evident. Should some of the limiting values be found to overlap, as for instance, if the smallest allowable current should be found to be greater than the maximum, it shows that the conditions cannot all be met by those proportions of the machine.

To illustrate this by an actual case, let it be required to determine the winding for a certain machine which generates 50 amperes and 100 volts. The exciter also has 100 volts, which is equivalent to assuming the first to be a self-exciting shunt machine. The frame is of the type shown in figure 26 (p. 186) with four coils. The cores are oval, the cross-section being 9x3 inches, having a periphery of 20 inches; length of cores 10 inches. From the test with temporary coils it was found that 15,000 ampere-turns were required to excite the magnets while the machine was generating the required potential and current. To calculate the smallest diameter which the wire may have it is necessary to find the mean length of one turn. Assuming a depth of winding of about one-third of $3 = 1$ inch, the mean length l_m will be, from the formula

$$l_m = l + \frac{2\,c\,l}{a+b} = 23.3 \text{ inches.}$$

The diameter of the wire will therefore be

$$d = \sqrt{\frac{.875\,(a\,W)\,l_m}{v}} = 61.8 \text{ mils,}$$

assuming a factor of safety of 20% by making $v = 80$ instead of 100. The nearest gauge number corresponding to this is No. 14 B. & S. which has a diameter of 64 mils. This is therefore the smallest wire which can be used, and is entirely independent of the current which may be chosen.

To determine next the greatest current from the heating limit, it is necessary to know the surface of the coils. The lengths of the outside and inside windings will be in the proportion

$$\frac{a+b+4c}{a+b} = \frac{9+3+4}{9+3} = \frac{16}{12} = \frac{4}{3}$$

in which a, and b, are the length and breadth of the oval and c, the assumed depth of winding, which in this case is one inch. The inside length being from measurement 20 inches, the outside will be $\frac{4}{3} \times 20 = 26.7$ inches; and as the coils are 10 inches long, all four will have a total surface of $26.7 \times 10 \times 4 = 1068$ square inches. From the heating formula the greatest permissible current, allowing a rise of 80° F., will be, E being 100 volts,

$$C = .36\,\frac{S}{E} = \frac{.36 \times 1068}{100} = 3.84 \text{ amperes.}$$

This should not be exceeded.

To ascertain next the greatest current considering the efficiency, determine what percentage of energy may be allotted to the magnets; as the machine is not large, six to seven per cent. should not be exceeded; assuming the latter gives 3.5 amperes as the greatest allowable current for that efficiency.

Finally, determine the least current or greatest number of windings from the coil space. A No. 14 B. & S. wire has an outside diameter of about 88 mils. As the coils are 10 inches long, there will be $\frac{10 \times 1000}{88} = 114$ turns per layer, and if the greatest allowable depth of winding is about one inch there will be $\frac{1 \times 1000}{88} = 11.4$ or about 12 layers making $114 \times 12 \times 4 = 5472$ windings on all four magnets. This gives for the least current $\frac{15000}{5472} = 2.75$ amperes, as there must be 15,000 ampere-turns. This current is considerably smaller than that obtained from the heating limit.

Summarizing these results, if the coils are to be wound as cheaply as possible, without regarding the efficiency, 3.8 amperes is the greatest permissible current. This gives $\frac{15000}{3.8} = 3950$ windings of No. 14 wire. On the other hand if the best efficiency is desired, the least possible current is 2.75 amperes, and 5472 windings of the same wire. As the cost of the wire of the same size, is approximately proportional to the number of turns, it will in the second case be $\frac{5472}{3950} = 1.4$ times as great as in the first case, while on the other hand, the percentages of energy in the coils will be 7.6 in the first and 5.5 in the second case. It is obvious that there would be no advantage in using a larger wire than No. 14, as the only apparent gain would be to reduce the resistance, thereby increasing the current and therefore decreasing the required number of turns or the length of the wire; but this current would be greater than 3.8 and would therefore increase the rise of temperature to more than 80° F. which was assumed to be the safe limit. On the other hand if a smaller wire than the one given by the formula were used the resistance would be so high that it would not be possible, with the same factor of safety, to generate the required number of ampere-turns in the limited coil space and with the given potential.

If coil spaces of the same dimensions be wound full with

Digitized by Google

wires differing in size in each case, the coils will have the following relative properties if the space occupied by the insulation is not considered. If d represents the diameter of the wire, the number of turns will be proportional to $\frac{1}{d^2}$, that is, for a wire having twice the diameter the number of turns will be one-quarter as great as before, or with half the diameter they will be four times as great; the resistance of the coils will be proportional to $\frac{1}{d^4}$. If the same number of ampere-turns are to be generated in each of these coils, the current must be proportional to d^2, and the electromotive force required to generate this current will be proportional to $\frac{1}{d^2}$ or to the number of turns; the energy in watts will then be the same in all the coils, and as the surface is the same, the temperature to which they will be raised by this current will also be the same. If instead of having the same number of ampere-turns the coils be subjected to the same electromotive force, as would be the case, for instance, in different coils for the same shunt machine, the current which will flow through them will be proportional to d^4, and the ampere-turns will therefore be proportional to d^2; the energy in watts being approximately equal to the current multiplied by the electromotive force, will then be proportional to the current (the electromotive force being the same) and will therefore be proportional to d^4, or to the square of the number of ampere-turns; as the surface is the same the temperature will also be proportional to d^4, or to the square of the number of ampere turns; furthermore, the energy required per ampere-turn or per line of force will be proportional to d^2. From this it will be seen that when subjected to the same electromotive force, any number of ampere-turns can be generated in a limited coil space by merely making the diameter of the wire great enough, but the heating of the coil will thereby be increased very rapidly so that a practical limit is soon reached, which may be determined from the heating formulæ; furthermore, the cost of generating the same amount of magnetism will increase as the square of the diameter, thus reducing the efficiency. If instead of having the ampere-turns, or the electromotive force the same in such coils, they have the same current passed through them, as for instance in different coils for the same series machine, they will have the following relative properties: the ampere-turns will be proportional to $\frac{1}{d^2}$ or to the number of turns; the electromotive force consumed by the current will be proportional to their resistance, and therefore to $\frac{1}{d^4}$; as the current is the same, the energy required and therefore also the temperature will be proportional to the electromotive force, or to the resistance, or to $\frac{1}{d^4}$; the energy required per ampere-turn or per line of force, thus representing the cost of generating the magnetism, will be proportional to $\frac{1}{d^2}$. What was said regarding an *increase* of diameter of wire for shunt machine, applies therefore equally well to a *decrease* of diameter for series machines.

From this it will be seen that it is desirable in many cases (for instance in shunt machines) to find the smallest diameter which the wire may have. The formula, mentioned above, for calculating the diameter gives the minimum value under the given conditions, namely, that its resistance shall be such as to enable the required number of ampere-turns to be generated with the limited potential, and with the given mean length of one turn. While a smaller diameter than this would make the resistance too high for the necessary current and therefore render the coil useless, a larger diameter could, of course, be used, provided it is not limited by other considerations.

It may sometimes require less calculation to determine the winding indirectly by trial calculations by assuming different sizes for the wire and calculating the resistance and number of windings for each case to find whether the required number of ampere-turns can be generated in them. While such a method may or may not be shorter it does not give the limiting values between which the designer can choose the one best suited to the case, nor does it indicate whether the best proportions have been arrived at, or whether any changes in the machine are advisable, or whether it is at all possible to meet the requirements. The direct method will therefore in most cases be found to be the shorter.

It is assumed that the dimensions of the frame, including the length and cross-section of the cores, have been determined as correctly as possible from the amount of magnetism required, prior to the determination of the winding of the coils. The calculated values of the diameter of the wire and of the necessary depth of winding, can therefore not be used to construct the cores from; they will however be found to be a convenient and reliable means of ascertaining whether the proportions of the cores and windings are the best, and if not, in what way they might be improved.

From the practical limitation to some of the proportions of the coils and from the general nature and size of the machine, it will readily be seen whether the calculated diameter of the wire is relatively small or large. Providing that the heating limit is not exceeded, and that the cores are not over-saturated more than is intended, then a relatively small value for the diameter of the wire indicates that either the ampere-turns are relatively small or that the potential is relatively great for those coils; in such cases a larger wire may be used if desired, provided the coil space is not too small, external resistance being added in case of a shunt machine to reduce the current to its former value. If on the other hand, the calculated diameter is relatively large, it indicates that either the magnet cores or the ampere-turns are relatively large, or that the potential is relatively small for those coils.

Similar deductions can also be made from the actual depth of winding as determined from the diameter of the wire, in distinction from the assumed depth. If, as before, the heating limit is not exceeded, and the cores are magnetized to the desired degree of saturation, then if the depth is found to be very small it indicates that the cores are too long, while if it is very great it indicates that they are overworked, being too short. It is understood, of course, that the depth of winding need not be limited in all cases to a certain proportion of the diameter of the core, the rule given above to this effect is, as described, to be used merely as a general guide in order to enable the mean length of one turn to be calculated approximately. In most cases it will no doubt be found to be a proper proportion, but there may be other considerations, such as the heating, the limited coil space or the length of core, which may necessitate a greater or less depth than that assumed; if such is the case it will be shown by the calculations.

Similarly if it is found that the energy required for exciting the magnets is relatively great, the magnets are poorly proportioned or overworked, while if the energy required is found to be relatively small it indicates that the magnets are not used to their full capacity, and might therefore be made smaller. Such general and obvious deductions from the proportions of the coils will often serve as a guide and will be particularly applicable for reconstructing and standardizing machines, and in designing from poorly proportioned machines as models.

In all these cases it has been assumed that the potential at the ends of the magnet coils was a fixed and limited amount, and that a choice of the current necessary to meet

Digitized by Google

the requirements was left to the designer; these are the conditions for shunt machines. If on the other hand the current is limited to a certain fixed value, as in series machines, while the potential consumed by the coils may be made anything that is required, the calculations of the coils from the ampere-turns is slightly different. The current and the ampere-turns being known at the outset the number of turns is their quotient. The diameter of the wire is then determined from the following limiting conditions: the limited coil space, the heating limit, and the desired efficiency of the magnets. The first may be determined approximately by multiplying the length of one coil by the allowable depth of winding, both in inches, and dividing this by the number of windings in one coil, the square root of this quotient is the diameter in inches including insulation; this is the maximum limit. The heating limit may be determined by finding the greatest allowable potential from the surface and the current in the formula already given, namely

$$E = .36\,\frac{S}{C},$$

which is then compared with the potential obtained from the desired efficiency; this latter, as described before, should be a certain percentage of the total voltage of the machine. From these two values the proper potential can then be chosen which will best meet the desired conditions of greatest cheapness of construction on the one hand (limited by the heating), or of best economy of energy on the other hand (limited by the efficiency). The diameter is then determined from this potential by the formula already given. This will give the smallest limiting value of the diameter. Or the diameter may be calculated directly for each of these two potentials giving two minimum values from which together with the maximum limit above given, the proper diameter can readily be chosen.

It is assumed herein that a machine is to be constructed which will generate a certain desired electromotive force and current. If, as is no doubt sometimes the case, the machine is built by guessing at the proportions and then running it to "see what it will give" such calculations as those described will not be necessary. But even in such cases the proper calculations made from the results of a test, may show whether the machine is running at its best or whether and how it could be improved in any of its parts.

Besides the formulæ already given, the following may sometimes be of use, especially as a check to determine the correctness of other calculations. Using the same letters and units as before, the resistance of the coils will be

$$R = .875\,\frac{W l_m}{d^2} = \frac{3.5\,W l_m}{4\,d^2}$$

at about 70° F.; every degree Fahrenheit increases the resistance about two-tenths of one per cent. (.2 per cent.). If the calculated resistance is found to be too great, owing to slight inaccuracies in the diameter or assumed conductivity of the copper, or other unavoidable causes, the diameter can, if the coil space permits, be made slightly larger without fear that the consequent increased length will again increase the resistance, as the latter will increase only slightly with a greater mean length of one turn, while it will be diminished greatly by a slightly larger diameter. The potential lost in the coils is equal to

$$v = Ra = .875\,\frac{a\,W l_m}{d^2} = \frac{3.5\,a\,W l_m}{4\,d^2}$$

The total length of wire, in feet, for all the coils may be calculated from the formulæ

$$L = \frac{W l_m}{12} = .0833\ W l_m.$$

If e is the length, in inches, of one coil, d_1, the outside diameter of the wire in mils including insulation, and n, the number of coils, the number of turns per layer in one coil will be

$$\frac{1000\,e}{d_1};$$

the number of turns per coil being $\frac{W}{n}$ and the depth of the winding being represented by c in inches, the number of layers will be

$$\frac{W d_1}{1000\,e\,n} \text{ or } \frac{1000\,c}{d_1},$$

or the thickness c, of the coil in inches will be approximately

$$c = \frac{W d_1^2}{1{,}000{,}000\,e\,n}.$$

The figures occurring in the formulæ for the heating of coils are based on the constants given by Prof. George Forbes in the paper before referred to. But as these constants may, and undoubtedly do, vary somewhat for different machines owing to their different general outlines, the ventilation, air blast from armature, exposed surfaces, etc., it is best whenever practicable to determine these constants for the particular style of machine, or for one similar in its cooling properties. This may readily be done by measuring the outside surface S, of the coils, finding their temperature T, in degrees Fahrenheit, after a long steady run with full load, and measuring the watts of energy W, which are consumed in the coils. Then $\frac{W}{T\,S}$ will be the constant to take the place of $\frac{1}{115}$ in the formula

$$W = \tfrac{1}{115}\,T\,S.$$

From this all the other heating formulæ can readily be deduced by substituting for W, its equivalents in terms of current, electromotive force or resistance. All heating formulæ are obviously only approximately correct owing to the greatly varying conditions, but if the limiting temperature is not taken too high, a moderate difference between the actual and the calculated heating will not be of any great importance.

The following formula by Brough, may sometimes be of use in calculating coils having a limited resistance. It is for determining the diameter d of the bare wire which, when insulated and wound to fill a limited coil space, will have the required resistance R. It is for circular coils only.

$$d = -i + \sqrt{i^2 + \sqrt{\frac{K\,e\,(A^2 - a^2)}{R}}}$$

in which i is the radial thickness of the insulation or *half* the increase in diameter due to insulation, e is the length of the coil space, A, the outer diameter of the circular coil, a the inner diameter, R the resistance of one coil, and K, the resistance of a piece of wire $\frac{\pi}{4}$ units long and one unit in diameter. All dimensions must be in the same units, either mils or inches. If they are all in inches, then K is about .000000687. For oval coils, which are by far the more common in dynamos, the writer has deduced the following similar formula in which, however, the quantities are given in the usual units, namely, d and i in mils, and the coil dimensions (c, depth, e, length and l_m mean length of one turn) in inches. It can be used for both circular or oval coils.

$$d = -i + \sqrt{i^2 + \sqrt{\frac{875000\,c\,e\,l_m}{R}}}$$

In winding the coils it is very important to insulate the wire carefully from the core and at the ends of the coil. One or two layers of strong, tough and flexible cardboard about .015 to .020 inch thick placed around the core, and the same or even more at the ends, prior to winding the wire, will, in most cases, be sufficient. It is well to soak the cardboard in paraffine or thin shellac to keep it from

Digitized by Google

absorbing moisture. When there are many layers, and particularly when very fine wire is used, it is well to place thin sheets of cardboard between every three or four layers, particularly under the last layer, in order to keep them smooth and regular. For the sake of appearance, the last layer should always be wound full, which can readily be done when there are a large number of turns, by simply omitting or adding the odd number of turns, but when the whole number of windings in the coil is comparatively small the odd number of turns should be wound in the next to the last layer, and the remaining space filled with cardboard, the last layer being then wound over all.

When the coils are oval it is well to wind them so that at the ends of the oval the wires lie in the position shown in figure 12, chapter v, instead of as shown in figure 13, as they may otherwise slip into the former position and thereby become loose, which should be carefully guarded against, as loose wires, by the vibrations of the machine, are apt to abrade their insulation.

The method of winding shown and described in chapter v, figure 14, bringing both beginning and end of the wire into the last or outer layer, may be used to advantage in magnet coils, but as these are generally wound in lathes it would be attended with such difficulties that it will, in most cases, be impracticable.

In the ordinary method of winding, the inner end of the wire which has to pass out at the end of the coil, should be very well insulated with two or three extra insulations where it passes the other wires. A strong, hard cord wound closely around this part of the wire and afterwards shellaced and taped, forms a very good insulation. This end should be secured firmly where it leaves the coil to prevent vibrations of the wire. It is well to take one turn with this wire in the outer layer in order that if it should break off short at the coil at any time a splice can readily be made.

When the wire is thick and has been bent by having been wound once before, it may readily be straightened by drawing it, while it is being wound, through a series of grooved rollers as shown in figure 31. The tension necessary in winding may also be adjusted by these rollers. The practice of hammering the wire straight after it is wound is very objectionable, and should be resorted to only when absolutely necessary, and then only with great care. An iron hammer should never be used for this except in connection with a piece of soft wood grooved at its end to fit the wire.

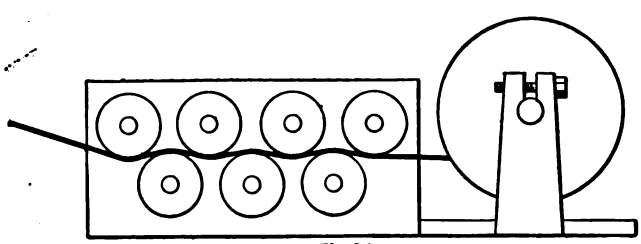

Fig. 31

If it is desired to measure the length of the wire as it is being wound, it may be passed between two rollers of known circumference with a thin layer of leather or rubber on the surface, and an ordinary speed counter attached to the shaft of one of them, the length being calculated from the circumference and number of turns of this roller. If the apparatus in figure 31 is used, the speed counter may be attached directly to one of these rollers.

Magnet coils should not be connected in multiple arc unless there is no alternative, as there may be an unequal distribution of the magnetism, unless both the resistance and the number of turns is the same.

It is evidently unnecessary, so far as polarity is concerned, to wind the coils in any particular direction, and they may, therefore, always be wound in the direction which is most convenient, as they may always be so connected with one another and with the binding posts of the machine that the magnets shall have the proper polarity. The only object in winding the coils in particular directions is, that the connections between the coils and with the binding posts may be as convenient and as short as possible for the sake of appearance. In applying Ampere's laws to determine the direction which the current must have in order to develop the required poles, it must be remembered to face the end of the coil. The current in the connecting wire between those ends of two coils which terminate in the same pole-piece, will describe the letter **U**, while that between those ends which terminate in the same yoke-piece, will describe the letter **S**.

In making the preliminary test to determine the required ampere-turns, it is well to examine the polarity of the pole pieces with a compass needle (being careful that the polarity of the needle is not reversed in doing so), in order that the finished machine may be connected to have the same polarity. In self-exciting machines it is also well to note the direction of rotation and of the current of the armature, in order that all the connections in the finished machine may be made correctly at first, as much time may thereby be saved, particularly for more completed connections, as in compound machines. In shunt or series machines, it is evident that with certain connections between the brushes and the magnet coils the machine will give absolutely no current.

As it is not always possible to carry out the specifications for a machine in all details, it is well to keep a complete record of all the parts and properties of each machine wherever they vary from the original determination or plans. Such records may often be of future use, especially for determining constants which may be of service in designing other machines, or in improving those already built.

(To be continued.)

EFFICIENCY TESTS OF A GAULARD AND GIBBS' TRANSFORMER.[1]

BY P. CARDEW, CAPTAIN R. E.

THE excellent articles by Mr. Kapp, on the determination of the lag of primary current behind impressed E. M. F., and of magnetization behind primary current in a transformer, have been of great service to me, as I happened just at the time that they appeared to be engaged in determining the efficiency of one of these instruments, specially wound and submitted for test by the company connected with Messrs. Gaulard & Gibbs. I was preparing to wrestle with the problem myself when I found this labor saved by the articles mentioned, and as a slight return for this benefit, I give herewith the tests taken with the lags worked out and expressed as angles, and the external efficiency deduced. The tests do not pretend to anything like exact accuracy, as time and the present importance of the question to the war department did not permit of elaborate precautions being taken. Nevertheless, and in spite of considerable variation in all the quantities measured, the resultant efficiencies are very close, and the sum of the angles φ and ψ still more strikingly close in all the tests. The turns of the primary and secondary conductors were to each other in the proportion of 4 : 5, which obviously would not be suitable for a practical instrument,

1. From *Industries* (London).

Digitized by Google

but which was very convenient for our means of measuring. The weight of the transformer was about 90 pounds.

The angle φ is the lag of primary current behind E. M. F., as used by Mr. Kapp in discussing a single magnetic coil. I think it is a pity that he called this ψ in discussing a transformer; ψ is the lag of magnetization behind primary current. The efficiency is

$$\frac{\text{Secondary current} \times \text{secondary E. M. F.}}{\text{Primary current} \times \text{primary E. M. F.} \times \cos \varphi}$$

The resistance of the two coils was: Primary, .023$^{\omega}$; secondary, .036$^{\omega}$. This indicates equal mass of each conductor, in which case the resistances should be to each other in the proportion of the square of the conversion factor, not in the simple proportion, as I think I have seen it stated. The calculated external efficiencies are certainly too high, for the following simple reason, as pointed out by Mr. Kapp, viz., whatever power is absorbed by the iron core should be expressed as current × E. M. F.; the current must oppose the magnetization, and its ampere-turns should be added to those of the secondary current in calculating ψ, making ψ greater and φ less than as now calculated. This, of course, will make the number of watts in the primary somewhat higher. It is quite hopeless, I think, to attempt this correction; but, from estimating the radiation from the core, I should put the power wasted at full load at about 2½ per cent., leaving an efficiency of conversion of 97.5 per cent.

However this may be, I consider the results undoubtedly show a very high efficiency for these transformers, and I must say that, in my opinion, great credit is due to Messrs. Gaulard & Gibbs, and the company connected with them, for what they have done in the face of every sort of discouragement to perfect the system, which I am convinced has a great future before it.

The interchange of energy between the transformer and the supplying circuit is a curious phenomenon. When φ is appreciable the transformer begins to return energy during a portion of each alternation, and when $\varphi = \frac{\pi}{2}$ the energy given to the transformer during one-quarter of an alternation is returned during the next quarter, except what is exhausted in heating the conductor. There is a sort of ebb and flow of tide enduring in the case of the last experiment but one, for about $\frac{1}{100}$th second, and only a little leaks out each time. In this experiment the calculated primary watts are 55.4, of which 40.57 are absorbed in the primary coil, and 15.4 in the secondary circuit, so that in this case we get an apparent efficiency of conversion of $\frac{55.97}{55.4}$, just over 100 per cent., but of course this should be reduced on account of the power absorbed by the iron core. The fact that the primary current absolutely rose to a higher value in this experiment as compared with the previous one is very curious.

The primary circuit was connected to a 32-magnet Wilde machine, the secondary circuit to 50 c. p. 60 volt lamps. In the first series the volts at machine were maintained constant by the engine driver altering his speed to suit the load, and the tests were taken on one Siemens electro-dynamometer and one Cardew voltmeter, by rapidly changing the instruments from one circuit to the other. In the second series an attempt was made to keep the speed constant by altering the strength of field in the machine; but as no suitable rheostat was available and the engine was not governed this could not be exactly effected, and the volts on the primary circuit show considerable variation. Two dynamometers and two voltmeters, however, were used, so that absolutely simultaneous readings were secured. In the third series no attempt was made to keep any value constant, but simultaneous readings were taken. The angle φ is the lag of primary current behind impressed E. M. F., ψ that of magnetization behind primary current; their sum as shown is in all cases nearly 90°.

EFFICIENCY TESTS OF A GAULARD & GIBBS' TRANSFORMER.

* Primary volts probably read too high. † Estimated current in voltmeter.

NOTE.—The dynamometers were very insensitive for the currents used, it being considered desirable to avoid self-induction in them.

THE ELECTRO-DEPOSITION OF IRON.[1]

BY PROF. W. CHANDLER ROBERTS-AUSTIN, F. R. S.

THE great interest which would attend the investigation of the properties of pure iron has long been recognized, and although but few results have as yet been obtained, elaborate preparations for such an inquiry have from time to time been made. A committee appointed by the British Association described in 1869 a method which yielded iron of a high degree of purity, the work being entrusted to the late Prof. Matthiessen, who ignited pure ferrous sulphate mixed with sodium sulphate, reduced to oxide of iron, so obtained by pure hydrogen, and melted the spongy iron in a lime crucible before the oxy-hydrogen blow-pipe. The committee reported "that, with regard to the physical properties of pure iron, owing to the want of time, nothing has as yet been accurately determined." It appears, however, that many of the physical properties of the pure metal differ considerably from those of the commercial. The work appears to have been interrupted by Matthiessen's lamented death, which occurred in the following year. It may be that metallurgists have been satisfied that Bessemer metal is sufficiently pure to afford a basis for investigation without resorting to elaborate chemical methods of preparation, for but little has hitherto been done to prepare on a large scale a material in which the above-mentioned impurities are entirely absent. The

Digitized by Google

volume of the reports of the British Association, to which reference has just been made, also embodies a paper by M. H. Jacobi, of St. Petersburg, whose name is so well known in connection with electro-metallurgy. M. H. Jacobi and M. Eugène Klein took out a patent in this country in 1869 (No. 2,456), which was, however, allowed to lapse. Jacobi worked for some days in the mint laboratory, and communicated to me the details of the methods of manipulation, and in 1870, I visited St. Petersburg, and had the advantage of seeing the iron deposited on a large scale with a view to the preparation of plates to be used for printing the paper money of Russia.

The deposition of iron is attended with many difficulties, and in this country, so far as I know, iron has only been deposited electrolytically on a very small scale, and the metal deposited has been considered rather a metallurgical curiosity than as possessing any practical value. It may be well to describe briefly the method of procedure. "The bath used is a solution of ferrous sulphate and magnesium sulphate in equivalent proportions of specific gravity 1.155. The solution must be so far neutralized by the addition of magnesium carbonate that blue litmus paper barely shows any acid reaction. A wrought-iron anode of about the same size as the object which is to receive the deposit must be employed, and the best interval between the poles proved to be 4 c. m. The secret of success appears to be in the use of very feeble currents. Mr. W. H. Preece, F. R. S., electrician to the post-office, has kindly afforded me facilities for determining the strength of the currents employed, and it may be sufficient to state that the current best suited for the deposition of an iron medallion, the surface of which measured 560 sq. c. m., proved to have a strength of only 0.089 ampere, and such a current was yielded by two Smee's cells, each having a silver plate of 50 sq. c. m. area coupled up for intensity. The only objection to the process is the length of time required for its completion. It was not found possible to deposit such a medallion of sufficient thickness for use in the reducing machine in less than three weeks. The adherence of the deposited iron to the surface of the copper gives rise to considerable difficulty in detaching it, and in order to reduce this adherence it was found best to throw down on the copper model a thin film of nickel, and after exposing this for a short time to the air in order to slightly tarnish its surface to cover it with a second film of nickel, on which the iron was subsequently deposited. Even when this precaution was taken several moulds were spoilt by partial adherence of the iron and copper through the nickel. I am now conducting some experiments on the deposition of iron on copper moulds covered with a thin layer of silver iodide, that substance being well known as an excellent conductor." The metal has a high degree of purity. Mr. A. Dingham, a skilful analyst in my laboratory at the Royal School of Mines, finds that a specimen submitted to certain physical tests, to which reference will be made presently, contained only the slightest trace of magnesium and 0.005 per cent. of sulphur. Its density is 7.675, which becomes 7.811 when the metal is annealed. By annealing carefully measured strips of metal they were found to contract about one per cent. of their length. I found in 1869, that the metal as deposited occludes from 17 to 20 times its volume of hydrogen. Cailletet showed that iron deposited under certain conditions occludes 248 times its volume of hydrogen, the pressure of which gas renders the metal very hard, and augments considerably its coercive force when magnetized. Notwithstanding the purity of the metal its magnetic capacity does not appear to be high. Tested by the magnetic balance designed by Prof. Hughes, it would appear to possess less than two-thirds the magnetic capacity of a strip of Russian sheet of the same dimensions. The magnetic capacity of the strip of electro-iron rises considerably when the metal is annealed, which tends to show that the defective magnetic quality is due to the aggregation of the metal, and not to impurity, as well as to the partial expulsion of the occluded gas. With a view, however, to set this important question of magnetic influence at rest, I have deposited a carefully turned rod of copper, 1.01 foot in length, 0.511 inch in diameter, and of a maximum thickness of 0.035 inch. Dr. John Hopkinson having expressed a wish to conduct some experiments in this direction, the rod (now exhibited) will be placed in his hands.

From the point of view of its molecular structure the electro-deposited iron promises to afford interesting experimental results. Strips of the iron about 5.4 inches in length, 0.033 inch in thickness, and 0.75 inch in breadth, were tested for tensile strength. It was found that the deposited metal crushed in the jaws of the machine, and it was therefore necessary to anneal the ends of the test-piece before submitting it to stress. A piece of deposited iron so treated broke in the centre of the strip with a load of 2.7 tons per square inch. A similar strip annealed at the temperature of molten zinc (about 412° C.) was found to possess a tensile strength of 13½ tons per square inch, and another piece annealed at a temperature between the melting point of silver (940° C.) and that of the melting point of aluminium (about 300° C.) had a tenacity of 15½ tons per square inch, two separate experiments agreeing very closely. The elongation was in each case very small, and very delicate instruments would be required to determine its amount with accuracy. It will thus in future experiments be possible to examine by photographic methods, described by Mr. Sorby, the change in structure of a pure, brittle, and non-coherent metal to one having a considerable tenacity.

The use of electro-deposited iron for printing purposes has already been mentioned. One other application remains to be described.

Many years ago I suggested that electro-deposits of iron should be employed with a view to test the capabilities of a machine devised for reducing designs modeled in low relief, and the reproductions in metal and ivory were so faithful that the superiority of such iron deposits to the metal casts or copper electrotype ordinarily employed was at once demonstrated.

The preparation of the dies for the coins to be struck on the occasion of the jubilee of Her Majesty, the Queen, presented a favorable opportunity for the more extended application of similar deposits of iron. The designs modeled in plaster were reproduced in "intaglio" by the electrolytic deposition of copper, and on the copper moulds so prepared iron was deposited. The iron proved to be hard and of excellent quality, and up to the date of this paper obverse dies of all denominations of gold and silver coin, as well as the obverse of a medal, have been produced by a reducing machine from such deposits.

If they were to take a plate of copper and deposit on it a layer of iron, then glue to the back of the iron a piece of wood, and wrest the iron away from the copper, the iron did not separate cleanly, but the iron slipped off copper, just as it was asserted that a bank note could be split by glueing it between two surfaces of wood. What this meant he did not at present know, but it was a question that he was investigating. The paper was by no means in a state in which he could have wished to present it to the Institute; but he thought that the interest attached to the exhibition for the first time in London, of a medallion, and that medallion in iron, and a portrait of Her Majesty, was likely to be of far more interest to the members of the Institution than any remarks he could have to offer in the interval between now and the next meeting.

THE MEDICAL AND TESTING BATTERY OF DR. CHARLES PIPER.

A NEW battery with some interesting characteristics has recently been brought out by Dr. Chas. Piper, of Moline, Illinois, through the Electrical Supply Co. of Chicago.

Digitized by Google

The doctor in the course of his practice has recognized the want of portability in any ordinary battery, and this invention is intended to fill the void which has heretofore existed in batteries for medical and other uses, away from the office or laboratory. A battery which could be carried in the pocket in a dry condition, and in a condensed space, having about 30 volts E. M. F.; these were the requirements, and they seem to be fulfilled in Dr. Piper's battery.

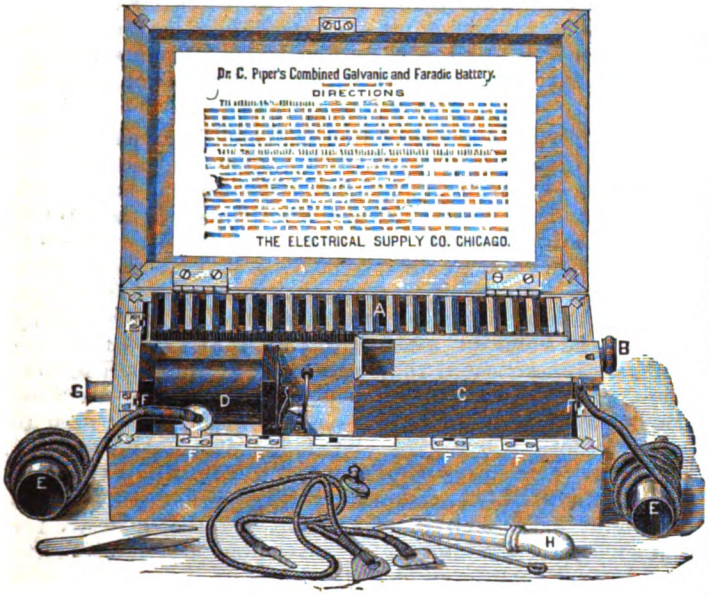

FIGURE 1.

Figure 1, is a representation of the open case, $5\frac{1}{2}$x9x$2\frac{1}{4}$ containing the battery and appliances for charging and using. Binding posts and wires are dispensed with, the flexible cords connecting the terminals taking the place of the latter. The cells are shown at A, and are so made up as shown in figure 2, as to leave a cavity between the two elements, carbon and zinc, for the solution; contact between the cells is made perfect by a screw B. The size of the cells is $1\frac{1}{4}$x$1\frac{1}{2}$x$\frac{3}{8}$ inches.

FIGURE 2.

In the box C, is found a quantity of paper slips, each covered with a crystallized salt of mercuric and potassic nitrate. One of these being placed in the cavity of each cell, water is then carefully dropped into the cell by means of the dropper H, great care being taken to keep the fluid from overflowing. D, is an induction coil, which is furnished with the usual sliding shield G, by which to regulate the strength of the inductive effect.

Through the use of a chemical for an electrolyte which is rich in nitric acid, there is no polarization, as the hydrogen liberated is at once oxydized by the oxygen of the electrolyte; and this, being uniformly spread on the strip insures uniform action in the cell.

Means are provided by which a limited number of cells may be used at one time, one or more.

The constancy of the Piper battery is best told by a test, in which a single cell was placed in circuit with a galvanometer coil measuring 800 ohms, the needle being deflected 75 degrees when first connected. After having remained so joined up for 24 hours, the needle had only fallen off one degree. The E. M. F. is 1.65 per cell, so that the combination shown, gives the operator an E. M. F. of over 30 ordinary gravity cells.

In addition to the medical form, Dr. Piper has constructed a still more compact case, 9x4x2 inches, for measuring and testing electrical instruments, wires, etc.

In both the forms the great advantage of portability is very marked, while its cleanliness and the readiness with which it can be handled, seem destined to make it a general favorite among electrical men as well as physicians. The medical battery weighs, complete, $3\frac{1}{2}$ pounds. The testing battery much less, but either is capable of transportation in a coat pocket.

NOTE ON THE ELECTRO-DEPOSITION OF ALLOYS, AND ON THE ELECTROMOTIVE FORCES OF METALS IN CYANIDE SOLUTIONS.[1]

BY SILVANUS P. THOMPSON, D.SC., B. A.

It is known that the electro-deposition of such alloys as brass, bronze, and german silver is not practicable from mixed solutions of the sulphates or chlorides of the constituent metals, but can be accomplished by using cyanide solutions or neutral solutions containing cyanide of potassium in excess, thereby apparently departing from the law of Berzelius, that out of a solution of mixed metals the least electro-positive metal is deposited first.

To ascertain the cause of these facts the author has investigated—

(*a*) The electromotive forces of a number of metals in aqueous solution of cyanide of potassium.

(*b*) The dependence of these electromotive forces, in particular those of copper and zinc, upon the degree of concentration of the solution.

(*c*) The variation of the electromotive forces of copper and zinc in a standard solution of cyanide of potassium at varying temperatures.

(*d*) The electromotive forces of zinc and copper in a "brassing" solution, consisting of the mixed cyanides of zinc and copper, having excess of cyanide of potassium present, and their variation at different temperatures.

It is found that the effect of higher concentration of the cyanide solutions is invariably to increase the electromotive force of copper more than it increases that of zinc.

In a cold dilute solution of cyanide of potassium the electromotive force of zinc against carbon is 1.158 volt, while that of copper against carbon is 0.948 volt, or zinc is 0.210 volt higher than copper. In a boiling saturated solution of cyanide of potassium, the electromotive force of zinc against carbon is 0.768 volt, and that of copper against carbon is 1.300 volt; or copper is 0.532 volt higher than zinc.

It is, therefore, possible to construct a voltaic battery containing one metal only, namely, copper, and one electrolyte only, namely, an aqueous solution of cyanide of potassium, kept hot at the anode and cold at the cathode of the cell.

In cyanide solutions, containing about the following number of grms. of cyanide to the litre, the following were the electromotive forces observed with a carbon cathode :—

Solution containing per litre.

1. Paper read before the Royal Society, June 16, 1887.

Digitized by Google

Several of the metals exhibit maximum electromotive force at an intermediate concentration.

The following figures were obtained for zinc and copper in solutions of cyanide of varying strengths at 17° C.:—

Grms. per litre.	E.M.F. zinc.	E.M.F. copper.	Difference Z—C.
2.9	1.158	0.948	+0.210
5.9	1.167	0.967	+0.200
11.2	1.184	1.018	+0.166
23.8	1.221	1.058	+0.163
47.7	1.269	1.130	+0.139
95.5	1.303	1.220	+0.080
191.1	1.355	1.360	−0.005

In a mixed solution of cyanides of zinc and copper there is a neutral condition where the electromotive forces of zinc and copper are equal, and this neutral condition varies with the relative amounts of metal present, with the concentration of the solution, and with the temperature. The neutral temperature for a solution of given concentration is lowered by adding cyanide of potassium, and is raised by adding ammonia. The neutral point, however, is not well defined, the behavior of copper being very uncertain ; in general the electromotive force of clean copper in a cyanide solution rises, in some cases, as much as 0.06 volt, in a few seconds after immersion, but is rapidly though temporarily lowered on agitation.

Since the degree of concentration of the solution greatly affects the electromotive force of the metal, and since, in the act of deposition of a metal from its solution, the concentration of the liquid around the cathode is reduced, owing to slowness of diffusion, it follows that in electrodeposition the counter electromotive force at the cathode will vary with the rate at which metal is being deposited, and will, therefore, vary with the current density employed. And since, moreover, the variations in electromotive force due to differences of concentration are greater for copper than for zinc, it follows that in the deposition of brass from a mixed solution of cyanides of a medium concentration, in which zinc is slightly more electro-positive than copper, there will be a certain density of current with which the metals will be deposited in nearly equal quantities, while for weaker current densities the less electro-positive metal will be deposited in excess, and for stronger current densities the more electro-positive metal will be deposited in excess.

Hence, to variations in the concentration of the electrolyte near the cathodes are due the departures, observed with all currents except weak ones, from the law that out of a solution of mixed metals the least electro-positive is deposited first.

ABSTRACTS AND EXTRACTS.

PROFESSOR TYNDALL AND THE SCIENTIFIC MOVEMENT.

* * * * * * *

Others will rank beside or above Prof. Tyndall as investigators, but in the promotion of the great scientific movement of the last fifty years he has played a part second to none. The English people are a determined but somewhat slow-witted race, and it has been no easy task to convince them that a new era—that of science—was dawning. They have been content to pride themselves on industrial successes due for the most part to isolated efforts of genius, which was hampered by unnecessary difficulties, and which cannot be produced at will. They were long in seeing, they do not yet fully see, that our industrial position can only be maintained if armies of well-equipped followers are ready to seize the ground which the leaders win.

There is, however, a still harder lesson to learn. The industrial application of a scientific principle—vitally important to the well-being of the people as that application may be—requires nevertheless a lower form of intellectual energy than the discovery of the principle itself. The triumphs of applied science, of the physician, the engineer, the telegraphist, are readily "understanded of the people." The research laboratory, on the other hand, is open to few. The flash of genius which has wrung a fresh secret from Nature can only be fully appreciated by those who are intellectually competent to understand the difficulty and the success. And yet, if a widespread knowledge of science was to be, as it is, an essential condition of national well-being, it was absolutely necessary that the people should know something of, and be in some sort in sympathy with, the methods and conditions of scientific thought.

In supplying this need, Prof. Tyndall's greatest work has been done. Uniting scientific eminence of no ordinary kind with extraordinary gifts of exposition, he has, by his lectures and his books, brought the democracy into touch with scientific research. In dozens of lecture-rooms experiments devised by him are proving that a living science is a nobler instrument of education than a dead language. In hundreds of libraries his nervous English is convincing men of the value of a career like Faraday's, and teaching them to appreciate, if they cannot always in detail follow, the methods by which the victories of science are won. He has done perhaps more than any other living man to compel those who regard knowledge as valuable only in so far as it is immediately useful, to admit that the seed which is sown in the laboratory often produces the most abundant harvest in the workshop, and that a desire for knowledge is the mother of inventions which necessity could never have brought to the birth.

Such has been Prof. Tyndall's work ; and yet we venture to think that among those who met in Willis's Rooms a deeper feeling was aroused than admiration for an eminent worker and a useful career.

Many of the greatest masters both of the moral and intellectual life have sought the attainment of their highest ideals in a more or less complete withdrawal from society, and it may well be that some natures can best achieve in seclusion the concentration which a supreme effort demands.

But although the scientific movement of to-day may receive its highest inspirations from men who, like Darwin and Joule, have worked in self-imposed retirement, its distinguishing characteristic is that it is sweeping along with it all classes and all opinions. It is a new habit of thought in the light of which the foundations of our educational, industrial, and political systems are being reconsidered. It is a new and deliberate attempt to put into practice the belief that "the sovereignty of man lieth hid in knowledge, wherein many things are reserved which kings with their treasures cannot buy, nor with their force command ; their spials and intelligencers can give no news of them ; their seamen and discoverers cannot sail where they grow."

Thus it has come to pass that science has gathered round it a crowd of workers, engaged in very various tasks, but all of whom would be ready to admit that the cardinal principle of the movement in which they take part is the investigation of truth for truth's sake alone. They may be professors or manufacturers, soldiers or physicians. If only they are imbued with the desire to penetrate a little further into the mysteries which surround us, if only they are willing and able to add something to the sum of human knowledge, they are scientific men.

In part this army is organized. There is in England no Academy of Literature. The Academy of Arts, it is admitted, needs reform. The principal scientific societies, however, with the Royal Society at their head, perform the duties of an Academy of Science to the general satisfaction. No human institution is perfect, but it may be fairly said that they set in their Transactions a high

Digitized by Google

standard of scientific work, and that their judgment, whether of men or of investigations, is seldom challenged.

In spite of this advantage, neither the outside world nor scientific men themselves have as yet sufficiently realized that these societies constitute a great guild of that learning which is the most powerful and the most characteristic influence of our age.

On an occasion such as the Tyndall dinner this realization is quickened. The curious magnetic influence of numbers is felt. Minor differences disappear in the knowledge that all are workers in the same cause. Men become more vividly conscious that though students of Nature are excluded from the state recognition which is extended to the church, to medicine, and to the law, they too are members of a great profession. They realize that, though state rewards are given only to those who have applied their knowledge to some directly useful end, in a gathering of the profession of science the true leaders are those who have wrested the deepest secrets from Nature, careless whether they could be turned to gold or no.

A meeting held in great numbers and for a common purpose may have an influence which many an apparently more useful testimonial would lack. Prof. Tyndall has done service in the cause of science which merited the unique compliment he received. He would, we believe, be the first to rejoice if in the future the Tyndall dinner was remembered not only as a tribute to his own work, but as marking the beginning of a period in which the ranks of science were drawn closer together, and in which the further organization of the investigation of Nature claimed and received the attention which its importance demands.—*Nature.*

PROFESSOR TYNDALL.

EXTRACT FROM HIS ADDRESS AT THE BANQUET GIVEN HIM IN LONDON, JUNE 29.

"In 1850, during a flying visit from Germany to England, I stood for the first time in the bright presence of Faraday. In February, 1853, I gave my first Friday evening lecture in the Royal Institution; and three months afterwards, on the motion of Faraday, the old Chair of Natural Philosophy, which had been filled at the beginning of the century by Thomas Young, was restored, and to it I was elected. It causes me genuine pleasure to think that I shall be succeeded in that chair by so true and so eminent a man as Lord Rayleigh. It is not my intention to overburden you with egotism to-night; but, casting an earnest glance back upon the past, a few words seem due from me to the memory of one or two of the group of good men, no longer with us, with whom I was so intimately associated. Regarding Faraday, I will confine myself to stating that years have not altered my estimate of the beauty and the nobleness of his character. He was the prince of experimental philosophers; but he was more than this—in every fibre of his mind he was a gentleman. I might point to the industries which affiliate themselves with Faraday's discovery of benzol, and with his discovery of the laws of electrolysis. But I need not go further than the fact that in this our day a noble and powerful profession has been called into existence by his discovery of magneto-electricity. The electric lamps which mildly illuminate our rooms, the foci which flood with light of solar brilliancy our railway stations and public halls, can all be traced back to an ancestral spark so small as to be barely visible. With impatient ardor Faraday refused to pause in his quest of principles to intensify his spark. That work he deliberately left to others, confidently predicting that it would be accomplished. And prompted by motives both natural and laudable, but which had never the slightest influence on Faraday, others have developed his spark into the splendors which now shine in our midst. It would be a handsome Jubilee present, if it were a possible one, to roll up the career of Faraday into portable form, and to offer it to the Queen as the achievement of one of Her Majesty's most devoted subjects during her own reign. Faraday's series of great discoveries, however, began in 1831, which throws his work five or six years too far back. During the rest of his fruitful life he was a loyal son of the Victorian epoch. But, passing beyond the limitations of the individual, what is science as a whole able to offer on the golden wedding of the Queen with her people? A present of the principle of gravitation—a handing over to her Majesty of the bit and bridle whereby the compelling intellect of Newton brought the solar system under the yoke of physical laws—would surely be a handsome offering. I mention this case of known and conspicuous grandeur in order to fix the value of another generalization which the science of her reign can proudly offer to the Queen. Quite fit to take rank with the principle of gravitation—more momentous if that be possible—is that law of conservation which combines the energies of the material universe into an organic whole, that law which enables the eye of science to follow the flying shuttles of the universal power, as it weaves what the Earth Spirit in 'Faust' calls 'the living garment of God.' This, then, is the largest flower of the garland which the science of the last fifty years is able to offer to the Queen. The second generalization is like unto the first in point of importance, though very unlike as regards its reception by the world. For, whereas the principle of conservation with all its far-reaching and, from some points of view, tremendous implications, slid quietly into acceptance, its successor evoked the thunder peals which it is said always accompany the marriage of thought and fact. For a long time the scent of danger was in the air. But the evil odor has passed away; the air is fresher than before; it fills our lungs and purifies our blood; and science in its Jubilee offering to the Queen is able to add to the law of conservation the principle of evolution."

A PRACTICAL TEST OF STORAGE BATTERIES FOR TRAMWAYS.

In a paper read before the Electrotechnischer Verein, at Berlin, Herr J. L. Huber, the engineer of the Hamburg street railway, gives some very interesting details regarding the cost and operation of storage batteries on street railway lines. The system employed by Herr Huber is the Julien, in which the storage batteries are carried by the car.

In order to obtain reliable results, experiments were undertaken on a specially difficult line, both as regards curves and grades, and which, in addition, crossed much frequented streets, so that all the difficulties met with in railroad traffic in populous cities were encountered. The road extends from the Rathhausmarkt, in Hamburg, to the Berthastrasse, Barmbeck, over the Mühlendamm, on which line grades of 30 per cent. are encountered.

Herr Huber states, regarding the durability of the E. P. S. storage battery employed, that deterioration takes place only in the positive plates; and this is the more pronounced the greater and more frequent the normal strength of current for which the plates are designed is exceeded. With a well-regulated management—that is, by an arrangement of storage batteries and car, such that with the heaviest grades and loads no abnormal current is drawn from the battery—the wearing out of the positive plates amounts to from 2 to 3 per cent., or, in round numbers, 2½ per cent. for 1,000 kilometers traveled. If, in addition, the traffic be so arranged that with every charge of the accumulators only 50 per cent. of the distance is traveled which could be traveled with new plates, then a wearing out of the plates amounting to 50 per cent. is permissible—that is to say, that over 20,000 kilometers (12,500 miles) can be run before renewal becomes necessary. A car which, including passenger and storage batteries, weighs 7,000 kilogrammes (about 7 tons), and which is to ascend grades of 30 per cent., such as occur on the Hamburg

Digitized by Google

line, requires 800 kilogrammes of active material in the positive plates, and its renewal, including the cleaning of the grids, which can be used over again, as they are not oxidizable, costs 1s. per kilogramme (2.2lb.)—that is 4 pfennigs (½d.) per kilometer run. That would be 0.8d. per car mile for renewal of plates.

Under the same conditions the motive power required is ¾ horse-power hour per kilometre (⅝ mile) run. The cost for attendance, oil, maintenance, &c., for one horse-power hour is 1d.; consequently this cost per car kilometer is ¾d. To the above items must be added the maintenance, oil, &c., for the motor on the cars, which amounts to ¼d., and contingencies run up to an additional ¼d. The total cost, therefore, with the conditions given amounts to 1¾d. per car kilometer (2.8d. per car mile).

Comparing the cost of electrical traffic with that of horses, Herr Huber states that to operate the usual one-horse car, which, including driver and conductor, carries 26 persons, 7 horses are required on the same line for one day of 100 kilometers run. So that, as the electric car carries 31 persons, $8\frac{85}{100}$ horses would be necessary. The cost of maintenance for one horse during the last year, according to the *Jahresbericht der Strassen-Eisenbahn-Gesellschaft*, Hamburg, amounted to 1.96s. per day per horse; so that the cost per car kilometer amounts to 2d. (3.2d. per car mile). It follows, therefore, that even to-day electricity is more economical than horseflesh, and the cost of the former can be considerably reduced by improvements.

The results of experiments show that 88 per cent. of the energy stored in the accumulators can be drawn out, and Herr Huber only counts upon 80 per cent. for safety; that is to say, that of the electrical energy delivered by the dynamos 20 per cent. is lost by the use of accumulators, and this is independent of the length of the line and the power required upon the same, such as the overcoming of grades, &c. It is to be remarked, also, that for the electric traffic such as exists in Hamburg, any car driver can be employed and no trained men are necessary, as is the case with locomotives, so that the expense of trained hands is avoided.

The above are the results of experiments which were carried out from the end of May to the end of December of last year, with a public passenger car, and the distance traveled amounted to 12,000 kilometers (about 7,500 miles). As these experiments were undertaken in public traffic on an ordinary horse road made specially difficult by its grades, and not upon a road specially constructed for the purpose, Herr Huber is of opinion that the life and power of competition with other systems of the storage battery is definitely assured.—*Electrician* (London).

UNDERGROUND WIRES FOR FAST-SPEED TELEGRAPHY.

On the 11th of February, 1887, a note was published in the *Electrical Review* in regard to some experiments then being carried out at Callender's Cable Works, Erith, with the view of constructing an underground telegraph line, capable of being used over long distances, with high-speed instruments.

These experiments have now been completed, and a report of the results obtained may be of interest, especially in view of recent discussions on underground wires. They were carried out at the suggestion of Mr. W. H. Preece, in conjunction with the Postal Telegraph authorities; the tests were verified by Mr. H. R. Kempe, of the engineering department, G. P. O., and comparisons were made with lengths of gutta-percha covered wires in iron pipes, kindly placed for this purpose at the disposal of the Callender Cable Co. by the post office.

The plan adopted was based on recent researches, the results of which were contained in the paper (reproduced in our columns) presented to the Royal Society on February 17th, by Mr. Preece, "On the Limiting Distance of Speech by Telephone."

It was shown in this paper that the speed of the current varies inversely with the product of the total resistance and the total capacity of the circuit. From this fact all the experiments made in connection with the projected line take their start.

The intention throughout has been to combat the difficulties of obtaining a high current speed in both the above directions, viz., by increasing the section of copper in the conductor, and *per contra*, decreasing its resistance to the greatest degree consistent with the possible practical expenditure on an underground line, and also by reducing the static capacity of the completed line to a point much lower than obtained hitherto.

In the first case, that of reducing the copper resistance, two sizes of wire were tried, viz., .097 inch, as used on the Nevin line, having six ohms resistance per mile, and .128 inch (No. 10 legal standard gauge), having 3½ ohms resistance per mile. to compare with No. 18 gauge wire, with 23 ohms per mile, or 16 gauge wire with 13 ohms per mile; the former being the wire in almost universal use for underground work, and the latter being occasionally employed for important circuits.

These larger sized conductors were insulated so that the static capacity remained nearly constant for each wire, the wall of dielectric being increased *pro tanto* with the enlarged diameter of the conductor. Such a method of manufacture is not practicable except with a dielectric of relatively low initial cost, and for the purpose in question the material used, Callender's bitite, was specially suitable, as a heavy sheathing could be put on the wire at a very small increased expenditure.

The increased value in working speed obtained from the diminished resistance was represented by

697 in the No. 10 L. S. G. wire,
386 " Nevin size "

100 representing the ordinary No. 18 L. S. G.; whilst the cost of finished insulated wires was approximately in the ratio of

265 for No. 10 gauge,
175 " Nevin wire,
100 " No. 18 gauge.

In the second direction, that of reducing the inductive capacity of the finished circuit, a new method of laying was adopted, differing totally from the plan generally used of drawing wires into iron pipes.

An open case or trough, rectangular in form, was made of bitumen concrete. The pieces composing this were six feet in length, and all jointed together, *in situ*, into one continuous case, In this "spacing bridges" were placed at every two feet, for the purpose of carrying a tier of insulated wires and maintaining them parallel to each other. These bridges were fixed by molten bitumen being run in round them, and after the insulated wires were in position resting in the hollow arches of these bridges, more molten bitumen was poured in, completely embedding the insulated wires, and surrounding them on all sides. Second, third, and fourth tiers were laid in a similar manner, the whole available space within the case being thus utilized.

Various modifications were made in the positions and treatment of the insulated wires.

In one case, a solid block of 12 was laid in three tiers, the insulated wires touching each other, but the block being surrounded by a clear half-inch of solid bitumen on all sides. These were of No. 10 gauge, and on being tested in an iron pipe, they showed a capacity of .300 microfarad per mile. When laid complete, as described, their static capacity was reduced to .195 to .210 microfarad per mile.

In another case, 16 similar wires were laid, but in addition to having a half-inch of bitumen between the wires and the case, they had half an inch of similar material

Digitized by Google

between each insulated wire and its neighbor. The static capacity was reduced to .131 to .135 microfarad per mile, as against .300 microfarad in iron pipes, and about .200 microfarad when laid as described previously in block.

During the progress of the work, some tests were obtained showing the prejudicial effects of damp on underground work in respect specially to static capacity. Insulated wires laid in a precisely similar manner to the last series, but in wet fog and heavy rain, tested .170 to .180 microfarad per mile, and in damp weather, without rain, from .140 to 145 microfarad in place of the .131 to .135 obtained in dry weather. It was thought that any moisture adhering to the tape with which all the wires were served over the dielectric, would be expelled by the heat of the molten bitumen, but this is shown not to be the case, and the opinion already held by many is confirmed that tape, no matter how carefully prepared or dressed, must always act to a certain extent in increasing the static capacity. Various materials were tried as a serving, and a reduced inductive capacity was shown as a less absorbent material was used, the best results being obtained with core, simply insulated, and unprotected by any tape or serving. It was found that wires so insulated alone and laid in a block with half an inch of solid bitumen on all sides of the block, tested .145 microfarad per mile, as against .210 when laid in similar conditions but served with tape.

Laying in blocks has several advantages over the more elaborate method of placing each wire with its own sheathing of half an inch of bitumen between the outside of each dielectric, the most important being the saving effected in space and in cost. It will probably be found the best plan suitable for use, and the size of conductor which will doubtless be most suitable and economical will be the .097 inch wire.

The working speed of such a line will compare with the 18 copper covered with gutta-percha to 7½ taped and drawn into iron pipes, thus:—18 to 7½ C. R. × I. C. = 23 × .250 = 5.750; .097 C. R. × I. C. = 6 × .150 = .900 or about 6½ times as effective, whilst it is understood that the cost of laying such a line complete would be little in excess of an ordinary 18 gauge trunk line in iron pipes.

A number of experiments were made with the view of dispensing with insulation on the wire, but in every case it was shown that the conductor must first be insulated thoroughly, and that on this completed core the second process of reduction of static capacity must be made.

Bare copper wires were laid in ordinary refined bitumen and bitumen concrete, but the specific insulation was never high enough to obtain reliable tests, and no reading anyway approaching even .500 microfared could be obtained.

Wires served with cotton and tape and compounded were also tried with results but little better than in bare copper, thus showing that to obtain the low readings necessary for any improvement in working capacity a conductor will have to be well insulated.

The bitite insulation used in this case is said to be a vulcanized material whose base is pure bitumen, absolutely refined to purity, and not the ordinary refined bitumen of commerce. It is made to stand a high temperature and is not in any way injured by the molten bitumen run in around it. The total destruction of gutta-percha when subjected to the same treatment rendered it impossible to carry out a series of tests as to the comparative value of this material when so laid.

It appears from the foregoing that considerable progress has been made towards the production of an underground line such as will be suitable for the heavy work of the present day. It is not pretended by the Callender company that this system is applicable for town work, or for a network of short service wires such as exists in London and other cities, but it is claimed that it is suitable in all respects for main trunk lines to connect large towns, and that by its use means of rapid telegraphy are provided such as can be given by no other system at anything like the same cost.—*Electrical Review* (London).

POWER REQUIRED FOR ELECTRIC LIGHTING.

In the production of electric lights, the principal factor for commercial consideration is the power required as compared with the number of lights produced of stated candle-power. Contracts for electric lighting apparatus should, therefore, distinctly state all conditions which affect the cost and amount of power to be required in order that fulfillment of guarantees or the contrary may be demonstrated and settled without equivocation. Guarantees of horse-power economy are, therefore, to be made upon the coal required for producing the necessary steam power, or the number of actual or indicated horse-powers required for producing a given result in light, *i. e.*, number of lights of stated candle-powers. Where a whole plant is erected the best safeguard for the purchaser is a guarantee based upon coal consumption.

Guarantees of indicated power are the least satisfactory unless it has been distinctly agreed that the indicated power shall be taken by laying the dynamos on some particular engine, when that engine is already carrying a stated indicated load. The reason for this is, that all engines—in fact the same engine at different times—vary in actual power compared with the indicated for different loads.

Where the steam-power plant is not part of the plant furnished, then the best basis for guarantee of power is the number of actual horse-powers of 33,000 foot pounds to be delivered to the dynamos or machinery furnished by the electrician.

Power required should be agreed upon for not simply the whole number of lights taken at one time, but as well for fractional parts, as three-fourths, one-half, one-fourth, the whole number; for the commercial efficiency of dynamos decreases with fewer lights.

Should it come to a test, the constructor of the plant should pronounce conditions satisfactory. Unless conditions and results are carefully noted, no test of power should be regarded as of any value. As to conditions and results for purposes of test of commercial efficiency of an electric lighting plant, it is the duty of a person who measures the power to know simply how many lights he has in circuit and what "pressure" he has in the circuit as shown by the voltameter. Any of the lamps may then be selected and their candle-power tested when the identical voltameter used at the power test is employed and attains the same reading. These precautions as to results are especially applicable in case of incandescent lights.

In order to avoid any errors arising from difference of conditions of subsequent candle-power test, it is advisable that the horse-power expended should be measured simultaneously with test of lamps.

The following is a tabulated result of simultaneous tests of horse-powers and of lights. They are interesting in comparison, because they show improvements made in the past few years, and also how the commercial efficiency of electric lighting apparatus decreases with fewer lights. The first was made by us recently upon a 200-light machine, made by a prominent company four years ago, using the most improved lamps now made by that company. In both tests, lights were held to 16 standard candle-powers.

FRANKLIN VAN WINKLE, in *Light, Heat and Power.*

A POWERFUL GALVANIC BATTERY.

AMONGST the many claimants for improvements in galvanic batteries we note that Mr. Alfred Dun and Herr F. Hasslacher, of Frankfort-on-the-Main, have patented a combination for which they claim the high E.M.F. of 2.5 volts per cell, while in consequence of the small resistance of the exciting and depolarizing liquids employed, the strength of current is very considerable. Moreover, notwithstanding its considerable power, the element is so constant in its action that it may be used with great advantage for electric lighting, or for driving motors. The new element consists of a carbon negative electrode having as depolarizing liquid nitro hydrochloric acid (aqua-regia) either alone or mixed with ferric chloride. As positive electrode in the other cell zinc is employed, or any other metal soluble in soda lye, or, at any rate, on closing the circuit, and as exciting liquid soda lye of greater or less concentration is used. The chemical action of the element is as follows: The zinc is oxidized by the oxygen evolved, and the oxide formed is dissolved by the soda lye, while the hydrogen is at once taken up by the aqua-regia, forming hydrochloric acid with its chlorine. In the gradual decomposition of the aqua-regia there is produced chlorine together with chloro-sub-nitrous acid and chloro-nitrous acid, which can also give up their chlorine. When the aqua-regia is saturated with chlorine its decomposition ceases, and only begins again with a fresh production of chlorine, or of the two above-named compounds, when the free chlorine first evolved is taken up by hydrogen or any other body that absorbs chlorine, such as ferrous chloride. According to the quantity of hydrogen evolved by the action of the element, the development of chlorine is proportional to the absorption of the existing free chlorine, and this lasts as long as any aqua-regia exists. With the presence of ferric chloride the depolarizing process may be considered as consisting in the reduction of ferric chloride to ferrous chloride by the hydrogen, with formation of hydrochloric acid, the ferrous chloride being, however, at once reconverted into ferric chloride by the chlorine of the aqua-regia. This takes place as long as there is any trace of the aqua-regia present. Only after this has disappeared does a permanent formation of ferrous chloride begin, combined with an increase of resistance in the element. But this does not occur as long as all the iron is present in the form of ferric chloride. It is, therefore, advantageous always to have an excess of aqua-regia present. The addition of ferric chloride has, therefore, the important object of enabling the element to be utilized to the fullest possible extent without increasing the resistance, which explains the reason why a mixture of aqua-regia and ferric chloride renders the element more constant than when aqua-regia alone is used. The addition of the ferric chloride has, however, also the important advantage, that by means thereof a too rapid mingling of the inner and outer liquids is prevented. This is particularly important when a carbon cell is used in place of an earthenware cell, in consequence of the greater porosity of the former. On the ferric chloride mixing with the soda lye in the walls of the porous cell, oxide of iron is formed which fills up the larger pores without materially interfering with the necessary contact, and without increasing the resistance, which is rendered very small by the good conduction of the carbon cell. In addition, the oxide of iron assists the depolarization, and, therefore, also acts beneficially in this respect. As the hydrochloric acid is always formed afresh, it is advantageous to use aqua-regia containing much nitric acid, or, in replenishing only to supplement the nitric acid consumed. The very high electromotive force of the element is caused by the fact that to the electric tension between metal and carbon there is also added that existing between the aqua-regia with ferric chloride and the soda lye. If it is desired to avoid all smell during working the hydrochloric acid of the aqua-regia may be replaced by chromic acid or a chromate. In this case no production of free chlorine ensues, and any nitrous acid fumes are at once absorbed by the chromic acid. The depolarizing action of the nitric acid will then be assisted by that of the chromic acid. In this case platinum or aluminium may be used in place of carbon.—*English Mechanic.*

THE EQUIVALENT OF ZINC.

AT a recent meeting of the Chemical Society, a note was read by Lieut.-Colonel Reynolds, late R. E., and Prof. W. Ramsey, on the equivalent of zinc. The determination has been made by measuring the hydrogen evolved on dissolving zinc in acid, every precaution being taken to ensure accuracy; the weight of the hydrogen obtained was deduced from Regnault's determination of the density of hydrogen. The zinc used was separated by electrolysis from zinc sulphate purified to the utmost possible extent. The last sample prepared was so nearly pure that dilute acid would scarcely act on it. In all 29 experiments were made. Four experiments had to be rejected; nine were not fully corrected, and therefore were also rejected; the next 11 were considered preliminary, the mean atomic weight deduced from them being 65.2430; finally, five experiments were completed, and the results—free from all known sources of error—obtained as the mean yielded the figure 65.4787 + 0.016135.

A NEW MICROPHONE.

HERR HEMPEL, of Leipzig, has succeeded in making improvements in the Gower microphone, by which the clearness of speech and strength of tone is materially increased. In external appearance, this new microphone is similar to that of Ader, and in common with it the carbon contacts are not liable to get out of adjustment, the arrangement being such as to make them pratically self-adjusting under almost all circumstances. The carbon pencils are arranged star fashion under a wooden diaphragm of about six inches diameter. The instrument is capable of transmitting the faintest whisper equally as well as a vigorous shout, and there is hardly any change in the color of the tone; nor are there any extraneous noises produced, as is sometimes the case in other microphones. The instrument has been found specially suitable for the transmission of music, a successful trial having been made at the last technical exhibition at Görlitz, where music was transmitted over a distance of one mile. The efficiency of this transmitter is, however, largely dependent upon perfect workmanship, and this makes it rather too expensive for general adoption. —*Industries.*

TRAIN TELEGRAPHY.

TELEGRAPHING to and from a moving train, for which the above seems to be the best short title, is getting to be an old story on the Lehigh Valley road, the operators of the Consolidated Railway Telegraph Company having traveled on three trains each way daily between Perth Junction and Easton now for some months. Several modifications and improvements have been made in the apparatus and plant (if a thing of which there is so little may be dignified by the word "plant") and the facility with which the work is now carried on is such as to give added promise of the useful career in store for this invention.

It will be remembered that it was very soon discovered when the original apparatus (described in the *Railroad Gazette*, Feb. 20, 1885) was tried that the distance at which a current could be induced was not by any means so limited as had been anticipated, and that ordinary line wires could be successfully used. In

Digitized by Google

practice it is found, however, that a separate line is more satisfactory, for the reason that most of the ordinary lines of poles make occasional detours into swamps, over mountains, etc., and thus interrupt the operators, though the trouble from undesired currents from other wires on the same poles is found to be hardly worth noticing, "quantity" currents having little or no effect upon the "intensity" currents used in the train system. A pole line is preferable to a wire laid along the rails, for the reason that it makes so much less work for the line inspector. A well-built pole line on short poles (about as high as a car roof) is cheap and durable, and requires comparatively little attention from an inspector, while tracks must of necessity be constantly tampered with by repairers, and thus keep the wire inspector always on the go. A pole line is especially desirable on a new road, for it can be duplexed and used for ordinary business from office to office, thus in most cases providing for the whole business of the company and the towns on its line by a single wire; and an aerial line, as is well known, has great advantages over one on or under the ground in its freedom from retardation by the earth.

The metallic roof of a car and the truss rods on the under side thereof have been connected with each other and successfully used as the induction coil, so that it seems quite likely that the convolutions of wire can be dispensed with. All unsightly incumbrances in the car being thus unnecessary, the apparatus can be placed in a drawing room car or coach as well as in a baggage car or elsewhere. The operators on the Lehigh Valley now ride in the drawing room cars, the instruments being connected by a flexible cord with the baggage car. From the experience on the Lehigh Valley it is apparent that an important mission of this device, perhaps the most important, is the serving of the passengers on the train, and it is clear that the more convenient it is for the people to patronize the line the more popular it will be. A neat office (which, however, consists of nothing more than a board about 13 in. by 15 in. in the operator's lap) in the corner of a parlor car, therefore, is likely to be much more successful than one among the oyster-tubs and coat-tearing trunks of the baggage car. The company now use a telephone receiver at both ends, the vibrator of the sending instrument sending the currents so that the buzzing, which sounds like that of a very shrill bee, is exactly reproduced in dots and dashes in the telephone. To read these dots and dashes is like reading Morse characters made by a steam whistle, which to most operators is not so pleasant as the familiar sounder; but the train operators find no difficulty in it, nor are they disturbed by the noise of the train, even with the windows open.

Railroad superintendents, like everybody else, are making constantly increasing use of the telegraph, and the more they use it, the more efficient they want it to be; as trains multiply and cares increase, they come to want instantaneous communication with every one, conductors among the rest, so that what was at first mentioned as one of the chief uses of the system, that of sending despatcher's orders and facilitating train movement on single track, may become, so far as volume of business is concerned, secondary to its service in miscellaneous railroad business, such as is done by double track roads, which do little despatching. Already the Lehigh Valley has experienced the value of the service in some typical cases, one of which was that of a breakage in the engine, which delayed a train some five miles from a telegraph office and which under ordinary circumstances would have necessitated a wagon or foot trip that distance, but which by the aid of the apparatus on the train was settled at once, a relief engine being sent for and brought to the aid of the train in about ten minutes.

The system is not being tried on the road by mere sufferance; the railroad company not only affords ample facilities, but actively aids in perfecting the details, General Superintendent Goodwin, well known for his enterprise in other directions, taking, we understand, a lively interest in the success of the project, as does also Telegraph Superintendent Lattig.

The question of economy which is all important here as in everything else where a balance sheet periodically intrudes itself, would seem in a fair way to be satisfactorily settled. The company now charges ten cents above Western Union rates for an ordinary message; at this rate it seems quite likely that the principal trains on roads of the size of the Lehigh Valley or larger might furnish a remunerative amount of business. The company has not as yet "pushed" its business, but receives unsolicited patronage from passengers, who generally, of course, have not heard of the system before they enter the train.—*The Railroad Gazette.*

CORRESPONDENCE.

NEW YORK AND VICINITY.

Electrical Service During the Heated Term.—The Mutual District Messenger in Europe.—Electric Trucks for Hauling Freight.—The New Weston Factory in Newark.—A Pony Delivery Service. An Electric Yacht.—The Board of Electrical Control.—The Electrical Exhibition.

A HEATED term in New York city brings into prominence the various electrical and mechanical devices which have been brought into use for facilitating local intercommunication. In these days the public patronizes both the telephone and district messenger service freely wherever physical exertion may be lessened by their use. The street railways are crowded beyond comfort, while the telegraph receives its quota of summer business from the vast throngs who have left their homes and business to seek recreation and rest.

Novel uses for messenger boys have always been a favorite theme of the newspaper reporter, and the latest instance is that of despatching No. 1,222 of the Mutual District company to London and return, as a bearer of souvenirs and congratulatory letters to the surviving writers of "The Highest Bidder," and other persons in that city. He sailed by the *Germanic*, on July 27th, with his blue coat buttoned up to his chin, his shoes polished to the highest possible degree, and after delivering his various packages to Edmund Yates, Henry Irving, and others, but more especially to Nate Salsbury and Buffalo Bill, he will return to this city, and return his tickets duly signed with copious reasons for delay written on their backs. While it may be a popular belief that messengers are frequently absent long enough to complete a trip to Europe, this will probably be the first actual attempt in that line, and the manager of the office will not worry himself over the connundrum "Where is my darling boy to-night?"

Among the various uses proposed for electric power, a dry goods merchant has suggested the construction of an electric dray, which he thinks might be made so much more serviceable than the horse truck now so generally used, as to relieve our streets of those vexatious blockades which are continually occurring. A proper preliminary step might be the improvement of the pavements, or the establishment of a system of trucking by a monopoly of proper dimensions, which would replace the present "every man for himself" method which now prevails. There is a chance for considerable of a reformation before a successful electric truck is devised, but the problem has been gravely referred to Mr. Edison as worthy of his attention through the columns of the *Sun*.

Manager Feary, of Newark, is ever on the lookout for some improvement in the delivery of messages. He used the telephone to a considerable extent for this purpose, but having disposed of his interest in the telephone company he has since substituted for it the gay and festive mustang pony. It is difficult to decide whether the pony or the bicycle would prove most desirable to the average messenger, but either will tend to make the service attractive, even should it not facilitate the delivery of telegrams.

Since the burning of the lamp department of the Weston factory, at Newark, the United States Electric Lighting Co. has decided to buy the property at 111 and 113 Orange street, and rebuild on the ground where the fire occurred. The price paid is understood to be $75,500, and upon the clearing away of the ruins, which is now in progress, one of the finest factories in Newark, will be erected as soon as possible.

A novelty in aquatic circles will soon appear in the shape of a yacht which is now building at Newburg. She will be 37 feet in length, and be driven by the current from a storage battery. This is the first vessel of the kind which has been built in this country, and her appearance in the harbor will excite great interest among professional and amateur seamen as well as electricians.

Renewed activity in subway circles has followed the reorganization of the commission under the title of the "Board of Electrical Control." Although its powers have not yet been exercised in the direct reform of abuses in electrical construction it may be readily seen that there is an opportunity for it to undertake other work which is perhaps fully as important as putting the wires underground. The rules and regulations as published by it, look to the consolidation of different routes of electric lines devoted to kindred branches of the business. Whether opposing interests are to be sufficiently harmonized to effect such a result appears somewhat doubtful. Had something of the kind been done years ago, probably the various underground bills would never have been heard of.

The electrical exhibition in connection with the American Institute fair promises to be a leading event of the coming season. The most serious question as to its organization, is perhaps the limited amount of space which is to be devoted to it, when the magnitude of the present electrical interests is considered. As it is not to be competitive, the usual annoying controversies as to the respective merits of the exhibits will be avoided. The various committees appointed have been selected with care, and the experience of the managers of the American Institute in combination with the energy and zeal of President Pendleton and Secretary Wetzler of the electrical section, will certainly lead to the best attainable results. The appropriation of $2,000 for the preliminary expenses enables these gentlemen to work with confidence that their plans will be carefully executed, as they are not compelled to depend entirely upon voluntary assistance.

NEW YORK, July 28th, 1887.

PHILADELPHIA.

The Baldwin Locomotive Works to put in a Westinghouse Electric Light Plant.—A Large Dry Goods House will put in a 1,300 Light Plant.—Electric Railway Experiments.—Incandescent Gas Lights to Compete with Electricity.—Mr. Edison Visits Philadelphia.—The Philadelphia Lighting Co.

THE Baldwin Locomotive Works have made a contract with the Westinghouse Electric Co. for the placing of an electric plant in their establishment, with a capacity of 2,700 16-c. p. lamps, distributed through the offices and machine shops, and 200 150 c. p. lamps for the finishing shops, the boiler shops and the yard. This will require the use of four dynamos, arranged to be operated independently or together. This will be the largest isolated incandescent plant in the United States.

A Westinghouse plant with a capacity of 1,300 lights is now being erected by the Keystone company for Strawbridge & Clothier, one of the largest dry goods and notion houses in the city.

A practical test of an ordinary street car propelled by stored electrical energy, given a few days ago by William Wharton, Jr. & Co. on their premises at 23d street and Washington avenue, was witnessed by a large party of gentlemen. The experiment was demonstrated on a circular track of 1,050 feet, the car at times containing as many as 35 passengers. The motive power consists of an electric motor which is suspended upon one of the axles underneath the car, and 80 small cells representing the storage battery, concealed beneath the seats. The track contains several sharp curves and a grade with a rise of five per cent. The car starts and stops with perfect ease upon any of the curves or upon a grade with 50 passengers on board. The operator has perfect control over the mechanism of the car, can stop and reverse instantly or regulate the speed from one to 20 miles per hour. The whole propelling apparatus is entirely out of sight and out of reach, thus avoiding all danger. The car is lighted by electricity, which also operates the signal bells. Mr. Wharton is desirous of introducing this electric motor car in the park. The commissioners, it is said, are pleased with its operation.

The various electric light companies will have to look to their laurels, and beware of the encroachments of the "Limited Gas Improvement Co.," whose friends claim that the company are preparing to meet the electric light with an incandescent gas lamp which will do much better than the most perfect electric lamp. (They don't seem to have any doubt about this in their minds.) It is said the company has purchased from Prof. Auer, of Vienna, the right for the United States of the Wellsbach incandescent gas light, which has created such a sensation in Europe. Extensive works will be erected in New Jersey at once for the manufacture of this new lamp, and four companies have been organized already, each with a capital of $4,500,000, and each with a separate territory. The company that is about to erect factories in New Jersey will control the manufacture and sale of the new lamp in Pennsylvania, New Jersey, Delaware, Maryland and the District of Columbia. None of the new lamps have been made in this country as yet, and there are but a few of them here. The gas people seem to have unlimited faith in this new venture, which is clearly indicated in the fact that they are contemplating the investment of $18,000,000 in introducing and manufacturing the lamps. Each of the lesser companies will be controlled, probably, by a syndicate, and the proposed capital will be furnished from this city. This appears (on paper) to be a beautiful scheme, and no doubt those who are in on the ground floor will be rolling in wealth as soon as the electric light companies are extinguished.

Thomas A. Edison was in the city recently, purchasing electrical apparatus for his new laboratory at Llwellyn Park, N. J., which is to be devoted entirely to experimenting. At present he is engaged on experiments in submarine signaling, the underlying principle of which is the remarkable facility afforded by water for transmitting sound. With an outfit of steam whistles and transmitters he hopes to make it possible for ocean steamships to transmit messages a distance of at least seven miles.

The county clerk of Camden has authorized the Philadelphia Lighting Co. to begin business, with a capital of $3,000,000. The new company proposes to furnish electricity for heating and lighting purposes. The incorporators are Thomas Cochran, James D. Potts, Clement A. Griscom and H. H. Houston of Philadelphia; George S. Webb and H. P. Linnell, of Camden, and Hobart Baird, of Woodbury.

PHILADELPHIA, July 18, 1887.

BOSTON.

Midsummer Vagaries.—Success of Electric Lighting in the Hoosac Tunnel.—An Electric Railway for Westfield.—The New Gamewell Police Signal System to be Tried in Boston.—The Boston Electric Club.—Boston Aldermen to Study Underground Systems.—Output of Telephones by the American Bell Co.—Resignation of President Forbes of the American Bell Co., Mr. Howard Stockton his Successor.—Mr. John J. Carty to go to New York in the Service of the Western Electric Co.

As a specimen of mid-summer journalism the following concerning the gentleman who provides for us the greatest show on earth will be interesting:

> The French inventor of a cable, said to be peculiarly fitted for use with the telephone, invites Mr. Barnum's attention to a scheme for connecting the Paris Opera with New York. He says that the telephone can be used for other purposes during the hours when the Opera is not tapped, and great profits may thus be earned. But his calculations for profit on the opera connections are far astray from the probabilities. For instance, he suggests that each person in an audience of two hundred be taxed $5 for each act. Thus a four-act opera would cost each hearer $20. To say nothing of the difficulty there would be in changing the audience or collecting the fee for each act, there is to be considered the small chance of gathering an audience every day in the hours when the performance could be heard in New York only, say from 3 to 7 P. M. Furthermore, there is the interesting fact that performances at the Paris Opera depend largely for their success on the scenery and ballet, the singers not ranking very high. Merely to hear a work in that great house is not a great musical treat, as matters stand. To hear it filtered through three thousand miles of wire, so to speak, is certainly not worth $20. The letter, which is signed by Jules Grunkey, looks very much like a guy on the veteran showman, if it be not a little guy by the veteran showman on the *Bridgeport Standard*, which first printed the letter.

An exploiter, who has compassed one continent and the great English-speaking nations with his invention, which, by the way, is understood to have been first intended for a screw-nail, and after getting his second wind, applied it as a telephone conductor, writes as follows to a local paper about telephoning between this country and Europe:

> Telephoning through a wire being only and simply a wave of reproduction, similar to an air wave of sound, or I might say a wave of the ocean, is perfectly practical for three million miles, and in fact more so under water than aerial, for disturbances atmospheric do not occur under water, nor do disturbances occur at a depth below a given sounding distance below the surface of the water, as the water at that depth is at rest. The small steel wire which I already have used for four years under water is a perfect reproducer, and will reproduce three million miles far better than the one hundred miles now so long in my service, and giving clear reproduction of conversation, and without any induction whatever. I am hoping after three—yes, four—years' delay by illness abroad, to be ready in the fall to resume my work, and trust I may yet live to carry it out.

Word comes from North Adams that the week and a half trial of the electric light service in the tunnel has proved entirely satisfactory. The Westinghouse incandescent light company is meeting with a competitor in the Brush arc light company, who are arranging a set of their lamps as an experiment. After they have been tested for a time a choice will be made between the two systems and the entire length of the tunnel lighted. It is also possible that the system will be continued to the local yard and depot, where numerous lights will be distributed.

Formal application was made on the 8th inst. to the authorities for the privilege of running an electric street railway in Westfield. Two New York men with capital to invest furnish the bulk of the money to secure the plant, and offer to take the entire $25,000 of capital stock in case the local business men who have pledged $6,000 or $8,000 to the enterprise wish to withdraw. A meeting is to be called Wednesday night, when it will be decided whether to hold on to the local stock or let the New Yorkers have it all to themselves.

Captain Coulter, of Police Division 4, acting under instructions from headquarters, has made arrangements to test the Gamewell police signal system in his district. This system differs from the one now in use in South Boston, and its inventor believes it to be superior to all others. The coming test will be made with a view of deciding this question.

A meeting of the newly-formed Boston Electric Club was held on the afternoon of the 21st inst., at 70 Kilby street. The club is organized for the purpose of promoting harmony between those engaged in various electrical interests. A constitution and by-laws were adopted, and the following-named officers elected: President, Frank Ridlon; vice-presidents, W. J. Hammer, Thos. D. Lockwood, W. B. Hosmer, H. J. Pettengill; secretary, Allan V. Garratt; treasurer, Herbert H. Eustis; historian, W. J. Hammer; executive committee, C. N. Ransom, S. E. Barton, B. S. Flanders, A. F. Mason, F. H. Sawyer, W. J. Daniels, Thomas Roche, C. N. Woodworth, John D. Gould, E. M. Rice, Jr., A. F. Upton, C. J. H. Woodbury, W. Brophy, W. I. Barker, F. M. Gilley; membership committee, A. H. Chapman, M. M. Slattery, Alexander Robeson, Sewell Smith, J. T. Moriarty; entertainment and reception committee, P. H. Alexander, F. A. Gilbert, R. F. Ross, Dennis J. Hern, Samuel Sias, J. E. Talbot, George W. Adams.

A committee was appointed to secure suitable quarters.

Before adjournment the president said the members of the club should remember that they were working for a common cause, namely, the advancement of practical results in electric work, and that the common end in view was to impart such knowledge to would-be investors in electric enterprises as would enable them to form the same judgment in this investment as they are able to form in other commercial enterprises. The object of organizing the club, he continued, is to promote a better feeling between those interested in electrical pursuits. The discussion of matters of interest will add to our knowledge of the requirements best adapted for promoting the general business in which we are engaged. Together with insurance men, we hope for a common end, the advancement of electrical lighting in the direction of

Digitized by Google

safety to the property of those using electricity as a lighting medium.

Mr. A. H. Chapman, superintendent of private lines of the New England Telephone Company, receives names for membership. The club seems to be in a strong, healthy condition, and no doubt will prove a success. Nothing appeals more strongly to the membership of a club than a good dinner, but to *maintain* such an institution a good *digestion* is absolutely necessary; hence the necessity of providing an intellectual superstructure over the culinary department; if the two are evenly balanced the whole man is supplied. In a promiscuous club the intellectual is not apt to predominate. Just here is a difficulty, and one which the "electric clubs" now forming in the principal cities will have to make a note of. A "stomach" club runs to decay in a short time, and benefits nobody. The finer elements composing the electrical profession would soon sift out from such a club. Better things are to be hoped and expected for the electric clubs; they can be made to serve the social tendencies of their members, and also prove helpful to the accumulation of knowledge.

On the 27th ult. the municipal joint committee on underground wires, in response to an order of inquiry as to the feasibility of placing all electric wires underground, reported that in view of numerous complaints made concerning poles and wires, it would seem that a remedy should not longer be delayed. The only effectual method of relief that suggests itself at present is the placing of wires underground, and this plan, it is claimed, has not yet been sufficiently perfected to admit of its adoption in some branches of the business with any degree of success. The system of underground wires is in successful operation in other cities of the country, and the committee recommended the passage of an order authorizing them to visit the cities of New York, Brooklyn, Philadelphia and Washington. The order was passed.

This is supposed to be a little junket. When the report of the committee was reached Mr. Whitmore, of Ward 12, moved to limit the expenditure to $500, but the motion was lost by a yea and nay vote of 22 to 25. The order was then amended by limiting the amount to $800, and passed in concurrence. This was in the Common Council. When the order came before the Aldermen on the 5th inst. Alderman Carroll made some remarks in criticism of what he called the niggardly economy of the Common Council. He regarded the sum of $100 for each member of the committee to be inadequate.

The amendment was concurred in without any negative votes, and Alderman Carroll afterward offered an order, which was passed, authorizing the committee on electric wires, which is a standing committee of the aldermen, to visit the cities named to inspect electric wires, the expense, not exceeding $300, to be charged to the contingent fund of the Board of Aldermen.

The committee consists of Aldermen Maguire, Carroll and Sullivan. They also compose the membership on the part of the aldermen on the joint committee on underground wires. The arrangement as thus completed is that as of the joint committee, these aldermen get their share of the $800, which the "niggardly economy" of the Common Council provided, and also $300 besides.

It is to be hoped the committee will receive more information than a recent committee inspecting the new reservoirs of the Water Works did; at least one of them, Mr. O'Toole, we will call him. He seemed out of place and uncommonly thickheaded until the return in the cars. While gazing out of the window at the works he saw something that gave him great pleasure, and exclaimed: "That's the foinest patch of praties I've seen the day!"

The American Bell Telephone Co.'s statement of the output of telephones for the month ended June 20, and the year to date, is as follows:

June.	1887.	1886.	Increase.
Gross output	6,971	4,581	2,390
Instruments returned	1,598	1,216	382
Net output	5,373	3,365	2,008
Dec. 1 to June 20.			
Gross output	28,663	21,635	7,028
Instruments returned	11,114	9,262	1,852
Net output	17,549	12,373	5,176

At the directors' meeting of the American Bell Telephone Company, July 12th, Mr. Wm. H. Forbes resigned the presidency of the company and Mr. Howard Stockton was elected to the position. Mr. Forbes remains as a director. Mr. Forbes's retirement is on account of a need of more leisure than the requirements of the office afford. Mr. Stockton is the treasurer of the Essex Manufacturing Company, and a large stockholder in the American Bell company, a lawyer of ability, and the treasurer of the Cocheco, Salmon Falls and Essex manufacturing companies. He has held these latter positions for some time, and is well known in Boston business circles as a man of excellent judgment and high executive ability. He has for a long time been a large holder of Bell telephone stock, and has always taken an active interest in the affairs of the corporation. In assuming the presidency of the company, he proposes to pursue, in every particular, the present policy of the management, and no changes in any department are contemplated. As matters now stand, Mr. Stockton will take his new position just as soon as Mr. Forbes and the board of directors can make certain necessary arrangements, or some time by or before October 1. Mr. Forbes will still remain on the board of directors. Mr. Forbes has done great things for the Bell company; he came into the management of its affairs when money and the interest and support of capitalists were greatly needed; through his influence strong financial aid flowed to the company, and it became one of the most prosperous of corporations. It is understood that Mr. Forbes has made a fortune in the business.

Mr. John J. Carty, for several years the superintendent in charge of the operating room of the Boston Telephone Exchange, has resigned to enter the service of the Western Electric Company. He will be located at New York, and his special work will be in connection with the cable work of the Western Electric Company. Mr. Carty will be greatly missed, as the present fine condition of the Boston Exchange is due to his intelligent and faithful supervision. He has done good service as an inventor, having patented several ingenious and meritorious devices relating to telephony. Success may be expected to follow Mr. Carty in his new field of work.

BOSTON, July 18, 1887.

CHICAGO.

Break-up of the Carbon Combination.—Prospective Sharp Competition for the Chicago Electric Light Contracts.—The Death of Mr. A. C. Holland.—The Chicago Electric Club.—Success of "The Western Electrician."—Mr. C. H. Macliile Assumes the Western Management of the "Electrical World."—The Western Electric Company.—The Proposed City Tax on Telephones Declared Illegal.—Prof. Gray's Telautograph.—Troubles of the Central Union Telephone Co. in Indiana.--The American Cushman Telephone Co.

RECENT advices from St. Louis and Cleveland point to the disruption of the United Carbon Companies; in fact, the Parker-Russell Co. put the matter bluntly in a circular letter dated July 15th, quoting carbons at the old prices and soliciting orders direct, by saying they have decided that no one can attend to their business so well as themselves. The Boulton and Cleveland companies, at Cleveland, are said to have made large sales within the past few days at low rates. We believe that all consumers will be glad to see the combination broken. It commenced operations a few months ago in a high-handed way, under the leadership of E. C. Hawks, agent, by getting control of the old and leading manufactories of carbon points and then immediately doubling prices. The shoe has not pinched much, because large dealers have been protected by large contracts at old prices, and they have protected their customers. With the running out of those contracts came the recent agitation and the proposals of the gas men at St. Louis and the electric light companies at New York to make their own carbons. But now that the pool is broken the business will probably be left in the hands of the old and experienced manufacturers, and carbons furnished at prices satisfactory to them and their customers.

The different electric light companies will undoubtedly have a tussle over the sale of the plant for lighting a part of the river and bridges, bids for which will be called for in the course of a few days. It is well known how hard these companies fight for business, particularly for large city contracts, where the precedent is so valuable. May the best win in this case. The present limit of expenditure is $15,000 for lighting the river and bridges from Halsted street on the North Branch to Halsted street on the South Branch, and from these points to the mouth of the river. For this will be purchased dynamo capacity for 100 full arc lights, with 100 double-carbon lamps.

Much more business with the city than this is in view, however, as a vigorous effort is making to secure the lighting of the whole length of the river and all the streets in the city, and under these circumstances what electric light company would not work hard for the first contract and the advantage point to be gained by the satisfactory filling of it?

The many friends of A. C. Holland, and the firm of Johnson, Holland & Co., of which he was a member, were shocked to hear of his sudden death on the first day of this month. Only 25 years old, and with brilliant business prospects, it was shocking to learn of his death, as by lightning, in the spring time of life. The stroke came from an electric light current, the same murderous circuit, we are told, from which engineer Moeller got his death stroke a month ago. Mr. Holland was connecting a motor in circuit, for the purpose of operating a ventilating fan in the kitchen of a South Clark street restaurant. While working, thoughtless of danger, with his knee upon an iron trough, whose waste pipe made a good ground connection, he received the full force of the current, throwing him to the floor insensible. Every effort was made to revive him, but in a few minutes he breathed his last.

Permanent rooms have been selected by the Chicago Electric Club on the ground floor of the new building 225 Dearborn street. The committee who made the arrangements are to be compli-

Digitized by Google

mented upon their choice, as the location is central, being opposite the post-office, and the rooms, which are open to the members at all times, convenient for business and social meetings. The first meeting was held there July 11th, and a large number of the members of the club, with some visitors, listened to an interesting paper on "Unworked Territory," read by C. C. Haskins. Mr. Haskins, by way of illustrating the opportunities of electric light people for entering new fields, spoke clearly of the dangers to life and property from the use of oils on vessels; then he showed the advantages, both to owners and insurers, of the use of electric lights in the boats and on the docks. Mr. C. O. Mailloux, in commenting upon the main thought of Mr. Haskins's paper, showed the advantage of the use of storage batteries in connection with dynamos. An interesting discussion was then brought about by Mr. H. Ward Leonard's request that those present give their views of such cases as have come under their observation of loss of life from electric light currents. The electricians present could not agree upon the exact cause of death from strong currents, and Mr. Badt was unanimously requested to prepare a paper on this subject, to be read at the next meeting of the club.

The Western Electrician meets with a warm welcome, both in advertising and subscription patronage. The first three issues that have appeared show careful and good editing, and in its typographical appearance it has no superior among weekly journals.

The *Electrical World* is to be congratulated upon having secured the services of Mr. C. H. Maclilie as western manager. Mr. Maclilie comes from Kansas City, but he is no stranger in Chicago, and we apprehend that in his hands the interests of the *World* will be well looked after.

The Western Electric Company have secured contracts, of which they feel very proud, for a complete electric outfit for the mammoth new wholesale dry-goods house of Marshall, Field & Co. They will light the building throughout with 180 of their arc lights, and will introduce a telephone system with thirty stations, arranged so that any one station can call up and converse with any other station without disturbing the rest, no central switch-board or operator being required. Each floor will be protected by the electro-mercurial fire alarm, and will have electric call bells and other signals in abundance. The same company have recently fitted up the excursion steamer "Ivanhoe" with their electric lighting apparatus.

Your correspondent called attention in a previous letter to a proposed city tax on telephones, many members of the council putting themselves on record as in favor of taxing each instrument $25 per annum. The matter was referred to the corporation counsel, and he has settled it by submitting his opinion that the proposed ordinance is illegal.

It would be gratifying to be able to give your readers some exact information about the "telautograph," the latest invention of Prof. Gray, but he is not ready yet to have his process made public. Inasmuch as he has shown some of the results of its work to his friends, however, and they all express themselves as astonished at the invention, there can be no doubt but that the professor has something very interesting, if not revolutionizing. The writing is done upon a plate, with any kind of sharp-pointed instrument, and, by an electric current, is reproduced in fac-simile at a distance. There are old and well-known processes for accomplishing such work, but they have all been in the realm of the impracticable. What Prof. Gray claims is that his process is practical for every day use, and he is reported as saying that he is inclined to think the machine will be required in all cases where absolute accuracy in the delivery and filling of an order is required, and that it will eventually supersede the present system of telegraphic communication. Some interesting correspondence in the daily papers has been called forth by the published accounts of this invention, some writers seeming to think it worth while to put themselves on record already as knowing that there can be nothing original about Gray's invention, in spite of the fact that his process has not yet been made public.

The following is from an incisive reply by J. E. McKibby to a letter recently published under the title of "Gray's Invention a Chestnut":

The article headed "Gray's Invention a Chestnut," signed "Coates," does not reflect in the least on Gray's ability as an inventor, or upon his invention, neither of which need any defense nor laudation from any man's pen. In 1850, before Gray had completed the carpenter trade, F. C. Bakewell, of London, brought out his "Copying Telegraph," for transmitting anything that could be put on paper, by means of a pen, and reproducing it at the distant end. In 1856, Abbe Casselli, of Florence, Italy, introduced his pantelegraph (autographic), which before its final abandonment attained a speed of sixty messages per hour, averaging 20 to 25 words each, on the Paris-Lyons circuit. Then came Meyer, of Austria; Lenoir, of France; W. E. Sawyer, of Washington, D. C.; Amos E. Dolbear, Smith, Edison, *et al.*, up to 1879, when E. A. Cowper, of London, acquired United States patents for his invention. In 1881 Leggo gave his invention to the world, upon which was formed the American Autographic Telegraph Company, now the Postal Telegraph and Cable Company. In 1886 Robinson, of New Jersey, acquired United States patents for a machine very similar to Cowper's, who also acquired fresh patents in 1886. Except Robinson's, they are all housed where the public won't mistake them for O'Donovan Rossa's "missionaries." The history of the telephone is analogous. Borseul, 1858; Reis, 1867; Yeates, Varley, 1865; Meucci, Cushman, Drawbaugh, Vanderweyde, Pickering, Cross, etc., all had "telephones," "talking telegraphs," etc., but Bell made it commercially practicable in '76 and '77, twenty-five years after Cushman, in Racine, Wis., claims to have talked yards and yards of talk over miles and miles of wire. The dates and names on the autographic telegraphs herein given are from well-known electrical text-books treating of telegraphy, and are to be found in all electrical libraries and the Chicago public library.

Prof. Gray has consented to deliver a course of lectures at the Lake Forest University the coming collegiate year. His subject will be electricity and magnetism.

The Central Union Telephone Co. are having no end of trouble in their efforts to make a living in Indiana. Their change from rental to toll system is meeting with a great deal of opposition, and they have been obliged to close a number of small exchanges. At Lafayette the city council has passed a resolution depriving them of all privileges unless they conform with the law of the state; at Goshen they were ordered the first of this month to remove all of their poles and wires from that city within sixty days, and at Indianapolis there has been continual trouble. The plan of the Central Union Co. is to make each subscriber a toll station, the charge to subscribers to be three cents per connection, and to others five cents, but each subscriber is required to purchase four dollars' worth of tickets per month, with the stipulation that all tickets unused at the end of each quarter will then become void. And the only alternative the company offers is the removal of the instruments. To illustrate the temper shown in opposition in some places, some facts about South Bend, where the C. U. company has had a flourishing exchange with over 200 subscribers, are of interest. As soon as the change was made an agreement was signed by most of the subscribers that they would go without telephone service rather than accept the toll system, and a meeting was held in the council rooms, with Mayor Loughman in the chair, at which the following resolutions were adopted:

Resolved, That we regard the toll system offered by the Central Union Telephone Co. as one which to accept would require us to abandon dignity, forget truth, lay aside business principles, and array ourselves as in fact aiding to violate law; abandon dignity by making our offices and our homes public stations, agreeing to neglect our business and serve the public on demand, and have our homes ever ready with open door, all for the compensation of 5 per cent. of 60 per cent. of a nickel, equal to 15-100 of a cent for each service, an estimated aggregate probability of ¼ of a cent per day, for rent, fuel, light and personal attention—a proposition so clearly a farce and so impractical that to agree to it would be to consent and obligate to do that which we know we would not, and hence untruthful, and because undignified and untruthful and meaningless upon our part, unbusiness-like to sign such a contract, as it may have its full meaning and carry its full obligation in the hands of those to whom given; aiding to violate law, as there is now in force upon our statute books an act forbidding the taking of more than $3 per month for the use of a single telephone, and the requirement that $4 worth of tickets must be taken per month as a condition upon which a telephone may be had, as in fact but a rental of $4 per month as a minimum with a probability of much more.

Resolved, That the common council of South Bend be respectfully requested to notify the Central Union Telephone Co. to comply with the laws of the state limiting the charge for one telephone or instrument to $36 per year or $60 for two instruments, or remove their instruments and wires from the streets and alleys of the city by July 15, 1887.

The request to the common council was complied with, and on the 11th inst. the Central Union company were ordered to remove all their poles and wires from the city by the 10th of August. The cry for a competing telephone was heard by the American Cushman Telephone Co., who offered to open an exchange if they were given such a city franchise as the old company were losing, and could open with not less than 150 subscribers. The result of the agitation at this writing is that the Central Union company have about 12 lines in operation and the Cushman company have not secured the requisite number of patrons, and the people are getting along as best they can with messenger boys and the telegraph.

The American Cushman Telephone Co. have their headquarters in Chicago, and are doing a lively business. They sell telephone instruments, similar to the Bell, to whoever will buy them, and a good-sized exchange at Findlay, Ohio, is operating with their instruments. The Bell company appear to be somewhat inactive now in chasing infringers, but it is expected that they will take hold of such matters vigorously as soon as their case in the Supreme Court is decided.

CHICAGO, July 19, 1887.

SAN FRANCISCO.

The Postal Telegraph Company's Pacific Lines.—Canadian Obstruction.—Mr. N. S. Keith Supplying Dynamos and Motors.—Electric Railway Notes.—Contention Over Electric Light Bills in San Francisco.—Mr. F. B. Converse and the American Electric Light Co.—An Old Time Telegrapher.—Unjust Aspersions on the Course of Mr. Frank Jayres.—An Operator Under Charges of Misbehavior in Connection with Pool Sellers.

A RIPER field for a healthy competition than California was and is, has never been presented to an opposition company. Yet, considering the fact that the Western Union is doing an unprecedented business, and the Postal people know it, no move is being made nor contemplated, apparently, toward extending their lines south or east by some other and more reliable route. Mr. Robeson is concentrating all his energy upon a local business northward and is doing well, but his American energy is handicapped by Canadian apathy. He cannot place any reliance on an eastern connection *via* Canada; nor does he make any effort to secure eastern business save to notify the friends of the Postal once or twice a week "that the Postal is O K east." Do the

Digitized by Google

Canadians want to boycott American despatches as they do American ships from getting bait? Or are they so strongly entrenched in their ante-deluvian isolation that such an outlet to civilization is not desirable?

The agency of the Canadian Pacific railway has had photographic views of the scenery along that route on exhibition in this city. "The apparatus don't lie." We see a telegraph pole with one small cross-arm; one insulator holds a wire the other is empty, but about three feet below the cross arm is a cleat nailed to the pole, and a wire is loosely and slovenly attached. One soliloquizes: "No wonder the Postal have no wire east." Mr. Robeson has secured the Rocky Mountain Telegraph Co.'s wire from Medicine Hat, on the Canadian Pacific, to Salt Lake. This will pass through Spokane Falls, Helena, Butte and Northern Utah towns, and if it stands it will be a valuable local connection.

By the way, your correspondent is in receipt of several notes asking him to criticise the local management of the Postal and others. His criticism of the management of the Postal last February stands good, and he has had no reason to change it, but would remind the gentlemen that he is not, and never will be, the tribune for personal malignity, and he would remind them that vilification is not criticism. Were he that way inclined he could "unpack his heart with words and fall a cursing like a bawd" on his own account.

N. S. Keith has an office in the Nevada building and a factory in the Pacific Tool Company's establishment, where he superintends the construction of his dynamos. He is manufacturing many for various trades and enterprises, and it is believed he may furnish the San Jose electric railway with dynamos and motors.

The road-bed for the above road is being built, and it is now only a question of a month before the second electric road in California will be in operation. I have heard nothing authentic lately of the Sutro experiment, but I am told that it will be all right soon.

E. P. McCarthy, the city gas inspector, and a man who owes his place to the influence of the gas company, refused to audit the bill of the California Electric Light Co. for outside lighting because he claimed a 7-16 carbon was used instead of ½-inch and ⅝. Mr. Roe had N. S. Keith and others as experts, who demonstrated to the satisfaction of the supervisors that the diameter of the carbon had nothing to do with the brilliancy of the light, influencing only its duration, as the intensity of the light depended on the force of the current. Mr. McCarthy wants the writer to loan him "Prescott on the Electric Light." The bill was paid.

The American Electric Light Co. were sending Mr. F. B. Converse to Australia. He was here with his wife and son about to embark when he received a telegram canceling the engagement, thus throwing him back considerably. Pending a satisfactory explanation for this sudden change, he is working with the Western Union company.

It is a pleasure to meet a representative old-time operator, one who, at least, had the benefit of a common school education, and by his deportment demonstrated that he had associated with gentlemen. It was a pleasure of this kind a few days since to meet Mr. T. S. Davidson, ex-chief operator of Buffalo, N. Y., for the Western Union. Mr. Davidson is to be sent to Los Angeles to fill an important position, where a man of his calibre has been very much needed for some time.

Again the malignant shaft of disappointment, envy, hatred, or jealousy—call it what you will—has been hurled at Mr. Frank Jayres through the operators' organ. If it contained the truth, as regards Mr. Jayres, it might be allowed to pass unnoticed, but it says "he withheld the extra for two months after Col. Clowry allowed it." This is a base falsehood, and does the man—who paid salaries of $90 and $100 per month, and endeavored to keep it up, when eastern superintendents were only paying $60 to $75—a gross injustice. He may have faults, and one of them may be a blind confidence in men who abuse it through an insatiable desire to exhibit their ephemeral prominence, but that he is not the friend of the operators, or that his superior in executive ability holds a similar position in the Western Union, may be emphatically denied, and 25 years experience ought to qualify the writer to judge correctly. That the operators have many grievances in San Francisco must be admitted—their service is akin to slavery. Who is to blame? Mr. Jayres has no reports save the daily reports submitted to him by self-interested chief operators. Is there an office in the world where men working press wires for 6 to 10 hours a night would during a "let up" be taken from thence to clear up a city wire? It seems quite certain that if Mr. Jayres knew the actual state of affairs, redress would surely follow; but, no, being harshly treated by a chief operator and lacking the courage to go beyond him, the operators must resort to misrepresentation, and sometimes vilification and slander.

The newspapers and the bookmakers are making a great hubbub about one of the bookies being fleeced of $400 on "Kingdom," and an operator was suspended because he held the "post" message for a correct check. When the matter is thoroughly investigated it seems likely that the operator will be reinstated. If a skillful flank movement had not been made and suspicion directed towards him, it might have been towards some of the "favored few" who hug these wires and boast of their winnings. It is hardly fair to all parties for operators who work at "bucket-shops" in the day time to be employed as operators at night, having access to all "tips," etc. It has a greedy aspect at best, even if they were honest, but flesh is weak and money is enticing.

SAN FRANCISCO, July 21st, 1887.

ELECTRICAL NEWS AND NOTES.

RAILWAY TELEGRAPH SUPERINTENDENTS' ASSOCIATION.

SIXTH ANNUAL MEETING AT BOSTON, JULY 13TH AND 14TH.

THE sixth annual meeting of the Association of Railway Telegraph Superintendents was held at the Tremont House, Boston, on Wednesday, July 13th.

The following members were present:—

Benjamin, F. H., N. & W. R. R., Lynchburg, Va.
Blair, S. K., N. Y. C. & St. L. R. R., Fort Wayne, Ind.
Boyd, L. A. L. D. & S. R. R., Indianapolis, Ind.
Bogart, S. S., N. Y. W. S. & B. R. R., Weehawken, N. J.
Chevalier, C. M., N. Y. & N. E. R. R., Boston, Mass.
Cohen, I., H. & T. C. R. R., Houston, Tex.
Darlton, C. A., R. & D. R. R., Washington, D. C.
Davison, C. B., C. St. P. M. & O. R. R., St. Paul, Minn.
Drew, P. W., C. & E. I. R. R., Chicago, Ill.
Goode, J. B., Moberly, Mo.
Hill, J. H., Southern Kansas R. R., Lawrence, Kas.
Hilton, C. E., N. & W. R. R.
Higgins, T. J., C. C. C. & I. R. R., Cleveland, O.
Holmes, W. J., N. Y. L. E. & W. R. R., New York, N. Y.
Kinsman, G. C., Wabash R. R., Decatur, Ill.
Lang, G. L., N. Y. & N. E. R. R., Boston, Mass.
Lattig, J. W., L. V. R. R., Mauch Chunk, Pa.
Leonard, M. B., N. N. & M. V. R. R., Richmond, Va.
Morley, W. K., C. & A. R. R., Bloomington, Ill.
Magiff, M., Central Vt., R. R., St. Albans, Vt.
Reynolds, C. C., I. & St. L. R. R., Mattoon, Ill.
Ross, J. N., N. Y. & N. E. R. R., Boston, Mass.
Robinson, H. C., B. & L. R. R., Boston, Mass.
Rowell, H. N., B. & M. R. R., Boston, Mass.
Selden, Charles, B. & O. R. R., Baltimore, Md.
Swift, A. R., C. R. I. & P. R. R., Chicago, Ill.
Shaw, J. B., N. Y. P. & O. R. R., Jamestown, N. Y.
Sheldon, L. F., M. P. R. R., Sedalia, Mo.
Smith, N, E., N. Y. N. H. & H. R. R., Hartford, Ct.
Simpson, G. E., C. M. & St. P. R. R., Milwaukee, Wis.
Torrey, E. E., M. C. R. R., Detroit, Mich.
Topping, C. E., L. I. R. R., Long Island City, N. Y.
Williams, G. T., N. Y. C. & St. L. R. R., Cleveland, O.

The meeting was called to order at 10:30 A. M., by President A. R. Swift, of the Chicago, Rock Island & Pacific railroad, who expressed great satisfaction at the full attendance. The fact that so many had traveled long distances in order to attend, was, in his opinion sufficient evidence of the interest that was being shown in the work of the association.

The report of P. W. Drew, secretary and treasurer was read and accepted. On motion of Mr. Lang it was voted that invitations to participate in the meeting be extended to the superintendents of the Western Union, Mutual Union, Baltimore & Ohio, and United Lines companies, who were located in Boston. Mr. Lang also announced that the committee on electrical railway appliances appointed at the last meeting had secured a few such devices which were on exhibition in an adjoining room. Among them was a very complete exhibition of telegraph and signaling instruments from the factory of Albert L. Russell, of Boston, the Waters-Sweeny Telegraph and Telephone Switch, manufactured at Terre Haute, Indiana, also the magneto signaling apparatus of the Pennsylvania Steel Co.

Mr. Kinsman, from the committee on an automatic recorder for railway telegraph lines, reported that the committee had met and experimented a little with a view to the solution of the problem of keeping a complete record of the business of a line, but they had not been able to satisfy themselves. In the opinion of the committee a register operated by a clock might be arranged to answer the purpose.

Mr. Sheldon said that he considered the matter of such importance, that he hoped to hear it thoroughly discussed. He believed that in the experience of all present there was no more important object to be attained in railroad telegraphy than the securing of a record of everything that passes over a circuit. In all cases of error there is a dispute which could be at once settled if a record existed showing what had actually passed over the line. If nothing better could be done, he should be in favor of going back to the use of registers. Upon motion of Mr. Leonard, Mr. R. W. Pope, was given the privilege of the floor, as Secretary of the American Institute of Electrical Engineers, and invited to describe the system adopted by the Gold and Stock Telegraph Co., for accomplishing a similar purpose.

Mr. Pope stated that in the process of distributing stock quotations, the plan originally adopted had been continued to the present time, which was briefly the transmission of quotations from the stock exchange over a Morse wire to the central office where they were received by sound, and read off from the

Digitized by Google

operator's manuscript by the transmitting operator of the printing system. At an early stage in the experience of the company, it had been found impossible to locate the errors which arose in the transmission of these quotations over the Morse wire. A self-starting register was first introduced, which was placed in charge of the operator in the superintendent's office. A spring circuit closer was so arranged under the register weight that an alarm was rung when it had nearly run down. At intervals of half an hour, the time of day was marked on the tape. This arrangement was satisfactory when the register was in perfect order, but the proper adjustment of the mechanism had become one of the lost arts, and it was frequently found that the record was incomplete through failure of the stylus to give a smooth and regular impression. By reason of other duties the operator could not give it continual attention, so that with the growth of the business, and the corresponding importance of a perfect record, it had been found advisable to run the register continually, and entrust its care to an operator whose chief duty it was to keep it in order. The complete record of the day's business is thus preserved and filed away for reference.

Mr. S. S. Bogart suggested the use of an ink register for such a purpose as being more reliable in its operations.

Mr. M. B. Leonard proposed using paper having lines marked across it, to indicate the time at which any communication might have passed.

Mr. C. Sheldon said that some of his circuits were idle a considerable portion of the time. It was important to know whether wires were worked to their full capacity. Lines were sometimes constructed uselessly at great expense. Such a record would also show how many unnecessary messages were sent. He was satisfied that 33 per cent. of the business sent over the Missouri Pacific lines was telegraphed unnecessarily. He had introduced blanks which the operators were instructed to enclose with such messages as they might consider unnecessary, which were sent to headquarters for examination. He had had as many as 150 messages returned that finally had to pass. Mr. G. C. Kinsman agreed with Mr. Sheldon as to the evil spoken of, and had found the system as adopted of returning unnecessary messages very satisfactory. Such a message was sent to the head of the department from which it emanated, and if it was finally decided that the message could have gone by train mail without detriment to the service, the sender was called upon to pay the tolls.

Mr. S. S. Bogart inquired where the operator was to be found who could decide as to the importance of a message by merely reading it.

In his opinion the adoption of such a rule would make more trouble than it would prevent. He suggested that the gentlemen should call at the Western Union main office in New York, and witness the operations of the chronograph register which showed the minutest variation in the record of seconds of time, and had never failed to operate satisfactorily during years of service.

On motion of Mr. W. K. Moreley, it was voted that a committee of three be appointed to visit New York, and examine the apparatus mentioned at 16 Broad street and 197 Broadway. The president appointed Messrs. C. Topping, S. S. Bogart and M. Magiff, as such committee.

The discussion again drifted into the question of unnecessary telegraphing, regarding which a committee had been appointed at a previous meeting.

Mr. Sheldon was of the opinion that the highest officers were at fault, but although their names were signed to the telegrams it usually proved to be the officer's clerk who had prepared the message. Many messages referred back to him as useless had upon investigation proved to be important. If it was known that messages were liable to examination he believed that it would tend to lessen the number offered.

Mr. Charles Selden said that he had kept careful watch of this class of business over his lines, and was satisfied that four-fifths of it originated with the general officers of the road, and one-fifth with himself. The exercise of judgment in endeavoring to discriminate in this matter was liable to lead a person into deep water. As an instance he might mention a message to the general passenger agent, saying that "Miss Louise will meet you at train." This was considered as foreign to the management of passenger traffic, but upon investigation it was proved to him that the lady mentioned was the principal of a large female seminary, and that the object of the appointment was the fixing of a reduced rate of transportation west for the students at the close of the term. He was heartily in favor of the introduction of such a recorder as had been mentioned upon all train wires. The introduction of such an instrument was merely a question of time. It could be driven either by a weight, spring, or motor. It was his desire to introduce every possible protection against error or delay in the service.

Upon the suggestion of a member the president added Messrs. W. J. Holmes and Charles Selden to the committee, making five in all.

Mr. J. W. Lattig considered it a very simple matter to introduce the proposed recorders. It was merely a question of expense. Where several lines concentrated a good operator could attend all of the registers. His practice was to select a relay office where good men were employed. They examined the files and selected such messages as were considered useless.

Mr. Sheldon said that he had one office where eleven lines centered where the business handled amounted to 2,500 messages daily. Many messages were referred to him, but he believed 1,000 of the messages were of so little importance that they might be held, and they never would be inquired for. Although he had paid considerable attention to this subject he had not succeeded in stopping more than 5 per cent. out of the 33⅓ which he had mentioned.

Mr. Selden said that on the Wabash system business became very heavy by reason of messages regarding line freight being sent over their wires, because they worked better than the others. He was being continually called upon to reduce expenses. At one time they handled 150 messages regarding a shipment of tea, and the Chicago, Burlington and Quincy road finally secured the freight.

Mr. Holmes believed that all had met with varying success in connection with this matter. He had been at it for 30 years. It was his opinion, however, that the railroads needed more telegraphing rather than less, and that facilities should be provided for handling the increasing volume of business. What prospect was there of stopping any of the telegraphing of the general traffic agent? They should make the best possible use of their facilities, and if necessary, ask for more wires.

Mr. Sheldon agreed in the main with Mr. Holmes, but mentioned a case where the general passenger agent sent a message of about 400 words, regarding an excursion, and after the bargain had been closed, he sent another of the same length, arranging for the train, although the date of the excursion was two weeks in the future.

Mr. Simpson remarked that the expense of this unnecessary business was not the only point to be considered, but also the burdening of the wires and the consequent delay of more important business.

After some further discussion of the subject, Mr. Lang announced that an excursion to Nantasket Beach had been arranged for the afternoon, and as the heat of the room was oppressive, and many of the members were fatigued from their long journeys, an adjournment was taken until the following morning at half-past nine o'clock.

THURSDAY, JULY 14TH.

The meeting was called to order by President Swift at 9.45 A.M. After the election of several new members, Mr. Lang, chairman of the Committee on Symbols, was called upon to report. He stated that the committee appointed a year previous to the one which he represented, in undertaking to propose a substitute for the existing Morse character for the cipher—a long dash—had bitten off more than they could chew, and that in this respect he agreed with the old committee. They had held several meetings and consulted with representatives of the commercial lines as well as nine-tenths of the railroad lines centering in New York and Boston. From several letters which he had received from different managers and superintendents the various opinions were given that the old character was no more productive of error than a new one would be; that operators should be required to space properly; that there is no necessity for a change. General Superintendent Leslie suggested the character — — - — and objected to the character - - - which had been mentioned by the previous committee, believing as he did, that additional spaced letters should be avoided.

Mr. Selden believed that a change should be made, and remarked that the United Press had introduced several new characters which were gradually coming into general use. If necessary, he could upon his return make any change recommended, which would go into use from Philadelphia to Chicago. He was heartily in favor of the adoption of some symbol by the association.

Mr. Sheldon inquired what objection there was to the adoption of the Continental alphabet.

Mr Bogart said that in a test of four days made by the Western Union Telegraph Company some years ago, the Morse alphabet came out 1,728 words ahead. The ratio of speed was as 42 to 38 words per minute in favor of the Morse.

In reply to an inquiry from Mr. Sheldon as to the Continental alphabet being less liable to error, Mr. Bogart replied that it was not, and that he considered himself a good operator with either alphabet.

Mr Topping remarked that the efforts of the committee had arrived at naught. They had found no desire on the part of the Western Union Company to do anything in the matter.

Mr. Lang added that there was but one opinion in the association as to the desirability of a change, but no person has stepped forward and presented a symbol that will stand. Each one appears to have an opinion of his own as to how the reform should be made. This was the third meeting at which the subject had been discussed and nothing had been accomplished.

Mr. Drew believed that the trouble did not arise from the

Digitized by Google

use of the long dash for a cipher but where the letter L is used as an abbreviation.

Mr. Selden observed that it occurred elsewhere, as for instance where a car might be numbered as 0094 according to a system in vogue upon some railroads.

Mr. Sheldon said that an alphabet was like a language, it was not built up but it grew. The united authorities of the world had tried to introduce a universal pronoun but it could not be done. He knew of but one instance in which a word had been deliberately and scientifically coined which had proved a success, and that was the word "telegram."

Mr. Selden said that Mr. Walter Phillips, of the United Press, had taken this subject up and made it a special study. He talked it over with his men, and when they were satisfied with the desirability of a new character it was introduced and used wherever their wires ran.

Mr. Sheldon stated that in 1853 a telegraph convention was held at Washington. As one result of their deliberations it was recommended that the characters C and K of the Morse alphabet be transposed. An attempt was made to carry this idea into practice, but so many serious errors occurred that it was finally abandoned. He remembered a single instance where a message addressed to E. W. Klarc & Co., was undelivered for several days because no one knew the address which was intended for E. W. Clark & Co.

Mr. Topping thought it rather humiliating for the association to confess that they could not substitute a symbol for either the cipher or letter L, but he believed there ought to be a change. The committee had labored faithfully in the work. The confession of all who were interviewed was to the effect that an attempted change would merely make matters worse.

Mr. Sheldon said his operators worked with the Western Union offices, and that the contract between the companies required that the Western Union regulations should be complied with, which rendered it still more difficult to make the proposed change.

Mr. Selden believed that the Western Union officers recognized the strength they derived from their alliance with the railway lines, and that they were inclined to be progressive, and would adopt the new symbol as soon as it was convenient. It was his opinion that if a suitable character was introduced by the association it would come into general use within six months.

Mr. Lattig stated that the Western Union company had about 11,000 offices, of which 9,000 were railway offices, therefore if any considerable number of railroads introduced the new symbol as suggested, it would go into use. On the Lehigh Valley road blanks are used, designated by such numbers, for instance as Q 053. It was frequently found impossible to designate such blanks by telegraph without error.

Mr. Holmes felt certain that the Western Union company would co-operate in the work. The Erie people had made some attempts at innovations, but Prof. Morse had constructed his alphabet upon such scientific principles that they had not been able to improve it.

Mr. Sheldon remarked that he had instructed his operators to send whatever was written. All kinds of abbreviations were used on the Missouri Pacific, but he believed a universal system of abbreviations would be an improvement

It was finally voted that a committee of three be appointed to devise a symbol for the cipher to take the place of the present long dash, and submit the same to the members for approval. The president appointed Messrs. Selden, Topping and Holmes to serve as such committee.

Messrs. J. B. Shaw, G. T. Williams, and G. E. Simpson were appointed a committee on resolutions.

Upon motion of Mr. Selden, it was voted that the next meeting of the association be held at New York city, on July 14th, 1888.

Mr. Topping extended an invitation to the members to visit Manhattan Beach at that time, offering transportation for each of them, and space in the sea.

The association then proceeded with the election of officers for the next year, the result of which was announced as follows:

President, G. L. Lang, of Boston, Mass.; Vice-President, G. C. Kinsman, of Decatur, Ill.; Secretary and Treasurer, P. W. Drew, of Chicago, Ill.

A general discussion on signals led Mr. M. B. Leonard to remark that electricity was becoming a most important factor in railway service. It was used for lighting, and signal connections with locomotive cabs, and for other purposes. The Chesapeake and Ohio company was using electric signals at two or three tunnels. He believed that it was for the interest of the telegraph superintendents to enlarge their field of usefulness. While abroad we find telegraph superintendents rated as electrical engineers, and giving their attention to various electrical appliances in connection with the railway service, we were not extending our knowledge beyond the realm of the telegraph.

Referring to the use of electric signals, Mr. Lang stated that the New England company had about nine miles of continuous signals in operation which had operated satisfactorily until the road-master had ballasted the track with cinders which caused trouble.

Continuing, he announced that the Boston & Maine railroad company had extended the association the courtesy of a complimentary trip to Point of Pines in the evening.

A committee of three, consisting of Messrs. Bogart, Selden and Shaw, was appointed to examine and report upon various electrical appliances in connection with the railway service.

At the request of ex-president Swift, President Lang then took the chair, receiving from the hands of Mr. Swift the gavel of the association, a miniature telegraph pole of mahogany fitted with cross arms and pins, supported in a silver standard. It was originally presented to Mr. Swift by B. R. Verbyck, master car builder of the Rock Island railway.

In accepting the gavel, President Lang said that, although proper attention to the duties of the office required considerable work, he considered it a compliment, and believed that the holding of such an office should be properly appreciated by the incumbent as it was looked upon as giving a standing that was not only beneficial to the person accepting the position but to the company by which he was employed. He stated that the New England roads had given very little attention to their telegraph service, some of the most important companies depending upon the Western Union. He promised to continue as he had begun in doing all in his power to promote the welfare of the association.

Mr. Swift called the attention of the association to the existence of an operators' union which had been organized in the west, and although he had no knowledge of the extent to which it had been developed in the east, he believed that its growth was detrimental to the interests of the companies. The organization had been in existence about two years. Its headquarters are at Laporte, Iowa, where the officers devote their entire time to the interests of the order. The ritual of the order was read by Mr. Swift, and a general discussion followed, during which it appeared that organizing officers were working in the east, and that there appeared to be a considerable amount of ability shown in extending its operations. No definite action was taken but it appeared to be the sense of the meeting that upon their return to their homes, the members would look over the ground, and possibly step on the head of the animal, to see at what distance his tail would wiggle. The fact that it had been asserted that the order included some superintendents in its ranks led to a mutual glance about the room, and a felling that the absence of some of the members might be thus accounted for. The principal objection raised to the formation of such an order, was the fact that it entirely prohibited the teaching of telegraphy to any person without permission of the Grand Chief Telegrapher.

A discussion then ensued as to the advisability of placing the time service of railroads under the jurisdiction of the telegraph superintendent.

The committee on resolutions reported the following:

Resolved, That the thanks of the Railway Telegraph Superintendents' Association be returned to the Old Colony Railway Co. for an invitation to visit Nantucket and Martha's Vineyard, and to the Boston & Maine Railway Co. and to the New York & New England Railway Co. for courtesies extended; also that thanks be extended to the proprietors of the Tremont House for the hospitalities extended

Resolved, That the thanks of this association are hereby extended to G. L. Lang, for his unremitting efforts in making this meeting pleasant and profitable, and one long to be remembered.

Upon the adoption of the above resolutions the meeting at 1:30 P. M. adjourned.

Twenty-two new members were added to the association during the two sessions. The untiring efforts of Mr. Lang to provide for the entertainment of the members while in Boston, were so heartily appreciated that a large proportion of them devoted Friday to an excursion to old Plymouth, on the steamer Stamford, which was thoroughly enjoyed by all. A day on the salt water was quite a treat to many of the gentlemen, and the briny waves were calmed down so that there was not the slightest drawback to the enjoyment of the occasion, beyond a mild application of prohibition, which is naturally looked for in the land of the Puritans. There was a larger proportion of ladies in attendance than is usually seen at electrical gatherings, and they were profuse in their appreciation of the attention shown them by Mrs. Lang and her daughter, who devoted themselves to the skilful piloting of the visitors on various shopping and sight seeing trips through the intricacies of Boston's streets, squares, alleys and courts.

REGULATING POLE LINES IN NEW YORK.

RULES TO BE IN FORCE UNTIL CONDUITS ARE READY FOR THE WIRES.

The Board of Electrical Control (the re-organized Subway Commission) met July 15th, and began work by adopting the following rules governing the erection of telegraph and telephone poles and wires, which had been approved by Gen. Newton, Commissioner of Public Works:

No two lines of poles shall be on the same side of any street or avenue.

Digitized by Google

No two lines of poles bearing conductors for similar electrical service shall be on any street or avenue.

Electric light poles shall be of iron, at least 26 feet in height, with a diameter of not more than eight inches at the base, and having cross arms of wood, with glass, porcelain, or rubber insulators, and painted a uniform color.

Poles for telegraph, telephone, and other similar wires shall be at least 60 feet in height.

Poles shall be placed upon the sidewalk, as near the curb as possible, and no pole shall be placed within 10 feet of any lamp post or other pole.

All existing regulations of the local authorities in regard to the placing of poles and stringing of wires are to continue in force.

All wires shall be fastened upon poles or other fixtures with glass, porcelain, or rubber insulation.

No wires shall be stretched within one foot of any pole without being attached to the same with glass, porcelain, or rubber insulation.

No wires shall be stretched within 20 feet of the ground, or within four feet of any building, except when attached thereto with glass. rubber, or porcelain insulation.

No arc electric light or power wires shall be stretched over any part of any house or other building.

The companies or persons owning or controlling poles in any street or avenue shall allow the same to be used by other companies or persons operating conductors for similar electrical service when authorized so to do by the board on tender of proper compensation, to be determined by agreement between the companies or persons interested. In default of such agreement, the amount of such compensation shall be determined by the board. This rule imposes a contract on the part of each company or person owning or controlling the poles in any street or avenue, not only with the board, but also with each company or person who shall under its terms be qualified to demand the privileges it confers.

All permits of the board for overhead wires and fixtures are granted only pending the providing of underground accommodations in the neighborhood of the street or avenue for which the permit is granted.

Any member or officer of the board, and every inspector employed by it, as well as every member of the police force of the city, shall be entitled to examine permits under which work of any kind is being done.

No permit shall be granted for the erection of any overhead structure nor for the renewing of any lines already existing in any street, avenue, or highway in which underground accommodations for the service have been provided or are being provided.

All poles now standing or to be hereafter erected, shall be branded or stamped with the initials of the company owning them, at a point not less than five or more than seven feet from the street surface.

When an old pole is taken down, it must be removed from the street the same day.

New poles must not be brought upon any street more than two days in advance of their erection.

Any pole that shall be on any street more than two days shall be removed by the Bureau of Incumbrances of the Department of Public Works at the expense of the party owning it.

All electrical companies or persons having poles in the public streets shall give a bond to the city, in a reasonable amount, to be determined in each case by the board, conditioned for the payment of the cost of renewing dangerous and abandoned poles, and also for the payment of the expense of restoring the sidewalks and pavements where the same have been disturbed or injured in consequence of the erection or removal of any poles owned by them.

The violation of any of the rules and regulations of the board shall operate *ipso facto* as a revocation of the permit held by the company or person guilty of such violation.

A resolution was adopted requiring the chief engineer to furnish reports concerning the condition of poles and wires as to safety, and to suggest such changes as will conduce more to the safety of life and property. The engineer is given the power to appoint eight inspectors for this work at $4 each per day and a chief inspector at $250 per month. Acting Mayor Beekman voted against the salaries, as he considered them extravagant.

Chief Engineer Kearney submitted plans for the digging of conduits, which, he believed could be dug at from three to seven feet from the curb.

JOHNS HOPKINS UNIVERSITY.—COURSE IN ELECTRICITY AND MAGNETISM.

The programme in physics at Johns Hopkins University for 1887–88 includes the following announcement:—

SPECIAL COURSE IN ELECTRICITY AND MAGNETISM.

This is intended for advanced students, who have already completed their general education, and who are willing to devote two years to the study of electricity and of subjects connected with it. A knowledge of mathematics through the differential and integral calculus is necessary, and the instructor must be satisfied that the student is otherwise in a position to benefit by the course. An acquaintance with French and German is most desirable.

While a knowledge of the theory is important in every branch of applied science, this is especially the case with electricity, in which the applications increase so rapidly and the practice so frequently changes, that without sound theoretical knowledge it is impossible to keep abreast of the advance of the science, or even to understand the inventions which are daily made public. Yet theoretical knowledge is unfruitful without knowledge of the means of its application, such as can only be obtained by experimental work.

The course, then, is intended to teach the theory of electricity with a special view to its practical application, to familiarize the student with electrical instruments and methods of experiment, and to give him a knowledge of the theory and practice of those applications that are in successful use and with which he will probably work.

Dr. Duncan will give the following courses:

Electricity and magnetism. First year's course.

Three times weekly through the year.

The lectures for the first year are intended to give clear physical ideas of general principles, with the mathematical interpretation necessary to enforce and apply them.

The laboratory work will include measurements of resistance, currents, potential, capacity, etc., with voltameter and calorimeter work, and the student will be familiarized with the instruments used in electrical measurements, galvanometers, electo-dynamometers, resistance coils, condensers, etc. On finishing this work, the student will be given experiments, such as the construction and measurement of standard cells, the determination of the magnetism of iron, the determination of specific inductive capacity, etc., which will bring into use the methods he has already studied.

Besides the work in electricity, lectures on mathematics and such other subjects as the student requires, will be given.

There will be a weekly meeting for the purpose of discussing articles of interest appearing in the electrical journals.

Electricity and magnetism. Second year's course.

Twice weekly through the year.

In the second year will be given the theory of dynamos, motors, the transmission and distribution of energy, the telegraph, the telephone, storage batteries, etc.

The laboratory work will include the tests and running of dynamos and motors, the efficiency and practical working of secondary and primary batteries, photometer work, testing of telegraph lines, experiments on the electrical transmission of energy, telephone work, etc., with such original investigations as the student is able to undertake. There will be a weekly meeting for the discussion of the current literature of the subject.

The student will have time for other selected studies, and in either the first or the second year of this course he must take the second year's undergraduate work in general physics or its equivalent.

At the end of the second year an examination will be held, and on passing it the student will be given a certificate stating that he has taken the course in applied electricity and has passed the required examinations.

NEW YORK ELECTRICAL SOCIETY.

1887.

ELECTRICAL EXHIBITION OF THE AMERICAN INSTITUTE OF THE CITY OF NEW YORK.

September 28th to December 3d.

GENERAL COMMITTEE:

Prof. A. M. Mayer.	W. A. Vail.	M. M. Davis.	A. G. Holcombe.
J. M. Pendleton.	Dr. Van Der Weyde.	Ed. C. Davidson.	Sam'l Insull.
G. M. Phelps, Jr.	Geo. G. Ward.	T. A. Edison.	F. W. Jones.
L. J. Phelps.	G. Worthington.	Francis Forbes.	A. A. Knudson.
R. W. Pope.	Jos. Wetzler.	A. C. Fowler.	C. L. Levey.
Dr. M. J. Roberts.	T. Wolcott.	Jabez Feary.	Dr. Otto A. Moses.
J. A. Seely.	C. W. Hull.	D. R. Garden.	W. Maver, Jr.
Alf. Shedlock.	Dr. Bartlett.	H. R. Garden.	W. Marshall.
C. S. Shivler.	D. H. Bates.	Dr. Norvin Green.	T. C. Martin.
H. A. Sinclair.	C. S. Bradley.	H. D. Hall.	Robt. Grimshaw.
W. C. Temple.	F. B. Crocker.	Jas. A. Hamblet.	C. O. Mailloux.
H. C. Townsend.	C. A. Cheever.	Geo. A. Hamilton.	

SPECIAL COMMITTEES:

Committee on Finance,

Francis Forbes. Frank W. Jones. Geo. G. Ward.

Committee on Space.

A. C. Fowler. Geo. M. Phelps. Jr. W. C. Temple. C. G. Curtis. R. W. Pope.

Committee on Transportation.

G. Worthington. W. A. Vail. C. L. Levey.

Committee on Electrical Installation.

C. O. Mailloux. Geo. A. Hamilton. J. A. Seely. C. L. Edgar. C. S. Bradley. J. A. Barrett. A. A. Knudson. C. L. Clark. Dr. Waite.

Committee on Entertainment.

A. A. Knudson. Dr. O. A. Moses. Dr. Van Der Weyde. E. C. Davidson. H. A. Sinclair. Prof. A. M. Mayer. T. A. Edison. Jas. A. Hamblet.

Committee on Exhibits.

Dr. M. L. Roberts. C. O. Mailloux. Dr. O. A. Moses. S. S. Wheeler. Geo. A. Hamilton. W. B. Vansize. M. M. Davis. J. F. Kelly. T. Wolcott. F. B. Herzog. Alf. Shedlock. Wm. Hochhausen A. Knudson. Leo Daft.

Committee on Correspondence and Publication.

Dr. Van Der Weyde. Alf. Schedlock. C. E. Stump. G. M. Phelps, Jr

Committee on Historical Apparatus.

Dr. Van Der Weyde. A. G. Holcombe. J. A. Hamblet.

RULES AND CONDITIONS.

Classification.

The Electrical Exhibition will be divided into Six Sections, as follows;

Section I.—Production of Electricity.

1.—Dynamo and Magneto Electric Machines.
2.—Primary Batteries.
3.—Thermo Electro Apparatus.
4.—Static Electric Apparatus.

Section II.--Apparatus Requiring Powerful Currents.

1.—Electric Motors and Transmission of Power.
2.—Electric Railways.
3.—Storage Batteries.
4.—Electric Illumination.
5.—Electro-Metallurgy and Electro Chemistry.
6.—Miscellaneous Applications of Powerful Currents.

Section III.—Apparatus Requiring Comparatively Weak Currents.

1.—Fire and Burglar Alarms, Annunciators, Watchman's Time Detectors, Electric Bells, etc.
2.—Electric Telegraphs, Telephones, Microphones, Photophones and Radiophones, and other Apparatus for Electrical Communication.
3.—Electric Registering and Signaling Apparatus.
4.—Applications of Electricity to the Mechanic Arts.
5.—Applications of Electricity to Heating and Ventilation.
6.—Electric Clocks and Time Telegraphs.
7.—Electric Medical Apparatus of all descriptions.
8.--Applications of Electricity to Writing and Printing.
9.—Electrical Toys.
10.—Miscellaneous Applications of Small Currents.

Section IV.—Electric Conductors.

1.—Electric Light and Power Conductors.
2.—Telegraph and Telephone Wires and Cables.
3.—Insulating Materials, Electrical Joints and Connections.
4.—Electric Underground Wire Systems.

Section V.—Electrical Measuring Apparatus.

1.—Voltmeters and Ammeters.
2.—Galvanometers, Rheostats, etc.
3.—Condensers, Switches, Keys, etc.

Section VI.

1.—Historical and Miscellaneous Exhibits.
2.—Educational and Bibliographical.

Duplication of articles will not be permitted, except by written consent.

The Managers of the Institute do not agree to allot any special amount of space until the articles for which space has been desired are *within the building*, unless agreed to in writing.

Delay in Occupying Space Granted.

In cases where space has been allotted to an exhibitor, and the exhibitor has delayed in fully and properly occupying said space for twenty-four hours, then said space may be forfeited by the Board of Managers of the Institute, and assigned to another exhibitor on the same conditions.

Changes in Location—And Space Granted.

Changes as to position and space granted, will be made as often as may be required to properly group and classify the goods, or for the better apportionment of space; which change shall be entirely within the duties and power of the General Superintendent of the Institute.

Charge for Space in Main Building.

The *Minimum* charge for space *granted* on floor or table will be *Ten* dollars, this for space not in excess of *sixteen square feet*. If the exhibit for which this amount of space has been granted should not properly use or cover the same, then so much of said space as in the opinion of the General Superintendent of the Institute is not properly utilized, may be allotted to another exhibit; in such an event no deduction will be made in the original charge of ten dollars.

For space granted in excess of sixteen square feet on floor or table, the charge will be as follows: for the first *sixteen square feet, Ten dollars;* for *each additional square foot ten cents.*

The above applies to all floor and table exhibits excepting spaces granted in Machinery buildings, in which *Machinery is operated;* The following schedule shows the rates:

16	Sq. Feet	of	Space	or	less,	(minimum charge)	$10.00
20	"	"	being	4	additional	feet at 10c. per ft.	10.40
30	"	"	14	"	"	" "	11.40
40	"	"	24	"	"	" "	12.40
50	"	"	34	"	"	" "	13.40
60	"	"	44	"	"	" "	14.40
70	"	"	54	"	"	" "	15.40
80	"	"	64	"	"	" "	16.40
90	"	"	74	"	"	" "	17.40
100	"	"	84	"	"	" "	18.40
125	"	"	109	"	"	" "	20.90
150	"	"	134	"	"	" "	23.40

For any other number of feet same proportionate charge.

Charges for Space in which Machinery is Operated in Machinery Building.

For spaces granted in which machinery is *operated* the charge will be as follows: For space not in excess of *Fifty square feet* the charge will be *Ten Dollars*, if in *excess* of said amount the charge will be *Fifteen Dollars.*

If space granted be not fully utiiized, and space is needed for other exhibits, the General Superintendent of the Institute shall re-apportion so much space granted as he may consider equitable to other applicant or applicants, charging only for space in actual use on terms as above stated.

Foreign Manufactures.

Exhibits of goods of foreign manufacture can only be admitted upon special application, approved by the Board of Managers of the Institute.

Payment at Time of Making Application.

A check or money order for Ten Dollars should be sent at time of making application, the balance of charge for space will be due and payable when space is granted.

Arrangement of Goods.

The arrangement of all goods, *as to height to which they may be piled, as well as to space occupied*, shall be under the charge of the General Superintendant of the Institute, who shall have power to direct the arrangement of all goods, in such manner that the safety of visitors or the harmony of the exhibition may not be interfered with.

Steam Power.

Steam power will be provided to operate machinery only when approved by the management.

The management shall also determine upon the hours when said machines are to be in operation, and may, in all cases, regulate the amount of fuel to be supplied to boilers or other apparatus.

Shafting, Pulleys, Gas and Water Pipes.

The Managers will erect the main line of shafting, and provide the main line of water and gas pipes. All pulleys upon main shafting must be approved by the General Superintendent of the Institute, both as to size and method of fastening to shaft.

All pulleys, counter-shafting and belting must be furnished by exhibitor. No connections will be permitted with the steam, gas or water pipes, except by consent of the General Superintendent of the Institute, and then only at the expense of the exhibitor, and upon his agreement to pay weekly in advance for such gas or water as he may consume. In event of any dispute, the General Superintendent of the Institute may order the connection with said steam, gas and water pipes to be severed, without any liability for loss or damage to the exhibitor.

Rules and Regulations for Electric Wiring.

All electrical conductors for lighting or power purposes shall be installed according to the rules and regulations of the New York Board of Fire Underwriters. The disposition of these conductors, as well as all others, for whatever purposes required, shall be under the direction of the General Superintendent of the Institute, or his accredited representative, whose decision shall be final in all cases. The General Superintendent of the Institute shall have the right to make such changes in the disposal of wires, and require such tests as in his judgment will conserve the best interests of the exhibition.

Reception of Goods.

The buildings will be opened on 2d avenue for the reception of machinery on the 12th day of September, and for the reception of other goods on the 20th day of September, at the 3d avenue and other entrances.

Shipment of Goods.

All articles must be directed to "The American Institute Electrical Exhibition, Third Avenue, 63d and 64th Streets, New York." The name and residence of the exhibitor and the list of contents must be given on the package, freight and other charges on which *must be prepaid.*

Opening and Closing.

The exhibition will be formally opened to the public at 2 P. M., Wednesday, the 28th day of September. It will be opened each secular day thereafter at 10 A. M., and close at 10 P. M., finally closing at 10 P. M., Saturday, December 3d.

Correspondence.

Letters relating to the exhibition should be addressed to "Joseph Wetzler, Secretary, P. O. Box 3265, New York," who will send blanks and give any desired information to parties intending to become exhibitors.

We call the attention of exhibitors to the rules and regulations of the American Institute, in addition to the foregoing under which exhibits are accepted.

Tables.

Tables on main floor will be furnished, without charge, which will be of the uniform width of four feet. Tables other than these must be furnished by the exhibitor and approved by the General Superintendent of the Institute. Should an exhibitor desire to furnish his own table, notice must be given at time of making application for space.

Signs.

Signs shall only be allowed at place of exhibit. One sign only will be allowed exhibits on floors, if against walls or between arches, or if more than one is wanted, written consent must be had. Signs must be on a dark ground; where practicable they may be painted on both sides. Signs on *white ground* will not be allowed. Signs against walls, shall not exceed six feet in length by three feet in width. Signs between arches, or against sides of arches shall not exceed four feet in length by one foot six inches in width. Signs on floors of either of the buildings may rest on exhibits, or on show cases containing exhibits, *not elevated above*, and shall not exceed three feet in length by one foot in height. In cases of exhibits of furniture, machinery, and such other articles as are not placed in show cases, or piled up, the height of signs from floor shall be regulated by the General Superintendent of the Institute. Signs on show cases forming part thereof, if not of greater size than 400 superficial inches, or if in any way violating these rules, must be approved in writing. Signs will not be allowed to hang or project over passage ways. Under no circumstances will signs be allowed to obstruct the view or interfere with the harmony of the exhibition. The regulation of all matters relating to signs shall be within the powers of the General Superintendent of the Institute.

Circulars and Cards.

Circulars, Cards or Notices can only be distributed from the place assigned to the exhibitor, and then only such as relates to the goods there exhibited. None shall be distributed except they are approved by the Board of Managers of the Institute. The Managers reserve the right to prohibit the distribution or display of any circulars, cards, notices or signs, which they may consider objectionable. The exhibit of any person who refuses to comply with this rule will be removed from the exhibition.

Sales.

Sales may be made and orders taken for goods without charge, provided delivery is not made on the premises.

Sales and Delivery on Premises.

Goods can only be sold and delivered in such parts of the Exhibition Buildings as shall be set apart for said purposes by the Board of Managers of the Institute, excepting when goods are manufactured by machinery on the premises; then, if agreed to in writing with the General Superintendent of the Institute, they may be sold at the place where manufactured.

The fee charged for license to sell and deliver on premises must be paid at the time when application is made for the privilege, *it will not be accepted in installments nor will licenses be granted to sell on a percentage of sales.*

Licenses to sell and deliver on premises, when article to be sold has been approved may be had on application to the General Superintendent of the Institute, and payment of fee of $200 for such right; this for goods *not made on premises.* Licenses for goods *actually made on premises*, if approved, may be had on payment of fee of $50, this reduction in license fee, being made to encourage actual processes of manufacture. Solicitations to purchase which may annoy visitors, or other exhibitors, will not be permitted. The Managers of the Institute reserve the right to cancel any license to sell and deliver which may have been granted, upon tendering the pro-rata proportion of fee paid, estimating from the date of such tender to date of closing of exhibition; estimating such time in the proportion to the whole term of the exhibition, which tender whether accepted by the

Digitized by Google

licensees or not, shall abrogate and annul any rights to sell and deliver which licensee may have had; for which act neither the Institute, or any Manager, officer or employé shall be liable to said *licensee* for any loss or damage whatever.

Removal of Goods.

No article shall be removed from the building during the exhibition, unless by authority of the Board of Managers of the Institute.

Fires, Lights and Drapery.

Neither fires nor lights will be allowed except on written consent of the General Superintendent. Drapery used by exhibitors for the decoration of their spaces must be approved by the General Superintendent of the Institute.

Tickets.

Exhibitors' and employés, tickets are issued without charge and are not transferable. If transferred or loaned, the doorkeeper is instructed not only to refuse admission but to retain the ticket, which by this violation of the rule is forfeited. Admission may be had upon an exhibitor's ticket by an employé, provided the exhibitor sends with said ticket a note requesting admission for bearer, and certifying that the bearer is charged with the care of his goods. In case of the loss of a ticket, the loser is required to give immediate notice in writing to that effect to the Secretary of the Board of Managers of the Institute.

Employés' tickets will be issued upon an order of the General Superintendent of the Institute to such exhibitors only, who, in his opinion, require the constant services of an attendant. In no case shall he issue more than one employé's ticket, unless the exhibitor is engaged in operating machinery, or conducting some process of manufacture within the Exhibition.

Receipt for Goods.

A receipt will be given for goods when received and in order, which receipt will be accepted as evidence of ownership at close of exhibition, and upon which *only* goods will be delivered. In the event of the loss of this receipt immediate notice must be given in writing to the Secretary of the Board of Managers of the Institute and his acknowledgement of said notice taken in writing, that delivery may not be made upon presentation of the lost receipt.

Goods at Risk of Exhibitor.

All goods and cases in which they were packed are at the risk of the exhibitor; and it is expressly understood that the American Institute, Board of Managers, or any Committee, officer, or member thereof, is in no degree liable for any loss by fire, theft, or damage of any kind whatever.

Care of Exhibits.

Exhibitors will be required to keep their spaces and exhibits clean and in good order, and in cases when they are covered at night, to remove such covering by 10 o'clock, A. M., and not to cover same earlier than 10 minutes before closing hour.

All sweeping and cleaning of exhibitors' spaces must be done before 10 A. M.

Goods—When to be Removed.

All goods must be removed within one week after close of the exhibition, or they will be placed on storage at expense and risk of the owner or exhibitor.

Failure to Hold Exhibition.

Should the Exhibition Building be destroyed by fire previously to the date fixed for the reception of goods, or should it be impossible from any other cause, to hold the Exhibition, no exhibitor shall have any claim whatever against the American Institute, save and except for the return of any moneys he may have paid for entrance fee, or license to sell.

The Board of Managers of the Institute reserve the right to make such other "Rules and Conditions" as may serve to better regulate and govern the Exhibition.

Penalty for Violation of Rules.

Any Exhibitor or his representative who shall violate either of the foregoing rules or conditions, will be liable to the penalty of having his exhibit removed from the Exhibition, and his ticket of admission canceled. In case of the removal of an exhibit for cause above stated, the entrance fee paid will be returned, *the tender of which fee at any time* it is hereby agreed, shall be in full settlement of any and all damages, and all claims for loss arising from the removal of the exhibitor's goods, and cancellation of tickets of admission issued on his account. It is further agreed between the Board of Managers of the Institute and the exhibitor, that the said Board of Managers shall have sole power and right to interpret these rules and conditions upon which the exhibition has been accepted.

Improper Exhibits.

Any exhibit of goods which in the opinion of the Board of Managers of the Institute is of an improper or objectionable character, may at the option of said Managers, be removed at any time.

Improper Persons.

The Board of Managers of the Institute reserve the right to refuse admission to any exhibitor or employé whom they may consider an improper person, and also to remove the goods of such exhibitor.

ANOTHER TELEPHONE INFRINGEMENT SUIT DECIDED.

Judge Wallace, in the United States Circuit Court, Southern District of New York, handed down a decision July 21st, in the suit of the American Bell Telephone Co. against the Globe Telephone Co., to restrain the defendant from infringing the patent granted to Alexander Graham Bell, on March 7th, 1876. Judge Wallace granted the permanent injunction asked for by the Bell Telephone Co. His opinion is a long one, in which he says: "The Massachusetts courts held that Bell was the discoverer of the new art of transmitting speech by electricity, and in view of all the facts produced there is no reason why a permanent injunction should not be granted." In the answer to the complaint the defendant averred that they owned the patents of A. Meucci, who, they claimed, was the first inventor of the telephone. They claimed that so far they had never sold any telephones or manufactured them. The capital stock of the Globe Telephone Co. was $10,000,000, but from the evidence of witnesses very little of this was paid in. The directors of the company avowed that the reason they had not commenced business actively was because they did not wish to interfere with the Bell patents.

INSULATED RAIL-JOINTS FOR ELECTRIC SIGNALS.

In a communication to the *Railroad Gazette*, Mr. G. W. Blodgett, electrician of the Boston and Albany railroad, states that the wooden blocks formerly used for insulating the track sections for the automatic electric block signals, were abandoned on the Boston and Albany several years since, because they did not keep the rails well in place, and were not durable. Experiments with vulcanized fibre gave but little better results. The method now in use, consists in placing behind the fish-plate, a strip of "leatheroid" one-eighth inch thick, and moulded to fit the rail. The bolts are insulated from the rails by bushings of the same material, and a piece one-quarter inch long, of a size and shape corresponding to the cross-section, is placed between the ends of the abutting rails. The fish plates are planed off to allow for the space taken up by the leatheroid strip.

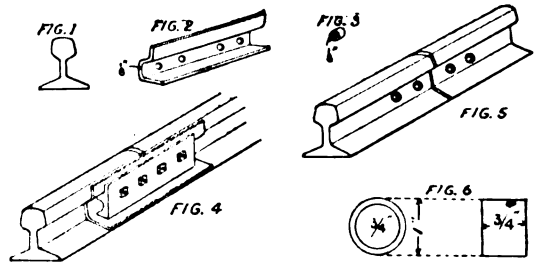

Figure 1, shows the piece of leatheroid between the ends of the rails and figure 2, the plate which insulates the splice-bar from the rail, figure 3, is the bushing which surrounds the bolt of which an enlarged section is shown in figure 6. Figure 4 shows the completed joint and figure 5 shows the joint before the splice-bar is put in place. Mr. Blodgett states that these joints hold the rails well and have proved to be very durable.

ELECTRIC ALARM SIGNALS ON THE BERLIN METROPOLITAN.

The Metropolitan railroad of Berlin has adopted the apparatus of Siemens Bros. for signaling from trains between stations. The stations being very near together the nature of the help required by a train signaling from an intermediate point it is not necessary to specify. In the case of a call the terminal station sends a locomotive at once, and it is sufficient to notify this station of help wanted, and to warn all other stations that a locomotive is to pass, coming from the extremity of the line. At each station, placed on a single wire, is an apparatus which consists of an electro-magnet, with the necessary mechanism, enclosed in a wooden case, below which are the call bells. On the face of the box is a dial, divided in two parts, one part having the names of the stations in black, the other the same names in red. Under the dial are two buttons, one below the other, and a crank which serves to set in motion the magnet. Turning the crank from left to right and pressing on the upper button, the index of the apparatus moves to the right; by turning the crank in the other direction the movement of the index is reversed. Pressing on the lower button, and turning the crank, sounds the bells. In calling for aid, therefore, the upper button is pressed, the crank is turned from left to right, until the needle is at the extreme point to which it can go, the lower button is pressed and the bells are sounded. Then by pressing the upper button and turning the crank from right to left the index is brought to the point on the dial containing the name of the station which calls for help. That is, the dial announces an accident, the index indicates the name of the station where help is required, as well as the terminal station from which it has been called, and the same signal appears all along the line.

ELECTRICITY "AS SHE IS TAUGHT" IN THE NEWSPAPERS.

The following is from a recent issue of a leading New York daily newspaper:—

TO RUN BY ELECTRICITY.

The Jersey City and Bergen Railroad will on Wednesday next move their cars with electric motors. President Thurston says that it will prove less expensive and bothersome than horse locomotion. The new motive power, contrived by Joseph Weiss, of Jersey City, has already been tested on the lines with the heaviest grades and found to work satisfactorily. A series of electric cells placed under the car seats feed batteries underneath the car. Three wheels are connected with the latter contrivance, two flanged or rail wheels, and a centre wheel which is flangeless. The rail wheels are charged with electricity, and are connected by a belt. The power is distributed by a small gear wheel, which makes 500 revolutions in harmony with a larger one of 250 revolutions, which in turn is connected with the friction or centre wheel, which makes 50 revolutions. With 30 cells the car can be driven 100 miles an hour, or as much slower as desired. The batteries will run it 15 hours and do the work of 12 horses. The cars will be lengthened five feet. It is proposed to employ the present drivers to run the new motors. At the opening, Wednesday, a number of distinguished guests will be in attendance.

THE BALTIMORE AND OHIO DEAL DECLARED OFF.

Mr. Garrett has published the following:—

ELBERON, N. J., July 20th, 1887

The Hon. William M. Singerly, Editor of the Record, Philadelphia:

DEAR SIR: In reply to your courteous inquiry as to the real status of the negotiations called by the press "the Baltimore and Ohio Deal," I beg to say that all such negotiations are terminated. The syndicate which was to acquire a

Digitized by Google

large block of the stock of the Baltimore and Ohio Railroad Co., in such a way as was believed would be beneficial to all the parties and railroads concerned, did not at the appointed time comply with their engagements, and all arrangements or negotiations with them are now absolutely at an end.

I have not purchased the stock of the Johns Hopkins University, as stated in some of the newspapers. I had an option on that stock, and also upon that of several other holders, but I have not exercised these options, nor do I intend to do so. The statement in some of the papers that I purchased large blocks of the Baltimore and Ohio stock is a mistake. As I have stated, I had options, but circumstances rendered it unnecessary to close them. The Baltimore and Ohio Railroad Co., its properties, including its large telegraph system and the ownership of its stock, remain now as they were at the opening of the negotiations.

The widespread public interest which these negotiations have excited and the many false and foolish rumors to which they have given rise justify me in departing from my usual course, and making this formal statement of their final termination. Thanking you for the kindly terms in which you have been pleased to refer to the Baltimore and Ohio Co. and its future, and acknowledging the correctness of your judgment and that of many other friends as to the propriety of making public this letter, I am, as ever, yours, very truly,

ROBERT GARRETT.

ELECTRIC LIGHT AND POWER.

The Sheboygan Gas Co. will erect an electric light plant at Sheboygan, Wis.

The Edison Electric Light Co. will erect a plant at Kansas City, Mo.

The Old Dominion Electric Light Co. will erect a plant at Manchester, Va.

The American Electric Manufacturing Co., of New York, are extending their business to Australia. A complete plant with engines, dynamo machines, lamps, boilers, wires and other apparatus was shipped last week for Sydney. An American plant is to be immediately installed there. A company has been organized with a capitalization of half a million of dollars to control the American apparatus in Australia.

The Columbus Electric Light Co. will make improvements to their plant at Columbus, Ohio.

The Badger Electric Light Co. is making improvements to its plant at Racine, Wis.

The Brush Electric Light Co. is building a new plant at Detroit, Mich.

The St. Cloud Water and Power Co. will erect an electric light plant at St. Cloud, Minn.

The Edison Electric Light Co. will build a station at Columbus, Ohio, to cost $15,000.

The Tuscaloosa Coal, Iron and Land Co. will erect an electric light plant at Tuscaloosa, Ala.

The Racine Gas Light Co. will erect an electric light plant at Racine, Wis.

Durgin & Merrill contemplate erecting an electric light plant at Quincy, Mass.

An electric light plant is contemplated at Augusta, Ga. W. A. Wright, agent.

An electric light plant will be erected at Grand Rapids, Mich. Address, Jno. L. Shaw.

Foreign.

Austria.—An electric railway is projected for Karlsbad, and a concession for this undertaking has already been obtained by a company from the minister of commerce. Messrs. Siemens & Halske will probably install a central electric lighting station at Graz. The central station in Salzburg, and a great portion of the distributing plant are already finished, and it is expected that regular work will begin in August. The first trial run of the central electric light station in the Schenkenstrasse, in Vienna, was made with perfect success a few days ago. When this installation is in regular work, it will bring up the total number of glow lamps running in Vienna and suburbs to 32,000.

Belgium.—The Societe Industrielle de l'Electricite of this town have established, under the direction of M. Goffin, a central station for the lighting of the commune Berchem-Antwerp. In this case the area over which the lighting extends is so large and the lights are so scattered that it would not have paid to put down a gas supply, and direct electric lighting on the parallel system would have been still less feasible. The company have, therefore, adopted the distribution by means of transformers placed at the principal lighting centres in the district, and all supplied from a central station, the distance to which varies between two and two and one-half miles. The potential maintained at the station is about 1,000 volts, the slight increase of pressure necessary to compensate for the loss through resistance if the current sent out is augmented being performed automatically. All the transformers are in parallel connections, and the lights are quite independent of each other.

France.—The Compagnie Francaise d'Eclairage Electrique inaugurated, late in June, their station Drouot, the first central station for the supply of electricity erected in the heart of Paris. The present capacity is reckoned for 1,500 lamps fixed, and the current is supplied by four compound wound Gramme machines, the distribution being on the three-wire system for 100 volts Swan lamps of 10, 16 and 32 c. p. The pressure will be kept on the mains night and day, and a battery of 120 accumulators has been provided in order that the machinery need not be kept running continuously. The Cauderay meters are employed, and the consumers will be charged according to the number of ampere-hour[8] supplied. Motive power at the station is derived from two steam engines.

Spain.—The municipality of Leon offers a monopoly of fifty years for lighting the town with 260 glow lamps of 20 c. p., burning each on an average 2,200 hours per annum, for the sum of £720. The contractor will be the only person allowed to fix cables or wires for the purpose of electric lighting, whether for public or private lights. No price is stipulated for private lighting. Tenders, which will be opened on the 6th August, are to be on the basis of a diminution of the number of years of the monopoly. Besides the lighting of the streets, the municipal offices are to be lighted by glow lamps of 20 c. p., to be paid for at the rate of about 0.4 pence per hour. The total number of lights likely to be used, including the theatre and private houses, will not exceed 600, but a price of 0.6 pence per lamp hour would probably be obtainable.

NEW INCORPORATIONS.

The Jamestown Electric Light and Power Company, Jamestown, N. Y., Millard White, Boston, Mass., and others, incorporators.

The Thomson-Houston Electric Light and Power Co., Buffalo, N. Y. Capital stock, $500,000. Richard K. Noye, and others, incorporators.

The Ridley Electric Light and Power Co., Ridley Park, Pa. Capital stock, $10,000. Robert Craven, incorporator.

The Palmer Electric Co., Palmer, Mass. Capital stock, $30,000. John F. Herry, and others, incorporators.

The Jerseyville Electric Light and Power Co., Jerseyville, Ill. Capital stock, $20,000. John G. Schwarz, and others, incorporators.

The Pittsfield Illuminating Co., Pittsfield, Mass. Capital stock, $25,000. William Stanley, Jr., and others, incorporators.

The Woburn Electric Light and Power Co., Woburn, Mass. Capital stock, $18,000. N. J. Simonds, and others, incorporators.

The Farrington Electric Light and Power Co., Farrington, Me. Capital stock, $5,000. Austin Reynolds and H. H. Rice, incorporators.

The Hyde Park Electric Light Co., Hyde Park, Ill. Capital stock, $250,000. Hugo Hoffman, and others, incorporators.

The Edison Electric Light and Power Co., of Petoskey, Mich. Capital stock, $13,000. H. O. Rose, and others, incorporators.

The Philadelphia Lighting Co., Camden, N. J. Capital stock, $3,000,000. Thos. Cochran, and others, incorporators.

G. F. Card, H. K. Lindsey, George W. Howell, Thomas F. Corry, W. A. Detrick, W. H. Mackoy, and others, have incorporated the Card Electric Brake Co., at Covington, Ky. The authorized capital stock is $1,000,000.

MANUFACTURING AND TRADE NOTES.

The Westinghouse Electric Co. has orders ahead to keep its full force of 775 men working steadily until November 1. Among the electric plants under construction are those for Colorado Springs, Easton, Md., Sheffield, Ala., Beaver Dam, Wis., Denver, Portland, Me., Charlestown, W. Va., Galveston and Austin, Tex., and a number of others. Work has been commenced on the new eight-story addition to the plant on Garrison alley, and will be pushed as fast as possible, as the company need more room. The electric plant put in by this company to light Hoosac tunnel is completed and doing its work satisfactorily.

The Standard Underground Cable Co., one of the numerous Westinghouse industries, closed on the 11th inst. a contract with the city of Denver for $40,000 worth of underground wires. The order will be filled at once. Nearly as large a contract was made by the Union Switch and Signal Co., with the Kings County (N. Y.) Electric Railway for interlocking and other appliances which this famous institution turns out for scientific railroading.

The old railway and telegraph machinery and supply house of E. S. Greeley & Co., successors to L. G. Tillotson & Co., has reorganized as a corporation under the name of The E. S. Greeley & Co., dating from July 1st. Messrs. Greeley and Parker retain their interest and position in the management. Mr. W. M Goodyear, in charge of the electrical department; Mr. Joseph Bailey, western sales department; Mr. E. S. Riggs, home office, railroad department, and Mr. J. W. Sands, accountant and cashier, are admitted as members of the corporation, and will retain the management of their respective divisions of the business.

The Capital Gas Co., Sacramento, California, are buyers of a 50 light plant of the Waterhouse system.

The Willimantic Electric Light Co., of Willimantic, Conn., operating the Waterhouse system, have doubled their dynamo capacity, and are adding lamps daily, running both the arc and incandescent on same wire.

The Pennsylvania Steel Co., at Steelton, Pa., made during the month of June (25 working days) 1,005 frogs, 722 switches and 553 switch stands, besides a large number of magneto crossing signals.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From June 21st to July 12th, 1887 (inclusive).

Alarms and Signals:—*Temperature-Alarm System*, A. E. Morrison, 365,069, June 21. *Signal Box*, F. W. Cole, 365,365. *Thermostat*, H. E. Jacobs, 365,438. *Electric-Alarm Clock*, M. Stecher, 365,493, June 28. *Electro-Magnetic Annunciator-Drop*, J. J. O'Connell, 365,935. *Signal-Box*, H. A. Chase, 366,154. *Police Telephone System*, W. H. Eckert and J. A. Seely, 365,911. *Thermotic Circuit-Closer*, J. C. Mackey, 366,176, July 5. *Electrical Alarm*, J. A. Galvin, 366,212, July 12.

Clocks:—*Electric Controlling and Regulating Device for Pendulums*, W. S. Scales, 366,513, July 12.

Conductors, Insulators, Supports and Systems:—*Composition of Matter for Insulating Material*, J. B. Williams, Re-issue 10,846, June 21. *Junction-Box for Electric Conductors*, J. Kreusi, 366,173. *Electrical Conductor*, same, 366,174, July 5. *Underground Way or Conduit*, S. W. Arnold and W. C. Cranmer, 366,195. *Underground Cable for Telegraph Wires*, R. F. Silliman, 366,263. *Conductor Support*, W. P. Zimmerman, 366,289. *Compound for Covering Electric Wires*, H. W. Merritt, 366,336. *Semi-Elastic Compound for Covering Electric Wires*, same, 366,337. *Electric Conductor*, G. Westinghouse, Jr., 366,361. *Laying Continuous Electrical Conduits*, A. C. Chenoweth, 366,457, July 12.

Distribution:—*System of Electrical Distribution*, T. A. Edison, 365,978; J. F. McElroy, 366,124, July 5. *System or Circuit for Electrical Distribution*, H. M. Byllesby and O. B. Shallenberger, 366,376. *Automatic Regulator for Electrical Distribution*, W. Stanley, Jr., 366,523, July 12. *Apparatus for Transforming Electric Currents*, L. Bollmann, 365,116, June 21. *Electrical Convertor*, A. Schmid, 366,347; G. Westinghouse, Jr., 366,362 and 366,544, H. M. Byllesby, 366,375. *Circuit Controller for Electric Circuits*, H. M. Byllesby and P. Lange, 366,374, July 12.

Dynamos and Motors:—*Electro-Magnetic Motor*, H. M. Paine, 366,021, July 5. *Automatic Regulator for Electric Motors*, W. Stanley, Jr., 366,267. *Regulator for Self-Exciting Alternate-Current Electric Generators*, O. B. Shallenberger, 366,349, July 12.

Galvanic Batteries:—*Electric Battery*, P. Germain, 365,359, June 21. *Galvanic Battery*, C. Seiler, 366,034, July 5.

Lamps and Appurtenances:—*Electric Arc Lamp*, E. Thomson, 365,553, June 28; A. G. Waterhouse, 366,613 and 366,614, July 12. *Incandescent Electric Lamp*, J. Smith, 365,351, June 21; P. O. Jenkins, 365,384; E. P. Thompson, 365,495, C. G. Anderson, 365,499, June 28. E. P. Thompson, 366,352, July 12. *Incandescent Lamp-Socket and Cut-Out*, M. J. Wightman and H. Lemp, 365,159 and 365,189, June 21. *Hanger for Electric Lamps*, F. Thompson, 365,414. *Electric Lighting of Railway Cars*, C. E. Buell, 365,460. *Globe for Electric Lamps*, G. L. Abbott, 365,498. *Filament for Incandescent Electric Lamps*, T. A. Edison, 365,509, June 28. *Process of Making Incandescents*, E. P. Thompson, 366,353. *Mast-Arm for Electric Lights*, F. H. Parker, 366,603. *Key-Socket for Incandescent Electric Lights*, F. L. Pope, H. M. Byllesby and P. Lange, 366,606, July 12

Measurement:—*Galvanometer*, H. B. Cox, 366,305; P. Lange, 366,409; P. Lange and O. B. Shallenberger, 366,410. *Electric Meter*, W. Stanley, Jr., 366,268, July 12. *Apparatus for Measuring Electricity*, J. Caudery, 365,702, July 5, and 366,202, July 12.

Medical and Surgical:—*Electric Belt*, R. E. Williams and T. G. Hammer, 366,058. *Electrolytic Vaporizer for Medical Purposes*, M. M. Gillam, 366,164, July 5.

Miscellaneous:—*Electric Valve Mechanism for Water-Mains*, G. B. Bassett, 365,040. *Printing Shell*, O. J. Smith, 365,352. *Coin-Operated Electrical Weighing Scale*, W. R. Smith and A. L. Washburn, 365,353, June 21. *Valve Gear*, T. A. Edison, 365,465. *Electrical Contact-Changer*, D. Davis, Jr., 365,585. *Electric Temperature-Controlling Device*, H. E. Jacobs, 365,600. *Fire-Extinguisher*, C. H. Shaffor, 365,639. *Electric Circuit-Testing Apparatus*, G. F. Bulen, 365,726, July 28. *Electric Block System for Pneumatic Dispatch*, A. Bryson, Jr., 365,787. *Electrical Cartridge*, E. A. Monfort, 365,842. *Electrical Breech-Loading Fire-Arm*, same, 365,843. *High Temperature Thermometer*, W. F. Brewster, 365,905. *Electric Rock Drill*, L. J. Phelps, 366,184, July 5. *Automatic Electric Temperature Regulator*, W. S. Johnson, 366,324. *Safety Strip for Electric Circuits*, O. B. Shallenberger, 366,350. *Electric Switch*, P. Lange, 366,407. *Core for Electro-Magnets and Method of forming the same*, same, 366,408. *Shaking Apparatus*, C. Collins, 366,460. *Electric Switch*, R. McRae and C. F. Tavener, 366,634, July 12.

Railways and Appliances:—*Guide Truck for Electric Railways*, B. F. Hamilton, 365,339. *Swivel Truck for Electric Railways*, same, 365,340. *Tramway for Elevated Electric Railways, with Means for Insulating the Rails*, same, 365,341. *Electric Railroad-Signal*, M. W. Long, 365,345, June 21. *Electrical Conductor for Railway Trains*, A. L. Duwelius, 366,209. *Car-Lighting Apparatus*, C. R. Arnold, 366,292, July 12.

Telegraphs:—*Printing-Telegraph*, S. V. Essick, 365,059, June 21; G. B. Scott, 365,705, June 28; C. L. Healy, 365,994, July 5; J. P. Hurley and G. F. Perkins, 366,319, July 12. *Transmitter for Printing Telegraphs*, S. D. Field, 365,982; C. L. Healy, 366,166. *Printing Telegraph Receiver*, H. Manken and C. L. Healy, 366,178, July 5. *Type-Wheel for Printing-Telegraph Receivers*, C. L. Healy, 366,628, July 12. *Automatic Telegraphy*, C. Selden, 365,103, June 21. *Polarized Relay*, G. T. Woods, 366,192, July 5. *Telegraphy*, L. Maiche, 366,229. *Telegraph Key*, A. S. Keating, 366,400, July 12.

Telephones, Systems and Apparatus:—*Telephone Transmitter*, J. W. Bonta, 365,776, 365,777, 365,778, 365,779, 365,780 and 365,781, July 5. *Mechanical Telephone*, J. Lauhoff, 365,525, June 28. *Angle-Hanger for Mechanical Telephone Lines*, A. W. S. Davis, 365,708. *Mechanical Telephone Switch*, G. F. Shaver, 365,868. *Electric Telephony*, A. G. Safford, 366,190, July 5.

The India-Rubber and Gutta-Percha Insulating Co.

MANUFACTURERS OF

ALL KINDS OF INSULATED WIRES AND CABLES.

Guaranteed to give satisfactory service under ground and over head. Specially adapted for CHEMICAL WORKS, PAPER MILLS, DYE WORKS, COAL MINES, Etc., Etc. Prices and Samples on application.

W. M. HABIRSHAW, General Manager.

No. 159 FRONT STREET. NEW YORK CITY.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, *115 Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, SEPTEMBER, 1887.

THE SEMI-CENTENNIAL OF INDUSTRIAL ELECTRICITY.

IN a learned work on the subject of atmospheric electricity put forth some years since by one Major Parnell, of the Royal Engineers of Great Britain (apparently a gentleman of Celtic extraction), it is maintained that "the lightning rod was the earliest instance of the useful application of electricity." Notwithstanding this dictum, we, in common, we are persuaded, with the majority of our readers, are still inclined to regard the electric telegraph as the one discovery which above all others, is entitled to that particular distinction.

While our transatlantic cousins have been celebrating, in their customary generous and hospitable manner, the jubilee of the electric telegraph in England, we on this side have apparently overlooked the fact that the present year of grace, 1887, is also the proper semi-centennial anniversary of the electric telegraph in America.

It is fifty years ago this present month, since Morse, having completed the rude working model of his conception of the recording electro-magnetic telegraph, exhibited its working in the presence of a number of scientific friends at his rooms in the University Building in Washington square. Here it was first seen by Alfred Vail, who in a manuscript found among his papers after his decease, now printed for the first time, has graphically recorded his first impressions of the electro-magnetic telegraph, and has accompanied it with a most interesting narrative of the early history of its practical development. It was on September 2, 1837, that this memorable interview occurred, and on the 22nd of the same month, a contract was executed by which Vail, in consideration of a share in the patent rights, agreed to construct a practical form of apparatus, and to supply the necessary means for exploiting the invention. By November 13th, the original instruments had been so improved as to be capable of working through 10 miles of wire, and on January 6, 1838, the new instruments having been completed, the first public exhibition to invited guests was given at the Speedwell Works in Morristown, N. J.

The apparatus was soon after exhibited to large audiences in New York, Philadelphia, and Washington, eliciting the unqualified admiration of every one who had the mental capacity to appreciate the inevitable revolution which the invention was destined to create in the business methods of the world.

But a long and weary season of discouragement was yet to follow. Year after year passed away, while government and private capitalists, in spite of every appeal, alike remained incredulous of the value and the importance of that which was perhaps the most extraordinary, if not the most useful, discovery of the nineteenth century; a fact, however, which is in part accounted for by the widespread and continuous financial exhaustion which followed the disastrous panic of 1837. But darkness is always followed by the dawn, and at length, in 1844, Congress voted the historical appropriation which placed the struggling infant upon its feet. From this time forward, for a quarter of a century, telegraphy stood almost alone as the exponent of applied electricity. Other applications, however, gradually followed; and in the last decade its field broadened year by year. Now, upon the fiftieth anniversary of the first exhibition of the telegraph in the University of New York, it would be difficult to name a single branch of science, art, or industry which does not owe at least something to the potent aid of electricity. Truly the electrical record of the past half century has surpassed the wildest flights even of such vivid imaginations as those which gave us the wondrous tales of the Arabian Nights.

THE PROGRESS OF ELECTRIC LIGHTING.

TEN months ago, in an article on the progress of domestic electric lighting, speaking of the inductive system of electrical distribution, then recently patented in the United States, we ventured the prediction that if this method proved practically successful, the problem of economical distribution over any area required in electric lighting, had received its final solution. While the article referred to was written in view of a knowledge of the results which had been obtained in the running of an experimental plant for over a year, yet we should scarcely have felt ourselves justified in looking forward to the making, within so short a time, of such a remarkable exhibit as that of the Westinghouse company, with its accompanying facts and figures, which we publish in another part of the present issue.

If any further evidence were needed that we have entered upon a new era in domestic illumination, the fact that other prominent electric lighting interests have apparently determined to adopt substantially the same sys-

Digitized by Google

tem as that of the Westinghouse company would be sufficient to establish the truth of the assertion. Of these, the Sun company and the Thomson-Houston company are the only ones who have as yet made actual installations; but the United States company have given notice that it also is about to enter the field, and it is fair to presume that the Edison company will, in due time, be heard from to the same effect.

As noticed in our news columns some months since, suit has been instituted against the Sun company by the Westinghouse company, alleging infringement by the latter of the Gaulard-Gibbs patent. It is said that the United States company will adopt substantially the same ground of defense against the Gaulard-Gibbs patent as that already taken by the Sun company, which, in substance, is, that the whole system was well known, and was public property, before the date of the invention of the patentees. If this be a fact, it is only fair to say that the further fact that no one seems to have thought it worth while to take up the system commercially until a comparatively recent period becomes somewhat difficult of explanation. One thing is certain, that with the well-known ability of the counsel engaged both against and in behalf of the patent, the question of the novelty of the invention can scarcely fail to be pretty thoroughly sifted, whatever may be the final result.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

Each semi-annual meeting of the National Electric Light Association develops greater interest and usefulness than its predecessor. The convention at Boston, August 9th–11th, excelled all previous meetings in point of numbers, and was inferior to none in the quality of papers read and of the ensuing discussions.

The entire proceedings, including the papers read and the discussions, are given in our columns for this month. All the topics treated were of immediate interest and significance.

The progress of alternate current distribution since the last semi-annual meeting was well set forth by Mr. M. M. M. Slattery, followed in discussion by Dr. Moses, Mr. Smith, Mr. Duncan and others; from whose united testimony it is quite clear that sufficient experience has accumulated to dissipate the somewhat tentative, not to say timorous, feeling towards the system that prevailed in the last convention.

Mr. Garratt, as chairman of the wire gauge committee, presented as a report a very comprehensive table of the mathematical properties of wires, based on a scale of diameters increasing by tenths of a millimeter from one to one hundred millimeters. The publishing of this table by the association as useful information for all who are accustomed to designate wires by diameters, and as an aid in extending the use of metric in place of inch fractions, rather than as a new wire gauge, seems a judicious proceeding. Mr. Garratt and his co-adjutors on the committee performed a huge task, at much sacrifice of time and personal convenience, in computing the tables, and well deserve the hearty thanks of the association.

Mr. Weeks's paper on "Electrical Education," was timely and to the point. We were pleased to learn, during the convention, from the superintendent of one of the large electric motor companies, that systematic instruction of employés in electrical science had been commenced in the works under his supervision, somewhat in a line suggested by the lectures of Dr. John Fleming, to electrical artizans, provided by the Messrs. Crompton, of England, for their workmen a year or so ago.

Mr. Arthur Steuart, in his report for the legal committee, not only *discussed* patent office reform, but presented his views in the tangible shape of a bill for presentation at the next session of Congress. It is to be hoped that the members of the association will do all in their power in furtherance of the plans outlined by Mr. Steuart.

Lieut. Murdock's paper on electric light requirements for the new cruisers, offered much valuable suggestion to makers of dynamos; particulary on the point of low speed dynamos for direct connection to engines.

Storage batteries received much attention at the hands of the convention, the subject being presented in suggestive papers by Messrs. C. O. Mailloux and A. Reckenzaun, the former treating of the applications of electrical storage in general, and the latter chiefly of its application to electric locomotion.

There was no paper on electric motors. The ample exhibition of many motors in operation upon electric light circuits, made by several enterprising manufacturers, in connection with the meeting of the association, constituted an object lesson quite as useful as papers and discussion would have been.

SOME PROPHETIC ELECTRIC LIGHT FIGURES.

Now that modern improvements in the methods of distributing electricity for incandescent lighting have rendered it practicable to establish and maintain central station plants at a profit, even in towns of not more than 4,000 inhabitants, it has become possible to ascertain with some approach to accuracy the dimensions of the field which is open to be occupied by this incomparable illuminant.

Experience shows that when house-to-house lighting has been thoroughly worked up in any town, the capacity of the central station plant will need to be equal to an average of about one 16 c.p. lamp for each inhabitant.

According to the census of 1880, of the 50,000,000 inhabitants of the United States, 13,000,000, or 26 per cent., resided in 580 towns and cities having a population in excess of 4,000 each.

At the normal rate of increase, we shall have, in five years from the present writing, a population of nearly 70,000,000, of whom some 18,000,000 will be gathered within the limits of towns of 4,000 inhabitants and upwards. Each of these individuals will represent one incandescent lamp, and the necessary power for operating the same. Even after deducting the lamps which have already been installed, there will be required a total output of more than 11,000 lamps and over 1,000 h.p. each of steam-engines, boilers and dynamos, every working day for the next five years, to supply the demand which from all present appearances will inevitably arise. This is entirely aside from the additional number of lamps which will be required for renewals—itself an enormous item. The change from gas to electricity which is now going on in connection with domestic lighting, will be not a little accelerated by the action of the gas companies, who are everywhere evincing an increasing disposition to take up electric lighting themselves; and a very sagacious policy it is too, in view of the present outlook for gas illumination.

THE ELECTRICAL EXHIBITION OF THE AMERICAN INSTITUTE.

The Electrical Exhibition to be opened September 28th by the American Institute and the New York Electrical

Digitized by Google

Society, will, undoubtedly, offer a very comprehensive display. Over 18,000 square feet of space have been already allotted by the committee.

Electric lighting will be represented by extensive exhibits by prominent companies. In this department a dynamo of 100 arc light capacity is engaged to be shown. A variety of incandescent light systems will be on exhibition, including a display of low-resistance lamps in series.

Electric motors will form a leading feature of the exhibition, nearly all the principal companies engaged in their manufacture having applied for space. One electric motor company expects to undertake not only an exhibit of their machines, but their manufacture in the exhibition building. Electric locomotion will be exemplified by a model street railway and by an elevator, both in operation. Mr. Edison will exhibit his pyro-magnetic motor.

The electric-welding process of Prof. Elihu Thomson will be shown.

An ocean cable recorder in operation will be a very interesting feature to the general public.

A great variety of minor applications of electricity will be on exhibition. The working exhibits, together with the historical collection of apparatus which the New York Electrical Society is preparing, will constitute a very instructive display of the history and progress of electrical industry in America.

In coming down-town on the Sixth Avenue line of the Manhattan Railway, a few days since, we noticed near Chambers street a number of mechanics suspended in the air in various uncomfortable and more or less dangerous positions, engaged in slowly and laboriously boring with hand-drills a large number of rivet-holes in the transverse girders, in view of some contemplated enlargement or strengthening of the existing structure. If a single man were provided with a drill run by an electric motor, receiving its current either from the electric light wires or from a portable steam engine and dynamo, which might stand anywhere in the vicinity, he could do the work in a tenth of the time, and at a hundredth of the expense of the primitive method actually employed. The number of labor and time-saving applications of the electric motor which suggest themselves to the well-informed practical electrician, whenever he takes his walks abroad, are literally without number. The above is but one instance of a thousand that might be suggested. As another fruitful field, take, for example, the distribution of power in large manufactories by the ordinary appliances of gearing, shafting and belting. We have been told by large manufacturers that instances are not infrequent in which 50 or 60 per cent. of the total coal-bill is properly chargeable to the friction of the power-distributing appliances. The wear and tear of belting and gearing is in itself no inconsiderable item. All this work will in time be done by electric motors, with much less expense and with an incomparably greater degree of convenience, efficiency, and safety. We saw a machine shop belonging to a wealthy amateur in England, a year or two since, which was fitted up in this way, each lather, planer, or other tool having its independent motor, which was really a model in its way; and there should be no obstacle to the general application of similar methods in all branches of manufacture. One great advantage is that the connections consume no power, except when the machines are in service—a most important consideration.

Now that currents of high potential are coming into increasing use for incandescent lighting and street-railway service, as well as for arc lighting, more attention should be paid to the character of the insulating supports used. Glass insulators and wooden pins are a miserable makeshift, and ought to be no longer tolerated. When coated with the carbonaceous deposits of a city atmosphere, and subjected to the effects of a driving rain, their non-conducting properties are pretty nearly *nil*. Heavy double-bell porcelain insulators, such as are used in France and Germany, mounted on substantial malleable iron brackets, would serve the purpose admirably, while a well-designed paraffine insulator would be still better. This warning ought to be heeded, but we fear it will not be,—at present.

A street railway electric conductor fell from its supports a few weeks since, in Montgomery, Ala., and killed a horse. It might have been a man, and a colonel, or even a brigadier-general, at that. This will doubtless be used for all it is worth as an argument against electric street railways, whereas, in fact, it is only an argument against cheap construction and earth circuits for high potential currents. If a double conductor is used, and the whole circuit kept under constant test, as it easily might be, the falling of a conductor could not possibly harm anybody. Our electrical engineers are enterprising, but they are much too prone to take risks,—or rather to subject other people to them. Accidents like these, which can perfectly well be avoided, do great harm in inciting the prejudices of the average citizen against electrical systems and appliances. Let us have a reform.

The misguided combination of electric light carbon manufacturers came to a speedy collapse. Captain Scott's coon was hardly quicker in coming down than were the carbon men when they descried the improvised gun of the carbon consumers aimed in their direction. Every one having now enjoyed his laugh over the affair, congratulations are in order on both sides. With or without the counter-combination of consumers, the attempt to monopolize the production of carbons was hardly less absurd than a like undertaking in brick-making, or say the manufacture of clothes-pins or slate-pencils. A survey of the constantly-increasing competition in the far more difficult manufacture of dynamos and electric lamps should have sufficed to indicate the hopelessness of the carbon-makers' project. Let their superfluous energy find employment in improving the quality of their wares and, if possible, reducing the cost of their manufacture.

A fuel-gas plant, having a capacity capable of producing one million cubic feet of gas per diem, from coal, is now being erected in Pittsburgh, for the purpose of exhibiting the new patented processes and appliances of the Fuel Gas and Electric Engineering Co. of that city. It is confidently expected that the operation of this plant will conclusively demonstrate the practicability of wholly displacing, by cheap fuel gas, the use of coal for manufacturing, domestic and metallurgical purposes. The ingenious contrivances for controlling and regulating gas, at high pressures, which are in use in the natural gas service in Pittsburgh, will be employed by the new company, so that the present illuminating gas plants, when displaced, as they soon must be, by the electric light, may be utilized, without reconstruction, for a low pressure domestic fuel gas service.

Mr. Edison's description of his pyro-magnetic generator, read before the American Association for the Advancement of Science during its meeting at New York, in August, has attracted much attention in electrical and other scientific circles. An abstract of the paper is printed in another column of our present issue. We re-print also, from the *Journal of the Franklin Institute*, for January, 1879, the description, with illustration, by Profs. Edwin J. Houston and Elihu Thomson, of a thermo-magnetic motor, devised by them while investigating the changes in the coercitive force of iron and steel caused by changes of temperature.

ARTICLES.

THE WESTINGHOUSE ALTERNATING SYSTEM OF ELECTRIC LIGHTING.

BY F. L. POPE.

It is not yet two years since the first plant for electric lighting from a central station, making use of a system of distribution in which alternate currents of high potential are converted by induction into consumption currents of low potential, was established in the United States by William Stanley, Jr., now electrician of the Westinghouse Electric Co. of Pittsburg, Pennsylvania. A comparatively short experience with this plant was sufficient to demonstrate its many advantages over direct current systems with lamps arranged either in multiple arc or multiple series—or as Prof. Forbes prefers to say, parallel or parallel series—having either two or three mains or distributing wires, which had, up to that time

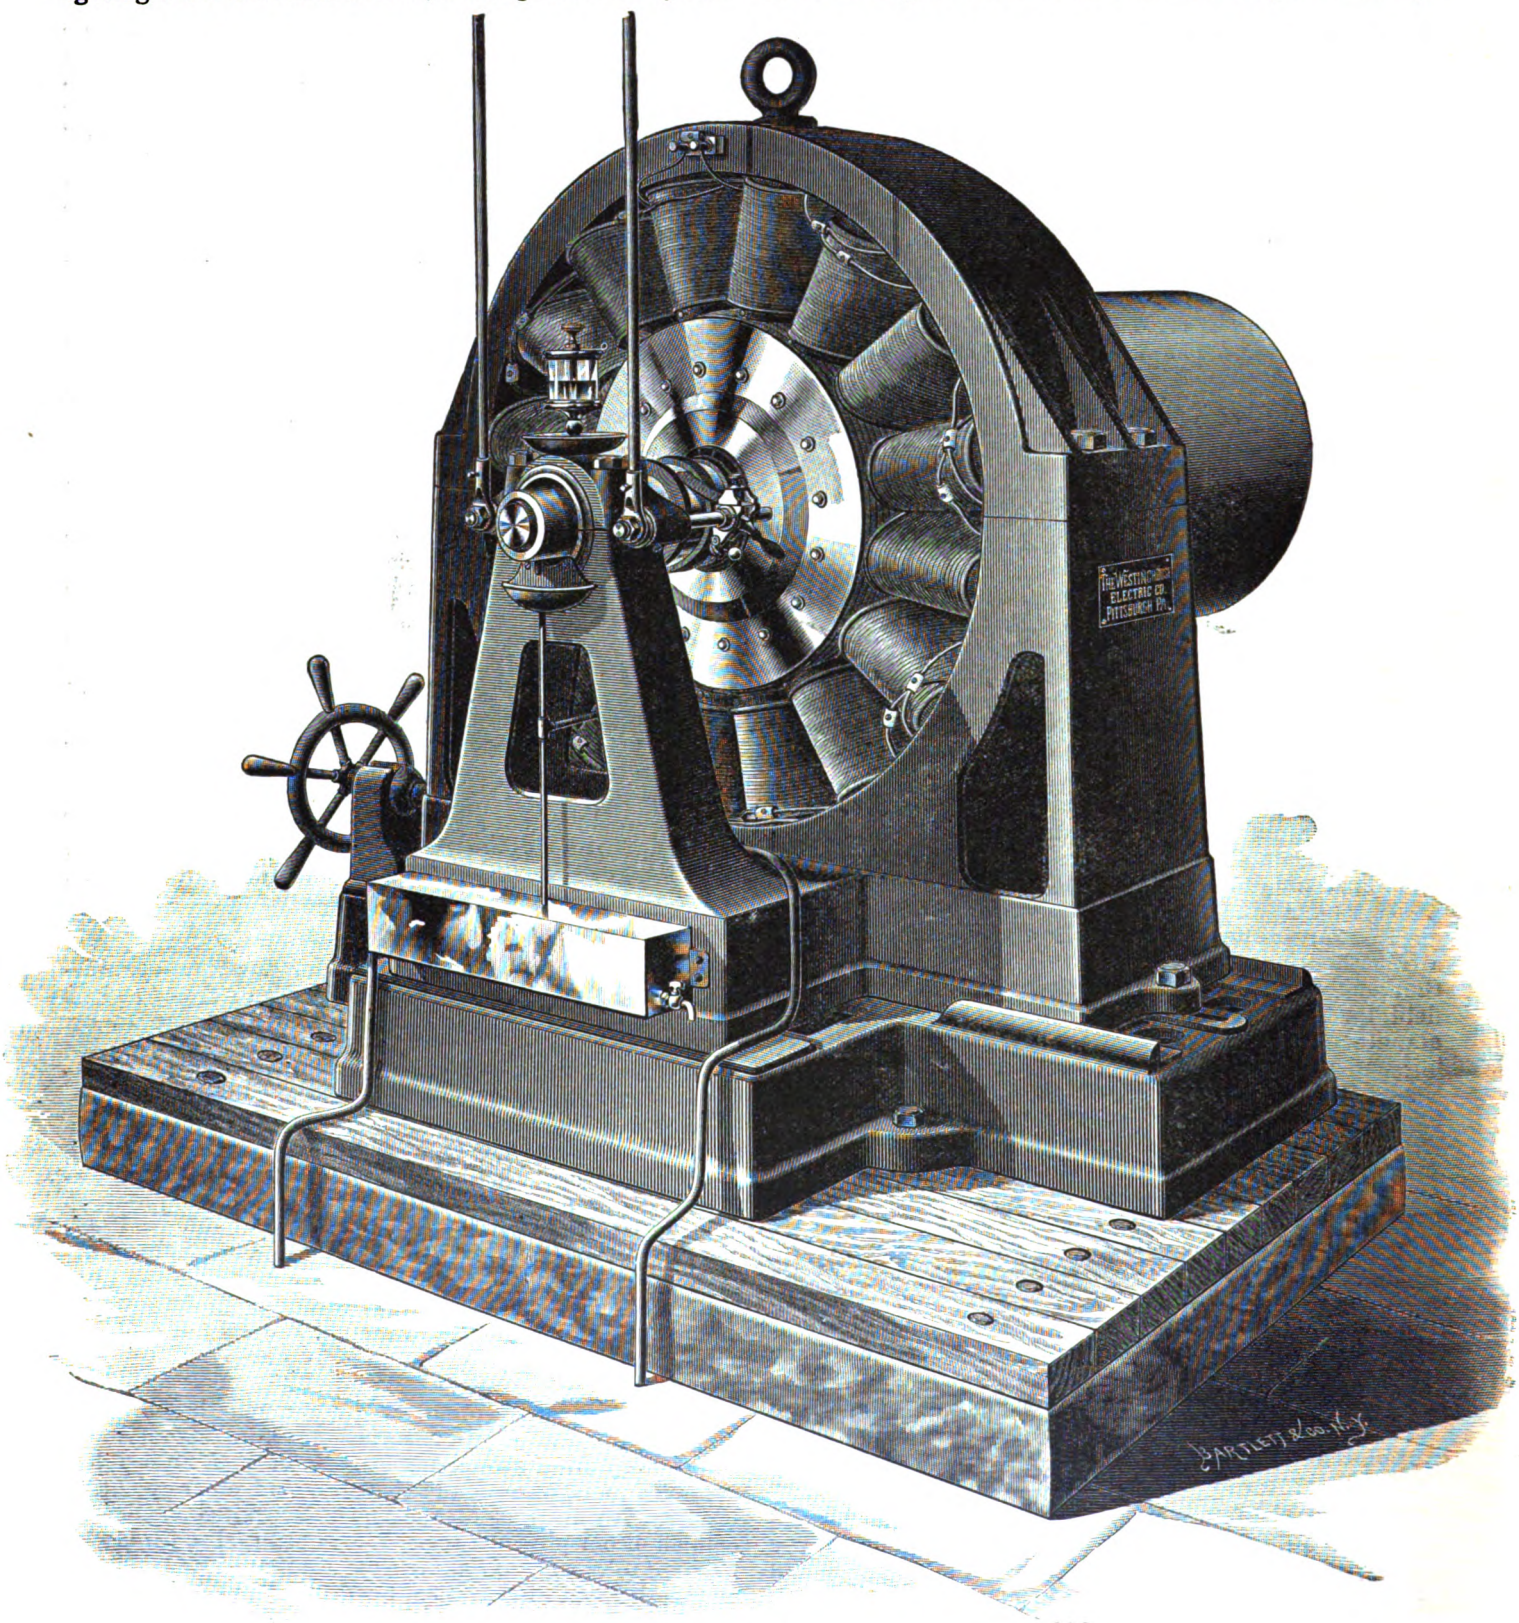

FIG. 1.

Digitized by Google

been in universal use in this country for incandescent lighting.

Not only does the alternating system in its present form dispense with the complicated apparatus of feeders, regulators, and the like, pertaining to the old systems, and with the accompanying multiplicity of wires at the central station, but it admits of a more simple and effective construction of the dynamo-electric machine, and what is of more importance, the plant as a whole may be installed at a vast saving in first cost, which is due principally to the comparatively small amount of copper required for the main conductors. The operating expenses are also materially reduced, as the conversion system has been found by experience to be capable of giving more light per horse-power, or per pound of coal consumed, than the direct system.

It is in lighting from central stations that the advantages of the alternating system are most strikingly manifested, and it is accordingly not a matter of surprise that the growth of the business of the Westinghouse company in this particular field during the past year has been quite unprecedented, the number of stations completed and in operation at the present moment being no less than 27, equipped with more than 75,000 c. p. of incandescent lamps.

The alternating system of the Westinghouse company is based upon the well-known secondary generator system of Messrs. Gaulard and Gibbs, which was first commercially introduced in London in 1883.[1] Although the fundamental principles of the Gaulard-Gibbs system have been retained in the Westinghouse apparatus, the manner in which these principles are applied has been considerably modified, while most of the details have undergone a radical and complete transformation at the hands of many skilfull and intelligent inventors, engineers, electricians and mechanics, the results of whose researches and labors have been utilized by the Westinghouse company. Especially important in this connection has been the work of William Stanley, Jr., one of the most talented of the younger electricians of the country, who has been connected with the company from the time of its first organization, and whose labors in developing and perfecting the present highly efficient methods and apparatus are deserving of special recognition.

While the ordinary system of direct distribution with lamps arranged in parallel is undoubtedly the most suitable for small isolated installations, both theory and practice have shown that except in very special cases, any considerable extension of the territorial area to be lighted necessarily entails an extravagant expense, either in installation or in subsequent operation, or both. If too small a main conductor is used with a view to economy in the cost of copper, the amount of energy wasted in heating the conductors becomes enormous; if, on the other hand, too large a conductor is employed, then capital is uselessly buried. A certain size should be selected with a view to offsetting one of these sources of loss against the other, in such a manner as to arrive at the maximum economy which circumstances permit.[2] The ingenious three-wire system of Hopkinson and Edison was regarded at the time of its introduction as an important improvement, as it effected a considerable saving in the quantity of copper required in any particular case, and thus correspondingly extended the area of profitable station lighting. The question as to the actual extent of this saving gave rise at one time to much discussion, but Professor Forbes has shown, by computations apparently conclusive, that assuming a two-wire system laid down under the conditions of the utmost possible economy in accordance with the law of Sir William Thomson, the maximum saving capable of being effected by the use of a third wire is 25 per cent.[3] In cases where the most distant lamp of the district to be illuminated is not more than 600 or 800 feet from the central station, the parallel or three-wire system is admirably adapted, but as soon as this distance is exceeded the cost of installation begins to mount up at a most alarming rate. A central station cannot be worked to the greatest advantage unless the engineer and firemen are fully employed, and hence it results that the maximum economy in steam plant, taking into account the cost of attendance, can hardly be reached with less than 1,000 h. p. It is clear, therefore, that the direct system can only be economically and advantageously applied in central station lighting in localities so densely populated as to require say 10,000 16 c. p. lamps within a radius of 800 feet; but in any such district space is usually very valuable, and the cost of the real estate required for the station becomes an important, if not a determining factor in the cost of the installation.

The controlling feature in all systems of direct distribution in which the lamps are individually regulable, is the resistance of the lamp filament. This is a necessary consequence of the law which governs the production of heat in a circuit traversed by an electric current, first enunciated by Joule, namely, that the heat developed by a current in any section of an electric circuit is in proportion to the resistance of that section.[4] In every system of electric lighting the problem is simply to develop the greatest possible amount of heat in the lamp filaments, and the least possible in the remaining portions of the circuit. Hence it is necessary to augment the resistance of the filament to the utmost practicable extent, which is effected by making the carbon of as small a cross-section and as great a length as is compatible with sufficient mechanical stability. It has not been found possible to increase the filament resistance of the ordinary 16 candle incandescent lamp, when alight, much beyond 200 ohms, without rendering it too fragile and delicate for ordinary use. Being thus limited in this direction, the only course remaining is to reduce the resistance of the remainder of the circuit to the lowest possible point; and in doing this, as already pointed out, it only remains to make the best available compromise between two antagonistic sources of expense, one represented by interest and depreciation calculated upon the first cost of the plant, and the other based upon the cost of power in each particular case, which will vary according as steam or water-power is used, and with the cost of coal. Thus the possible economy of the direct system is, in the present state of knowledge, strictly limited in every direction by natural laws, and can only be increased by increasing the resistance of the lamp filaments, a desideratum thus far sought for in vain. Moreover, should a means be hereafter discovered of increasing the efficiency of the lamp in this particular, its advantages would not be confined to the direct system of distribution but would be equally shared by the alternating system.

It has long been recognized that the commercial solution of the problem of electrical distribution from central stations must be sought for in the direction of a system of conversion by which the general distribution might be effected at a high potential permitting the use of small conductors, and the local distribution by currents of low potential adapted to supply incandescent lamps of ordinary resistance. Under these conditions the central station may be located at any convenient point where land is cheap, and where power can be economically obtained, without reference to its distance from the centre of consumption, and the station may be of any size, so that all the works may be concentrated in one place as they are

Digitized by Google

in gas distribution. Apparently all these conditions are successfully met by the alternating system, a circumstance due for the most part to its great flexibility. However great may be the area over which the system is extended, each lamp may be lighted, extinguished or regulated, without interfering with others, while the consumption of fuel remains proportional to the number of lamps alight, whether few or many.

The essential features of the Gaulard and Gibbs system are, first, a dynamo-electric generator producing alternating positive and negative currents of high potential, which are sent through a main circuit extending to the

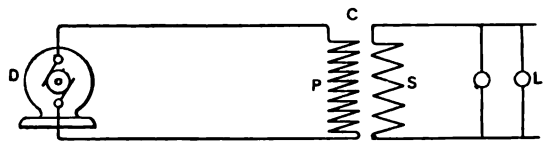

FIG. 2.

point of distribution; second, a reversed induction coil, that is to say, one having a greater number of convolutions given to its primary than to its secondary conductor, and third, electric lamps included in the closed secondary circuit of the induction coil. The general organization will be understood by reference to figure 2, in which D represents an alternate-current dynamo, C an induction-coil having a greater number of convolutions in its primary than in its secondary wire, and L an electric lamp. The extent to which the potential is reduced in transferring a given amount of energy from the primary to the secondary circuit depends mainly upon the ratio of the number of convolutions of the primary to those of the secondary. Thus, for example, if it were required to reduce the potential from 200 to 100 volts, it would be necessary to so construct the induction coil that the number of convolutions in the primary would be twice as great as the number in the secondary, and so for any other ratio of reduction. Such an induction coil has been termed by Gaulard and Gibbs a secondary geneaator. In the Westinghouse system it is more usually termed a converter.

The potential ordinarily employed in the main circuits of the Westinghouse installations is about 1,000 volts, and that in the lamp circuits 50 volts, the ratio of conversion being, therefore, as 20 to 1. The action of the apparatus will be readily understood in view of the foregoing explanation. The dynamo-electric machine D sends out rapid alternations of positive and negative polarity of high potential, and these induce other alternations of current of corresponding rapidity of succession, but of lower potential and increased quantity, in the secondary circuit

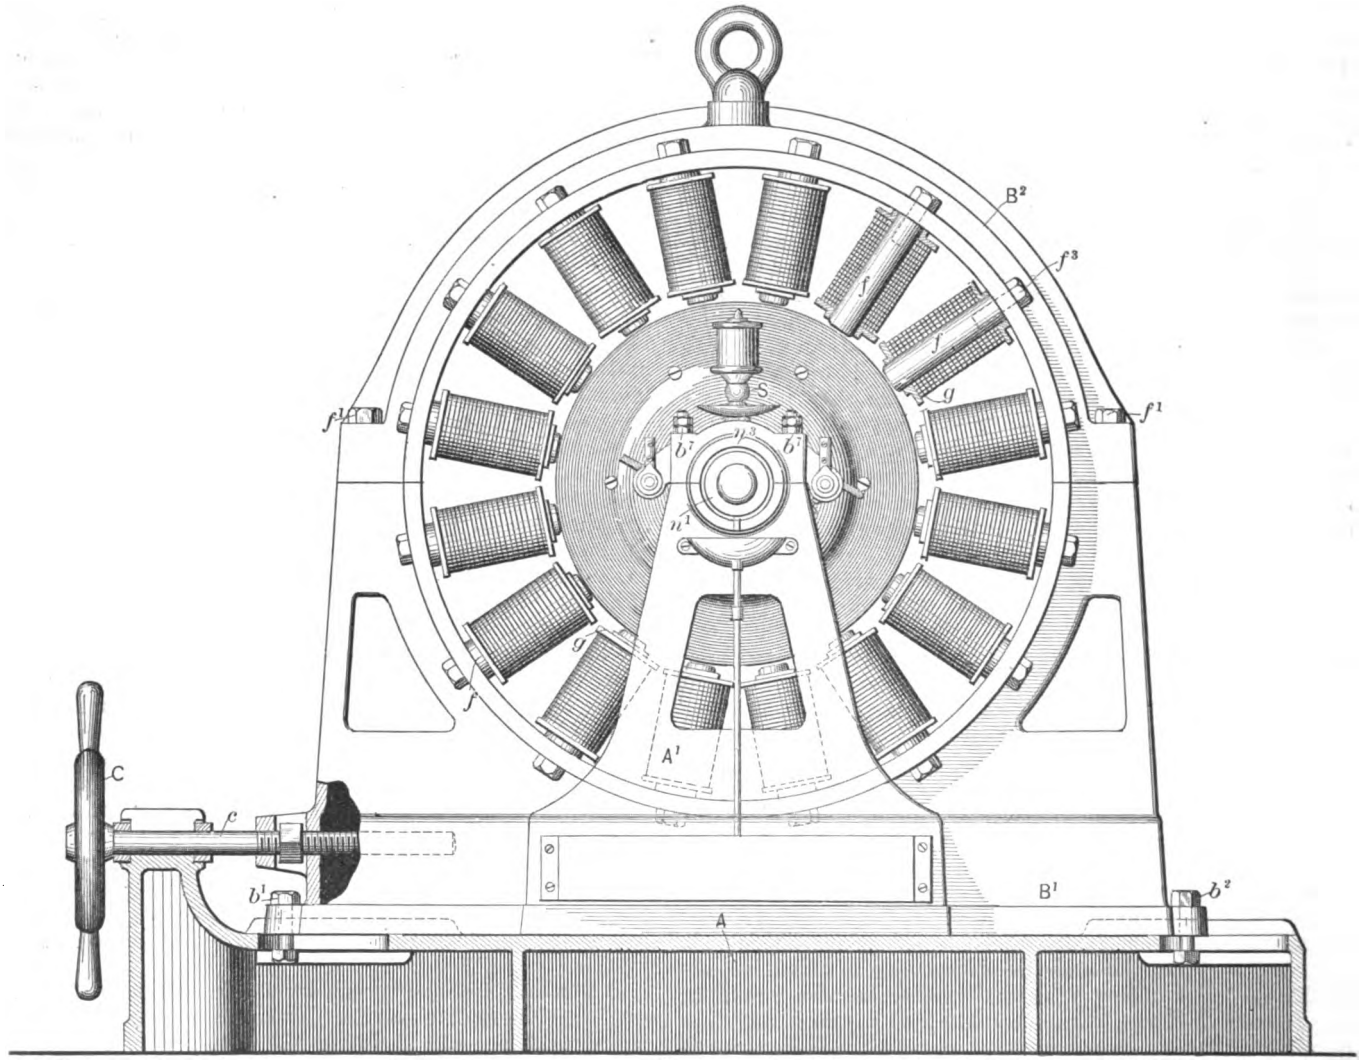

Fig. 3

of each converter. The rapidly alternating current has precisely the same heating and illuminating effect upon the filament of a lamp as the direct and continuous current, although experience has shown that the life of the lamps is considerably greater with the alternate than with the direct current.

The dynamo constructed by the Westinghouse Electric Co. for use with this system, was especially designed for this service by Mr. Stanley, and is of the separately excited type. It is at present manufactured in three sizes; No. 1 having a rated capacity of 650 16 c. p. incandescent lights, and Nos. 2 and 3 having a rated capacity respec-

Digitized by Google

tively of 1,300 lights and 2,500 lights. The engraving, figure 1, is an excellent representation of the external appearance of the No. 1 dynamo. The details of the construction of the machine will be best understood by reference to the sectional drawings, figures 3, 4 and 5. The foundation of the machine is a heavy cast-iron bed-plate A, having lateral projections upon which the standards A^1 and A^2 of the armature shaft K, are supported. These standards are an integral portion of a single casting B^1, which rests upon the bed-plate and is held in position by bolts b^1 b^2, passing through slotted holes, by the aid of which the lateral position of the entire machine may be adjusted by the hand wheel C and adjusting screw *c*, an adjustment which is necessary when several machines are belted to a single driving-shaft. The cores, *f*, *f*, of the 16 inwardly projecting field-magnets surrounding the armature are fixed to a circular yoke, the lower half of which is formed by the casting B^1, while the upper half constitutes a separate piece, B^2, the two parts being bolted together at f^1 f^1. The field-magnet coils are each wound separately, and afterward slipped over the pole-pieces, and secured in position by screws *g*.

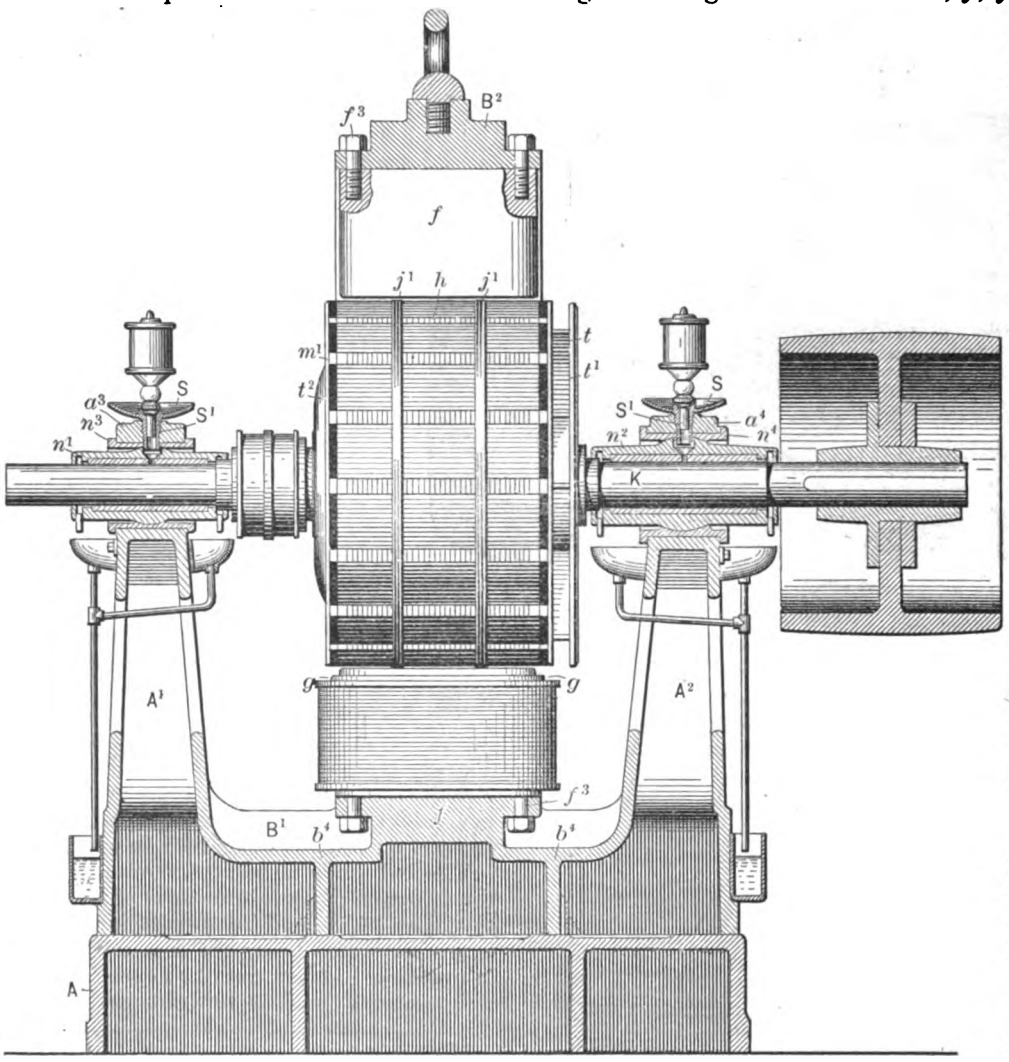

Fig. 4

The armature is cylindrical in form, and is made up of a great number of discs of thin rolled iron placed side by side and insulated from each other by paper. Each plate is stamped out with holes as indicated at *i* *i*, which serve to cool the armature when running as well as to diminish its weight. In putting the armature together, the holes in the several plates are made to register, so that they form openings ex-

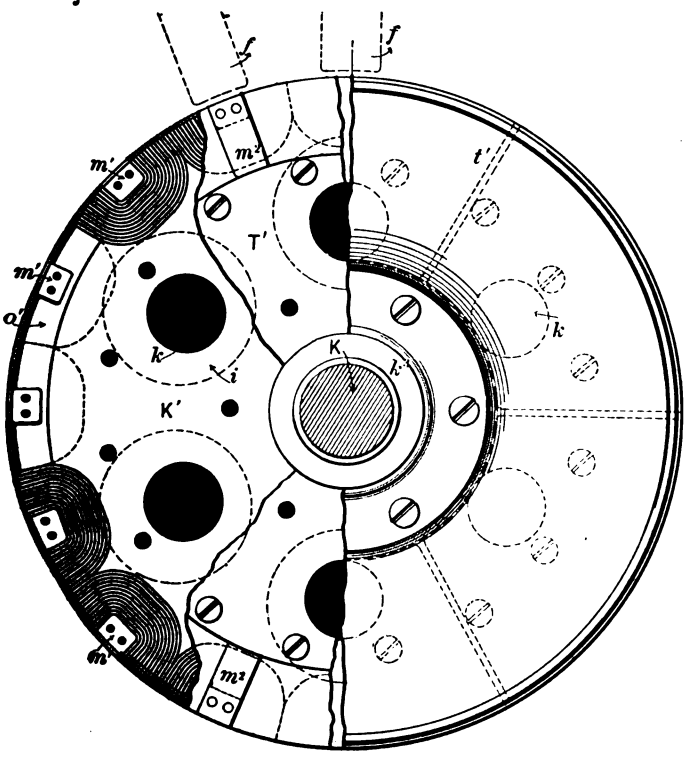

Fig. 5

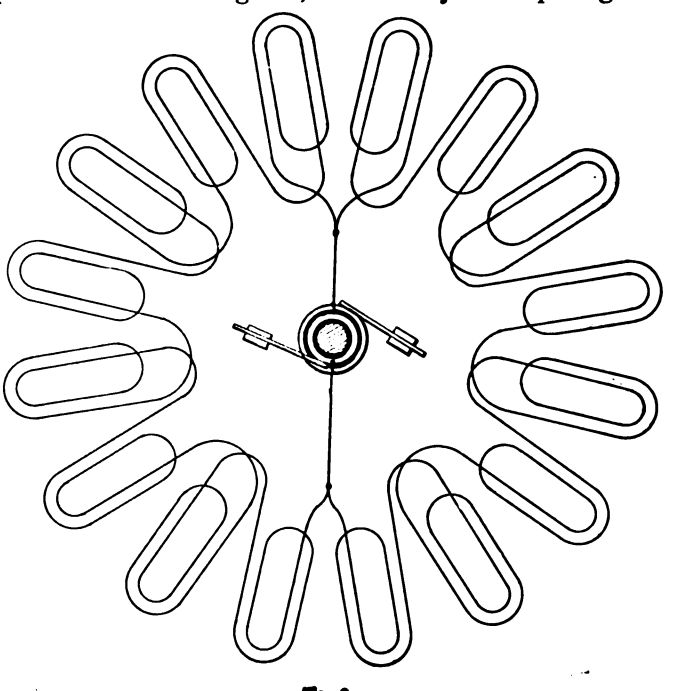

Fig. 6

Digitized by Google

tending through the entire length of the cylinder. The discs are clamped together by thick end-plates or heads, κ^1, κ^1, perforated with ventilating holes, k k, and provided with reinforcing plates, t^1, t^2.

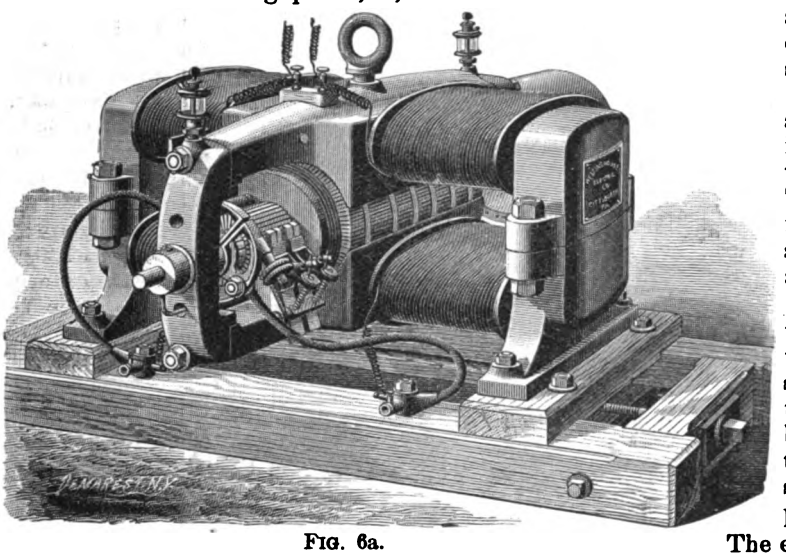

FIG. 6a.

The armature coils are wound as follows: Non magnetic plates or strips are secured to the periphery of the armature, at the ends of which are overhanging plates, m^1 m^1, secured to the ends of the armature. The wire is then wound across the face parallel to the axis, and over the corner of the armature, passing around the insulating strips and under the ends of the plates m^1, filling the spaces between them. In order to shield the wire from

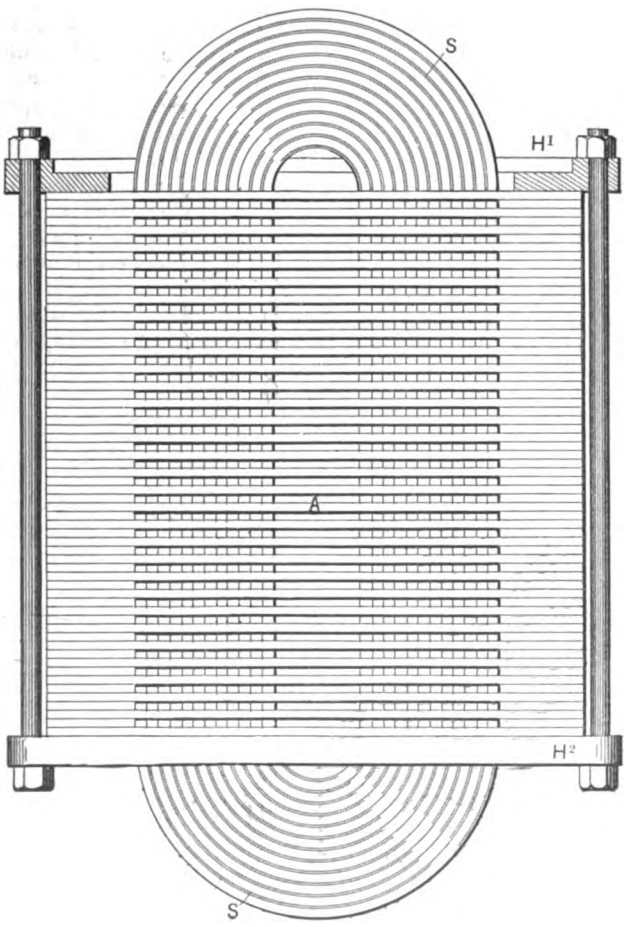

Fig. 7

the edge of the plates, and to avoid bringing the binding plates to the corner of the armature, rings o^1 o^2 are fixed at the edges of the armature, flush with its periphery and having their corners rounded so as not to produce too sharp an angle in the wire. In order to more effectually insulate the wire from the body of the armature, the surface of the latter is covered with sheets of mica, and again after the wire is in position, the whole is covered with mica. The parts of the armature are secured by belts of wire j^1, wound circumferentially.

In the larger machines, instead of winding the armature wire in a continuous circuit, it is divided in parallel in such a manner as to effectually separate the points of maximum and minimum potential. This method of winding is shown in diagram figure 6, and needs no detailed explanation. The smaller, or No. 1 machine, is usually wound in a continuous circuit.

The journals of the armature shaft are of the type known as "ball bearings" which serve to centre the armature automatically. These are designed in a very convenient manner, by making the ball-bushes, n^1 n^2 separate from the split bushes, n^3 n^4. The oil pipe, s^1, extends through the upper section n^2, of the split-bush and into the section n^1 of the ball-bush, and thus serves to prevent the latter from revolving.

The exciter employed for the field circuit of the Westinghouse dynamo is an ordinary Stanley direct current shunt-wound dynamo of the pattern shown in figure 6a.

The weight of the No. 1 alternate machine is 5,000 pounds; No. 2, 7,550 pounds, and No. 3, 13,500 pounds.

The first two are run at a normal speed of 1650 revolutions, and the latter at 1175 revolutions per minute. The electromotive force ordinarily employed in the main circuit is from 1000 to 1100 volts. Not more than an equivalent of two per cent. of the total energy developed in each machine is consumed in energizing the field.

The induction apparatus, commonly called the converter, is ordinarily made in three sizes, respectively adapted to supply 40, 30 and 20 50-volt incandescent lamps of 16 c. p. each, these being the dimensions generally called for in practice. Other sizes however are made, some having a capacity as small as 10 lights and others as large as 80

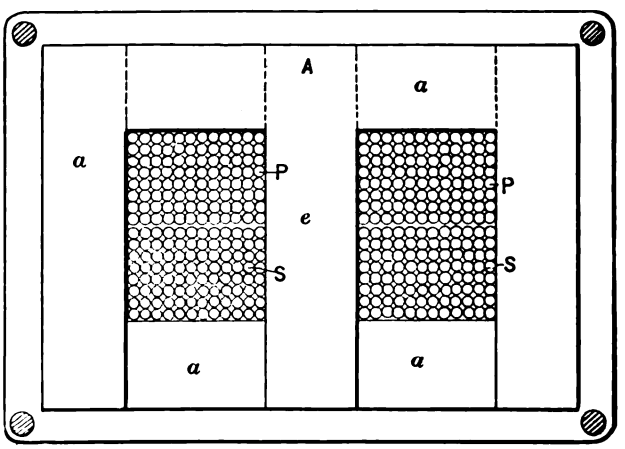

Fig. 8

lights. A 40-light converter contains about 85 pounds of iron and 25 pounds of copper, so that the total weight of metal in this converter is less than three pounds per lamp, while the same proportion holds good with trifling variation in the larger and smaller sizes. In the converters as now made, the efficiency of electrical conversion exceeds 95 per cent., when the potential is reduced from 1000 volts in the primary to 50 in the secondary.

The form of converter used, as originally designed, is shown in elevation in figure 7, and in cross-section in figure 8. The primary and secondary coils are separated and insulated from each other and are disposed side by side as shown at P and S. After these have been wound upon a form into suitable coils and wrapped with insulating

Digitized by Google

material, the inductive plates A, which are in the form of a capital letter E, as shown in figure 9, of thin sheet-iron

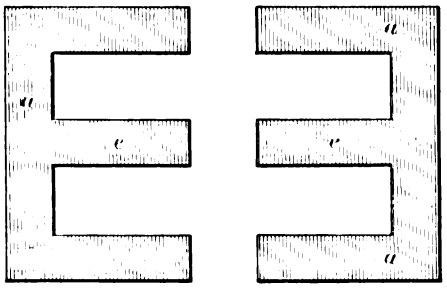

Fig. 9

with an insulating layer of paper applied to one surface, are slipped over the coils alternately from opposite directions, the alternate plates being interleaved with each other as shown at A. Thus the inductive core is composed of a mass of detached plates, each of which of itself constitutes a discontinuous magnetic circuit. The plates are insulated from each other by the paper, and as alternately arranged about the coiled conductors the mass of the core becomes symmetrically disposed about the mean axis of the conductors, a necessary condition for effective work. The iron plates are securely bound together in a solid mass by end frames or heads, H¹, H², which are connected together by longitudinal bolts. A more recent and in some respects preferable form of plate for the

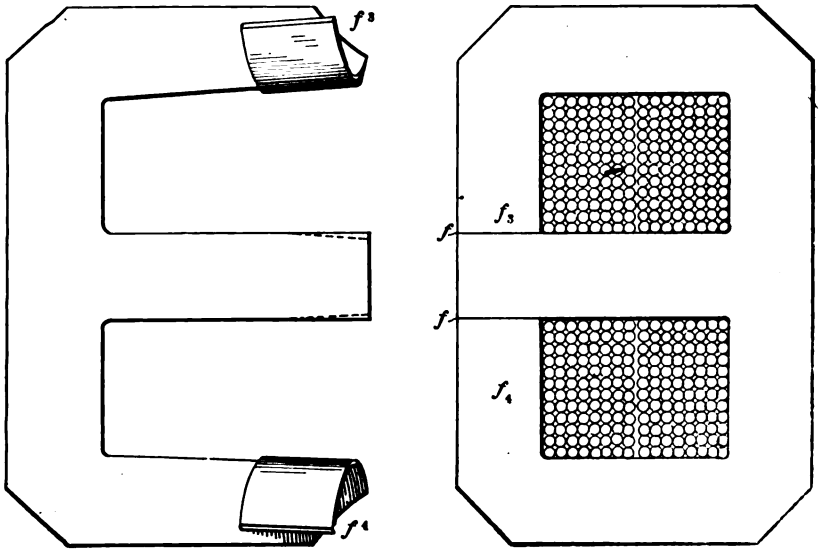

Fig. 10

cores is shown in figure 10, and for convenience of construction is the one now generally preferred. Each plate is in one piece, but is cut at *f f*, the ends f^3 and f^4, being readily bent back as shown to permit the plate to be slipped over the coils.

In order to protect the converter from mechanical injury, as well as from dampness, and also to avoid the possibility of contact with wires carrying currents of high potential, it is enclosed in a cast-iron case or box, made in two parts, and adapted to be secured to any convenient vertical support. Figure 11 is a front view, and figure 12 a transverse vertical section of such a converter-box, with the converter in position. The terminals of the primary coil P of the converter are led into the compartment D¹, and the terminals of the secondary coil into the compartment D². The terminals are secured to bolts or couplings *f f*, mounted upon insulating plates e^1 and e^2. Fusible strips *g*, and switch-plates *h* and *i*, with plugs *k*, are provided for protecting, and connecting and disconnecting the circuits. The fusible strips and their connected conductors are effectually insulated from each other by a plate of fibre r^3. The open fronts of the compartments D¹ and D², are

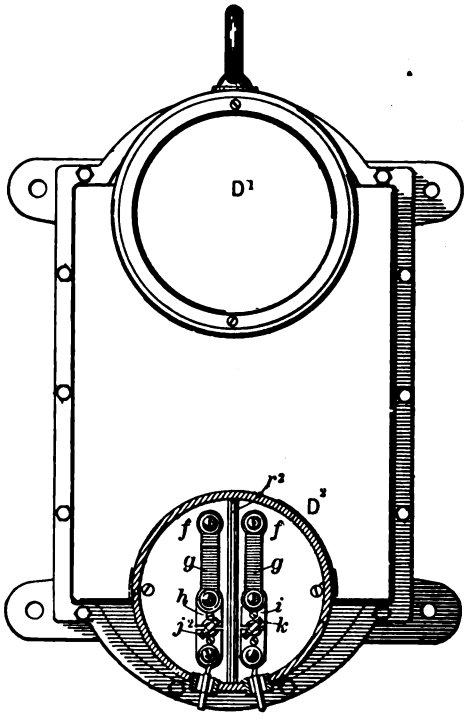

Fig. 11

closed by glass plates T, which permit inspection of the connections without entering the box.

The converter-box occupies but little space, and may be placed in any convenient situation in or about the premises to be lighted, much the same as a gas meter. It is usually preferred, where overhead conductors are used, to mount the converter-box upon a pole in the vicinity of the premises to be lighted, as shown in figure

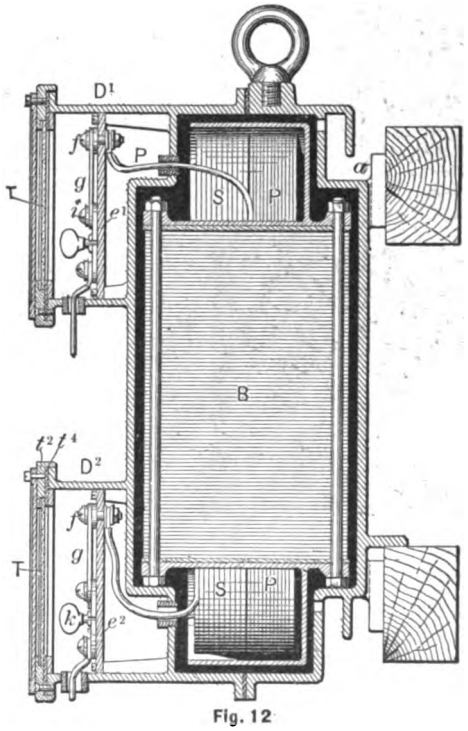

Fig. 12

13, and thus it is only necessary to lead the secondary or low potential wires into the building, the high potential wires remaining in an inaccessible position upon the pole. Figure 13 is a view in North street, Pittsfield, Mass., en-

Digitized by Google

graved from a photograph, showing a very neat form of tubular wrought-iron pole with its converter-box, designed by Mr. Stanley, and employed in the installation recently carried out by him in that town. These poles were manufactured by Robbins, Gamwell & Co., a local firm.

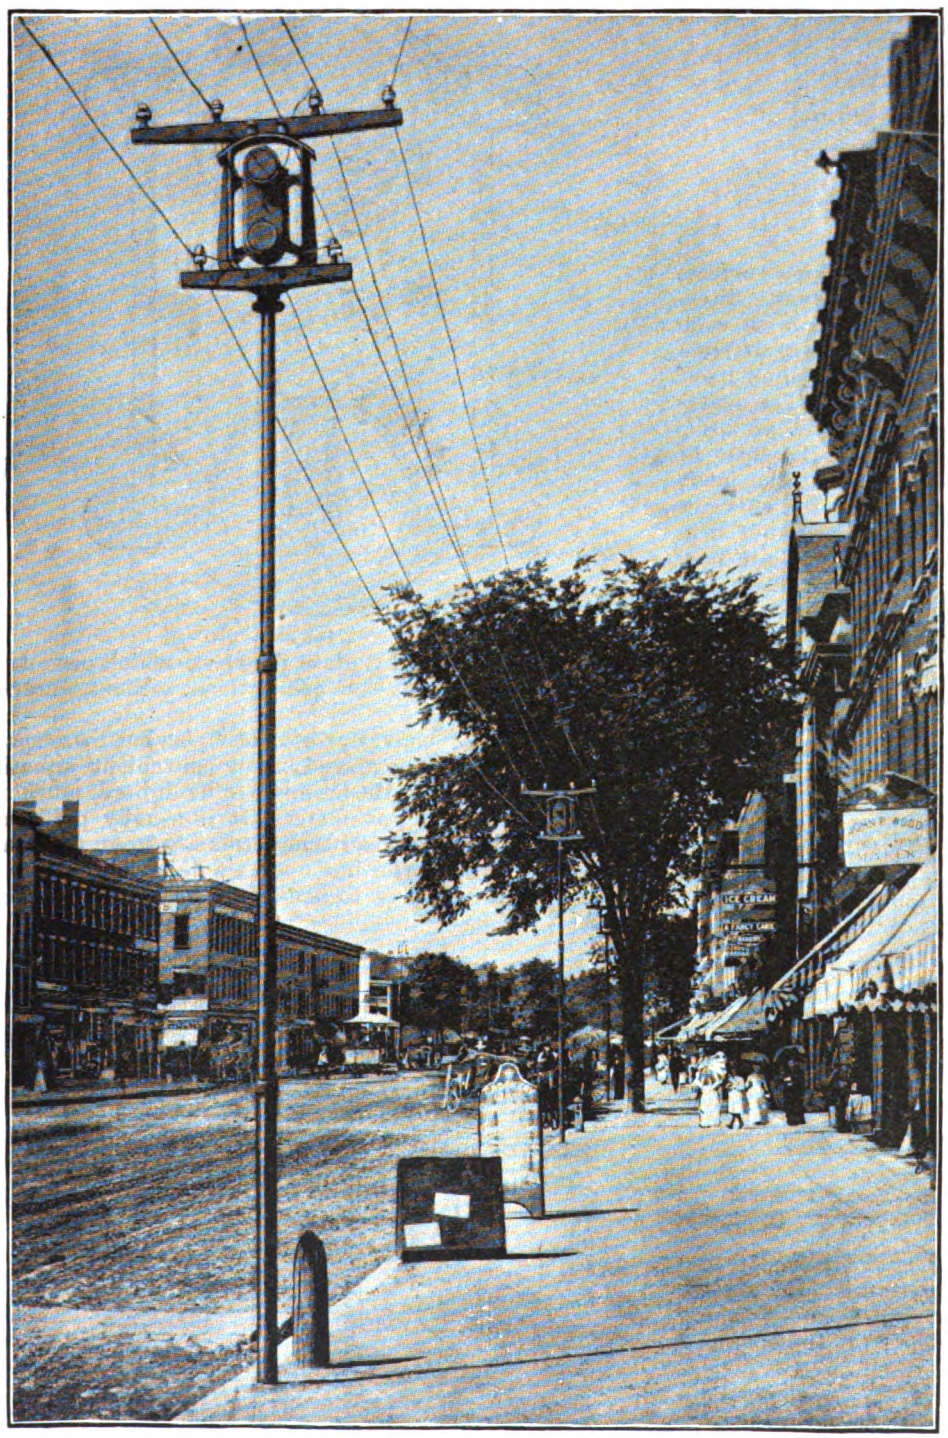

FIG. 13.

The incandescent lamps supplied by the Westinghouse company are made in four standard sizes, of 16, 25, 50 and 150 c. p. respectively. The greater number of lamps required are of course of the 16 c. p. grade, of which figure 14 is a correct representation in its natural size. The filament is of carbonized silk, a material which has been found to serve the purpose admirably when properly prepared and treated. The fittings of the 16 c. p. lamp are neat in design, ingenious in construction and arrangement, and extremely convenient and efficient in practical use. One of the terminals of the lamp is connected to the insulated brass tip shown in figure 14, and the other to the thimble or cup of sheet brass into which the neck of the lamp is inserted. The thimble is provided with a semi-circular circumferential groove at the end next the tip of the lamp for a purpose hereafter to be explained.

Figure 15 is a full sized perspective view of the lamp socket and key, of which figure 16 is an elevation, the outer casing being shown in section. Figure 17 is a plan of the socket, the cap being removed, and figure 18 is a section in the plane of the line $x\,x$ in figure 17. Figure 19 is a perspective view of the same. A perspective view of the socket showng the key and switch is given in figure 20. The various parts are supported upon a block of insulating material, A, upon one face of which is secured a cylindrical cap, B, having flexible resilient arms, b, adapted to grasp the semi-circular groove upon the lamp fitting, before referred to, when the lamp is shoved into its socket. The opposite face of the block A, carries a metallic conducting bar, D, provided with a spring-jack device d^1, d^2, adapted to receive and grasp the central contact tip of the lamp. The contact-spring e is brought into electrical connection with another similar spring, e^2, by means of a moving contact-piece, e, whenever it is desired to complete the circuit between the terminals B and D, for the purpose of lighting the lamp. The contact-piece e, is a metallic pin extending through the pivoted plate K, but insulated therefrom. The standard K^1 to which the plate K is pivoted, is affixed to a crank axis, k, provided with a thumb piece, k^3. The plate K receives its motion through the intermediary of a spiral spring, s, attached at one end to the elbow of the crank axis, k, and at the other to an arm, s^2, projecting from the plate K. When the crank-arm k is turned by the key, the end of the spring s is carried to one side or the other of the fulcrum of the plate K, and thus the tendency is to pull the latter suddenly in the corresponding direction the instant it is over the centre. This snap-movement effectually prevents the formation of an arc between the terminals when the circuit is broken. A tube K^1, of insulating material surrounds the switch mechanism, and secures it against accidental electrical contact with the metallic case T. The cap is secured to the case by small set-screws, o, o, which enter slots forming bayonet joints on each side of the cap, as seen in figure 15. It will be observed that the principle of the adjustable contact between the lamp and the socket in the Westinghouse lamp is precisely the same as that of the spring-jack device which has

Digitized by Google

been so long in successful use in the telegraphic service, the simplicity and continued efficiency of which has been well established.

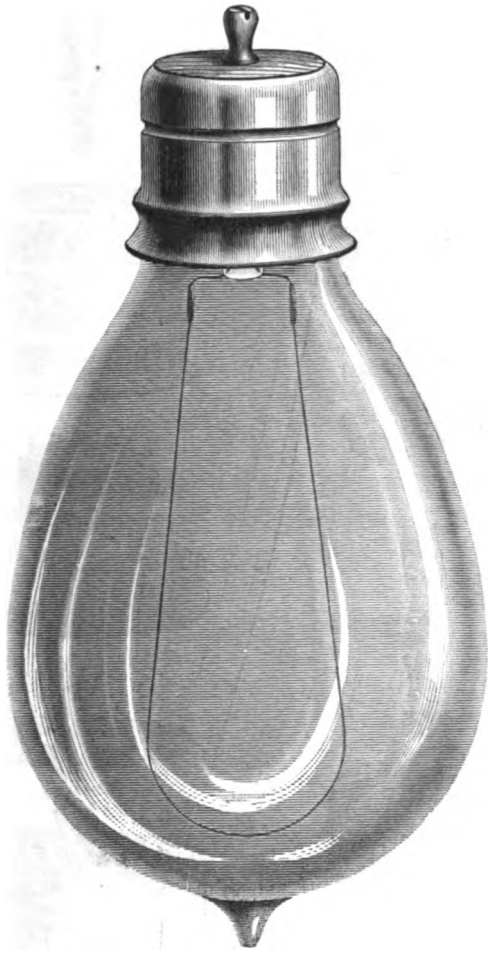

FIG. 14.

Figure 21 shows a fitting designed to be attached to a reading or other portable lamp, and connected therewith by a flexible cord conductor. This is adapted to be inserted into any convenient socket from which a lamp has

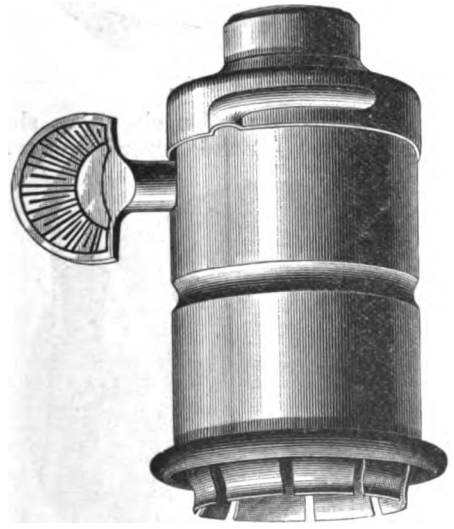

FIG. 15.

been removed, and will readily be understood without detailed explanation by referring to figure 22, which shows the same device with its component parts separated in order to more clearly exhibit its internal construction.

Figure 23 shows the external appearance of the switch which is designed to be placed in a building for turning off and on groups of lamps, either in the entire building or in any particular room.

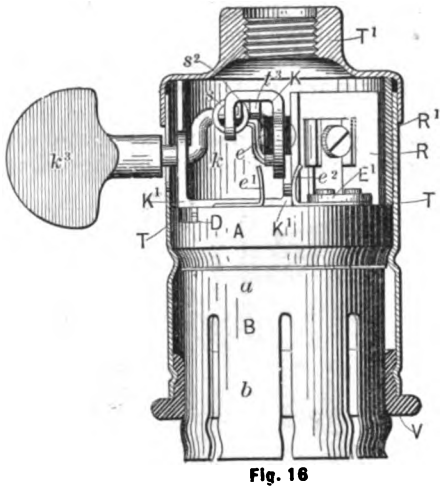

Fig. 16

The question of the arrangement of the converters in circuit for practical work is a very important one. The original plan of Gaulard and Gibbs was to extend a single main primary conductor throughout the district to be served, in which the primary wires of the secondary generators or converters were placed in series, in the manner

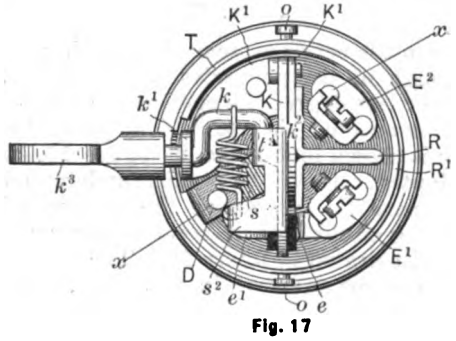

Fig. 17

illustrated in figure 24. In the installation erected in 1885, in the vicinity of Regent street, London, a double or looped wire was used in order not to interfere injuriously with the telephone service, and the converters were alternately put in one wire and the other all round the district, each pair of wires ending in a loop at a point remote from the station.

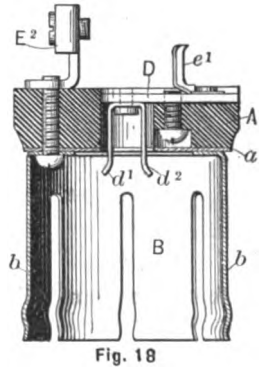

Fig. 18

When the converters are thus arranged it is necessary to maintain a constant current in the circuit. No especial difficulty has been experienced in doing this, as the problem is substantially the same as that encountered in arc lighting, but another difficulty in the series system has always been to maintain a constant potential in the individual lamps. To effect this automatically turned out to be no very easy matter, and many ingenious devices designed for that purpose failed to accomplish their end, largely for the reason that, up to a very recent period, the theory of the action of converters had been but little

Digitized by Google

studied except by specialists, and was not generally very well understood. A simple and effectual solution of the difficulty was found, by arranging the installation so as to bring the primaries of the converters in parallel arc with the generator. When thus situated any fluctuations in the strength of the primary current caused by variations in the amount of consumption in one or more of the secondary circuits, necessarily reacts upon the generator only, without traversing the primaries of any of the other convert-

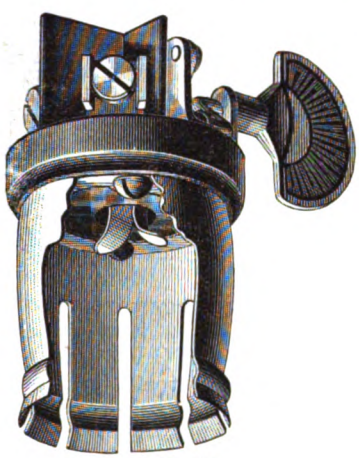

FIG. 19.

ers, whereas in the series system every such perturbation, passing through all the primaries in the system, affected in a greater or less degree the current in every one of the secondaries connected thereto.[5] The parallel system of distribution is shown in diagram in figure 25, and is the one now adopted. It will be readily understood without further explanation. In practice the method of running the distributing circuits where aerial lines are employed is usually that illustrated in figure 26. The poles are fitted with two cross-arms as shown in figure 13, leaving room

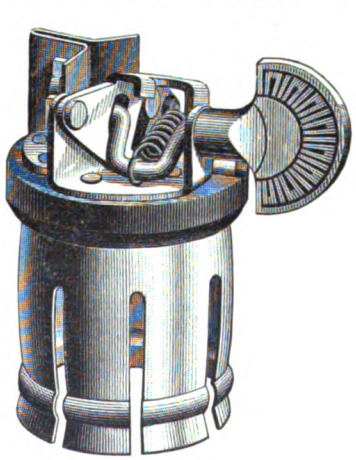

FIG. 20.

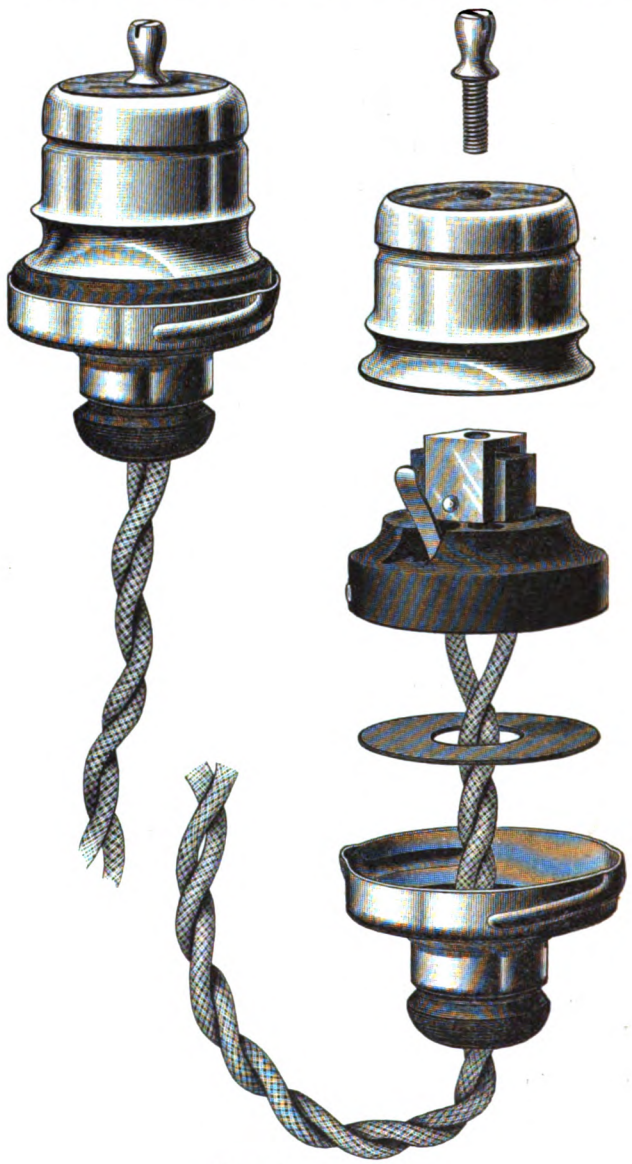
for the converter box between them. The upper cross-arm carries the main distributing conductors L^1 and L^2, upon insulators b^1 and b^2, while the secondary or consumption circuits are similarly carried upon the lower cross-arm. Instead of leading the secondary conductors directly to the point of consumption, the converters c^1, c^2, c^3, etc., upon the poles are connected directly to the consumption circuits on the lower cross-arm in parallel, and from these circuits the service wires 11 and 12 for supplying the lamps d^1 and d^2 in the adjacent buildings, are taken off as required. It is of course essential that an approximately equal difference of potential between the secondary conductors s^1 and s^2 should be maintained at all points, and this is effected without difficulty by locating the converters c^1, c^2, etc., at such points and at such distances apart



FIGS. 21 AND 22.

with reference to the consumption circuit as shall effect this result. Each one of the several converters (as

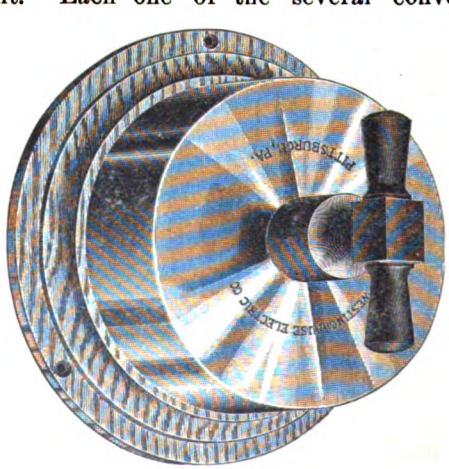


FIG. 23.

explained in connection with figures 11 and 12) is provided with a cut-out plug switch, so that it can be con-

5. This arrangement was first pointed out, though possibly not first tried, by Rankin Kennedy, of Glasgow. His communications were published in the London *Electrical Review*, June 9 and June 16, 1883, vol. xii, 486, 506.

Digitized by Google

nected to, or disconnected from the consumption circuit at a moment's notice, when required.

It is not difficult to understand the reason of the economy in the cost of electrical distribution which is effected by the use of an alternating system worked at a high potential. Considering first the cost of installation, not only is the alternating dynamo much less expensive in its construction than the direct current machine, but the cost of the necessary auxiliary appliances at the central station is comparatively small, and above all the expense of the conductors throughout the system is enormously diminished, as will be readily seen in view of the fundamental law that the electrical energy traversing a conductor of given sectional area is directly as the square of the difference of potential at its terminals; and hence in working at a mean potential of 1,000 volts, as

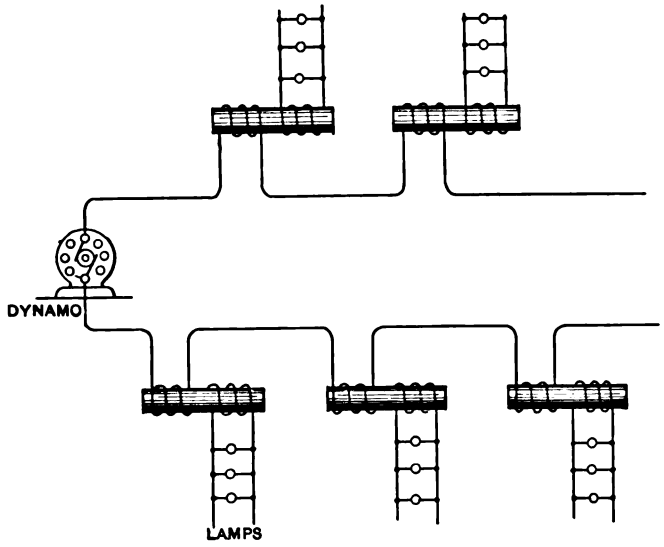

FIG. 24.

is ordinarily done in the Westinghouse system, only about one-thirtieth of the total weight of copper is required in the mains that would be necessary at the potential to which the direct current three-wire system is practically limited, namely, 200 volts. The diagrams, figures 27, 28 and 29, exhibit this difference in a forcible manner, showing as they do, the actual areas of cross-section of the total mass of copper necessary to supply 5,000 16 c.p. incandescent lamps situated at a mean distance of 4,000 feet from the dynamo. Figure 27 refers to the three-wire system, working at a potential of 200 volts with a fall of potential or loss of energy in the feeders of 10 per cent., the usual conditions under which this system is worked. Figure 28 shows the conductor required for the same work in a Westinghouse installation wired for a loss in the feeders of 2.5 per cent., only one-fourth as much as the direct system. If this loss were increased to 10 per cent. to equal the loss in the direct system, the same work might be done on a wire of the size shown in figure 29, but this would lessen the economy of working to an undesirable and unnecessary extent. It will of course be understood that the diagrams show the aggregate cross-section of all the feeders in each system, and not that of any single one.

The graphic diagram, figure 30, shows in an equally striking manner the saving in the cost of the conductors which is effected by distributing at a high potential under the above conditions.

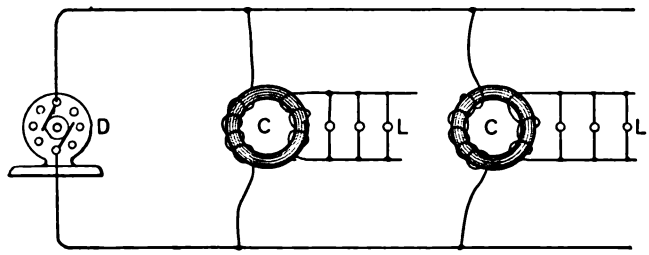

Fig. 25

The gain in economy of operation in the conversion system, though less apparent than in cost of installation, is nevertheless of great importance. The current in the consumption circuits is adapted to meet the requirements of a 50 volt lamp, which, by reason of its thicker filament, has a much longer life, and will bear a much higher energy of light conversion than the 100 volt lamps used in the direct system, so that it consumes 15 per cent. less energy per candle-power, a most important consideration. By reducing the fall of potential in the main circuits to two and one-half per cent., the feeder equalizers, pressure in-

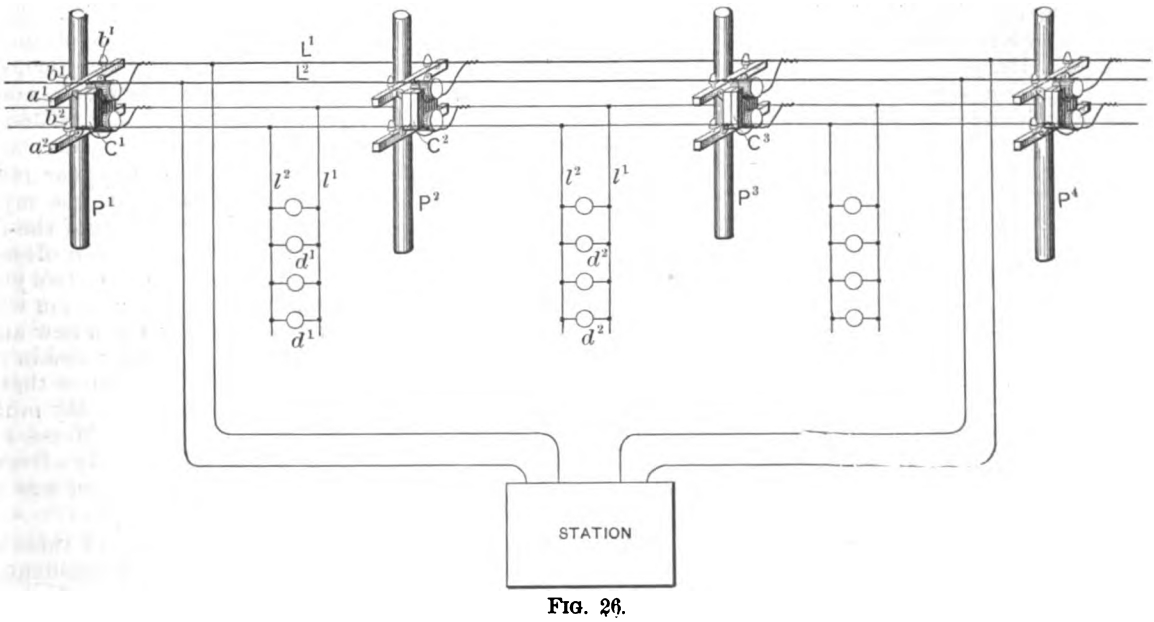

FIG. 26.

dicators and complex wiring of the direct system are altogether dispensed with, together with the services of

Fig. 27

Experience has demonstrated that the trifling loss of energy in conversion from high to low potential at the point of consumption is so much more than offset by the gain at other points, especially in the increased efficiency of the lamps, that an alternating plant may be counted on to give ten 16 c.p. lamps per indicated horse-power, as against six to seven lamps per indicated horse-power by the direct system, which is equivalent to a saving of about 25 per cent. in the quantity of fuel necessary for operating the station.

Recent experiments have proved that the arc lamp may readily be adapted to work on the 50 volt current from the secondary of the Westinghouse converter, which renders the alternate system peculiarly well adapted to fulfill the requirements of a mixed incandescent and arc plant, such as is sometimes required in towns of moderate size.

AN UNPUBLISHED CHAPTER IN THE HISTORY OF THE ELECTRIC TELEGRAPH.

THE following interesting account of the early development of the American electro-magnetic telegraph, was written by Alfred Vail, the partner and associate of Prof. Morse, its date, according to his diary, being January 15th, 1848. The manuscript is in his own handwriting throughout, and has never before been printed. The true history of the part taken by Alfred Vail in the invention and development of the invention known to the world as the Morse telegraph, is but faintly indicated in this hasty sketch, and in its entirety is yet to be written. The remarkable abilities and tireless industry of Vail, were only surpassed by his exceeding modesty, and thus it happened that the true greatness of his character was scarcely understood or suspected even by those of his contemporaries, most intimately associated with him in the ordinary concerns of life. The telegraph of modern times, though bearing the name of Morse and unquestionably suggested by his original conception, contains in its essential features scarcely a trace of Morse's work. It is in fact as it stands to day, an invention of Prof. Joseph Henry, adapted to commercial uses by Alfred Vail.—[ED.]

SOMETIME during the early part of the year 1837, having called at Professor Morse's studio (it was my habit to make him occasional visits, being a student of the University of the City of New York of which he was a professor, having had a previous acquaintance of some one or two years boarding at the same house), during a conversation with him he told me that he was about to bring out a new and important discovery which would make some noise in the world. I expressed a wish to see it, and he replied that he would apprise me and send me an invitation. My mind became deeply impressed with what Professor Morse had stated, and I called upon him the more frequently afterwards, but do not now recollect that anything further was said about the invention.

However, it so happened that on one of these occasional visits, prior to September 4th, 1837, I accidentally, without invitation, called upon him at the University and found Professor Torrey and Professor Daubeney in the mineralogical cabinet and lecture room of Professor Gale in the University, where Professor Morse was exhibiting

Digitized by Google

to these gentlemen an apparatus which he called his "electro-magnetic telegraph."[1]

There were wires suspended in the room, running from one end to the other and returning many times, making in all 1,700 feet. The two ends of this wire were connected with an electro-magnet fastened to a vertical wooden frame. In front of the magnet was its armature and also a wooden lever, or arm, fitted to hold at its extremity a lead pencil. This lever was supported upon an axis which permitted it to work freely. There was also a spring connected with the lever to carry the armature from the magnet when the wires were broken (separated) at the ends. To these vertical supports were also fixed a train of wheels, similar to those of a wooden clock, which with rollers drew off a strip of paper wound round a pulley by means of a weight. This paper passed over a roller directly under the point of the lead pencil in the end of the armature lever. The magnet and lever were so placed in the vertical frame that the movement of the pencil, always touching the paper, was across it and not parallel with its length.

There was another apparatus made of two long flat pieces of wood, so fastened together by their sides that the space between them would admit of pieces of metallic plates of type-metal, some of which were thick spaces, commonly used by printers for spacing lines, and had notches in them. There were others also which appeared to be cast. These types with their notches and spaces were used for breaking the circuit by raising the wire out of a cup of mercury and thus letting the battery into action or taking it out, producing magnetism in the electro-magnet and then divesting it of magnetism.

This instrument I saw work and produce that peculiar kind of marking which appears like the letter **V** or **W**, and described, page 75, in the work on the American electro-magnetic telegraph.[2]

I became thoroughly acquainted with the principles of its operation and I may say struck with the rude machine, containing, as I verily believed, the germ of what was destined to produce great changes in the condition and relations of man. I well recollect the impression it then made upon my mind. I rejoiced to think that I lived in such a day, and my mind contemplated the future in which so grand and mighty an agent was about to be introduced for the benefit of the world. Before leaving the room in which I beheld for the first time this magnificent invention, I asked Professor Morse if he designed to make an experiment on a more extended line of conductors. He replied that he did so intend, but desired assistance to carry out his plans. I then promised him assistance for a share in the invention, to which he assented. I then returned to my boarding house, locked the room door and threw myself upon the bed, and gave myself up to the reflection of the mighty results which were to follow the introduction of a new agent in meeting and serving the wants of the world. With the atlas in my hand I traced the most important lines that would certainly be erected in the United States, and calculated their length. The question arose in my mind whether the magnet could be made to work through great lengths, and after much reflection I came to the conclusion that, provided the magnet would work at a distance of eight or ten miles, there was no risk in embarking in the enterprise. And upon this I decided in my own mind *to sink or swim with it.*

An agreement was soon thereafter entered into, dated 23d September, 1837, in which for certain considerations and services a certain interest in the invention was to be made over to me. And upon the execution of these papers, Professor Morse and myself left the city for the Speedwell Iron Works[3] for the purpose of constructing suitable instruments for exhibition before the members of Congress. Immediately was the work set about. Ten miles of copper wire and a quantity of ribbon wire were ordered. The frame, wheels and drums of the register instrument were made, for then it was designed to put a sheet of paper upon a drum which slid upon a square bar of cast steel about 18 inches long. This drum had a single spiral on one end made of steel plate which projected beyond the surface of the drum. Between each drum there was a long brass bar containing teeth of the same gradation as the spiral and into which the spiral worked, so that at every revolution of the drum it would move on the steel bar the distance of one spiral on the end of the drum. The drums were placed horizontally and side by side, and the machinery was so constructed that when the paper of one drum was entirely filled with the markings of the pen it could be stopped and the other cylinder commence its movement. The pen was placed midway between each end of the steel shaft, whose length was nearly twice that of the drum.

This machine was never entirely completed as it was thought to be too cumbersome, and also on account of a better mode having been devised, so as to dispense with one of the drums. This improvement consisted of a single drum about three inches in diameter which opened through its centre. When it was designed to put paper on these two half drums the paper was inserted into a clasp on the side of each half drum, which shut down, holding the paper fast. The two half drums were then taken, one in each hand, and placed on the square cast-steel shaft, and when brought together a catch secured both half drums together and drew the paper tight to the outer surface of the drum. When on the shaft, the spiral on the end of the drum moves in a toothed rack below, and thus carries the paper along, making a sort of spiral written line on the paper. When one drum was about to be filled another was put on the shaft, and by a peculiar catch fastened to the one before it until the first was entirely filled, when it was taken off, the paper removed and new paper put on. There were two machines of this kind.

Dr. Gale, in the meantime, was engaged in superintending the construction of two batteries of the Cruikshank kind, of 60 plates, each 6 inches square.

During the construction of the register and magnets there was also constructed a machine for holding the type in convenient rules about three feet long, called port-rules, and also apparatus for carrying it along at an equal speed, so as to close and break the circuit.

There was also another instrument made for changing the poles of the electro-magnet, so that the current should pass through the helices of the magnet, first in one direction and then in another, the object of which was to counteract the effects of permanent magnetism which it was apprehended would increase to such a degree, from long use of the current in one direction, as to destroy its electro-magnetism by producing permanent magnetism. It was, however, found, after a short trial without it, that it was useless and could be dispensed with.

During the time these things were in progress it was a common question with those who visited the works to see our progress, and with whom we met at other places, how far the current could be transmitted through a length of wire. This question was always answered by Professor Morse and myself, that if the current would traverse the wire but ten miles it could be used for a hundred or more.

So clear was it to my own mind and so well did I understand Professor Morse's ideas upon the subject, that we were fully persuaded of its necessity, and so spoke to each other. It became a part of his plan and one supposed to

1. The original instrument which Mr. Vail saw on this occasion is preserved in the office of the Western Union Telegraph Co., at 195 Broadway, New York. An engraving and description of it is in Reid's *Telegraph in America*, pp. 54, 55.—[Ed.]

2. Vail's *American Electro-Magnetic Telegraph*, Philadelphia, 1845.—[Ed.]

3. These works are near Morristown, N. J., and were at that time owned by Judge Stephen Vail (the father of Alfred) and his son George Vail.—[Ed.]

Digitized by Google

be indispensable, since believing that the current would diminish in power as the distance increased, it was admitted by him that although such an instrument might not be required for twenty or thirty miles or more, yet nevertheless it would be necessary to use it at the end of a line of such length as should reduce the current down to a very feeble power. The construction of such an instrument as the relay magnet was not deemed at the time as necessary for the object in view, and its construction was therefore delayed until it was required by a more extended experiment. The design was to try the instruments with a coil of wire of ten miles and with such a battery as should work the magnet through the whole ten miles without a relay or receiving magnet. Had Professor Morse stopped short of this, the plan of making a suitable exhibition before Congress would not have been complete. The object of using ten miles at least was, that the new discovery might satisfactorily demonstrate that the current could be transmitted through ten miles of wire, and at that extremity be made to operate an electro-magnet, since visual telegraphs are usually at that distance apart, and were Professor Morse's plan capable of working at no greater distance it had this superiority over the semaphore, that it could be worked during the night and during fogs, rains, or any kind of weather.

These preparations having been completed at Speedwell Iron Works, the two instruments were put up in a vacant room connected with the works, and exhibited to the ladies and gentlemen of Morristown. On this occasion only two miles of wire were used, the remaining portion of eight miles not having been brought out from the city. A few days after this exhibition the instruments were taken to the City of New York and set up in the mineralogical lecture room of the University. Here three days of exhibition were given to invited ladies and gentlemen. The instruments were worked through ten miles of wire.[4] At this time the pencil was used for marking the paper fastened on the cylinders, as previously stated. After this exhibition the instruments were taken to Philadelphia and by invitation exhibited in the great hall of the Franklin Institute, Philadelphia. After a stay of a few days at Philadelphia the instruments were taken to Washington and set up in the room of the Committee on Commerce,[5] where they were exhibited for several weeks to members of Congress, President Martin Van Buren and his Cabinet (among whom was the Hon. Amos Kendall, the present agent for three-fourths of the patent interest), and also to such persons as were desirous of seeing the invention.

On the — of April, Professor Morse, Hon. F. O. J. Smith and myself set out for the north, the two former with the intention of preparing to sail at an early day for Europe, and myself to Speedwell Iron Works to prepare suitable instruments for them to take with them, in order to secure patents in European countries. On my arrival at Speedwell two instruments were commenced on a different plan from that so recently exhibited at Washington. The paper was to be ribbon-paper and the pens to hold ink instead of using the pencil as in the former case. New devices were also made for the port-rule, one of which was a groove in which the punctured type were to slide down an inclined plane until they came in contact with a brass wheel surrounded with small wire projections that matched the holes in the type. This wheel was driven by clockwork and gave a uniform motion to the type. Another plan was that in which the type were to descend vertically in contact with the wheel, as described in figure 17 in the "Description." The pen was made by taking a piece of plate brass about the 1-16 and $\frac{1}{2}$ thick and $\frac{3}{4}$ of an inch long and $\frac{1}{2}$ inch broad, slitting the plate into two plates for about half its width with a saw $\frac{1}{16}$ or less in thickness, and then sawing with a fine saw at right angles the opposite edge in four equally distant places until the cut reached the parallel division. The spaces were filed to a point so as to form pen points, and the wider saw-cut was then stopped at its two ends so as to form a reservoir for the ink. This, soldered to the end of the magnet lever, was used as a pen for making four dots or lines on paper instead of a pencil as in the former case. The paper was made to pass over a cylinder directly under the pen, so as to make the proper marks. The paper was driven by a clock train as in the other cases.

An alteration to some portions of the instruments was made in New York by Professor Morse after they left the Speedwell works, and on the 16th of May, Professor Morse and Hon. F. O. J. Smith sailed for England for the purpose of securing patents in Europe. Their first visit was to England, afterwards to France, and then back to England. During their stay in France they took out a patent for the electro-magnetic telegraph for the transmission of intelligence and also its application to railroads. Professor Morse also entered into a contract with the Russian minister at Paris for the construction of lines in Russia, and which required the approval of the Emperor to make it good. He also commissioned an agent traveling through various European countries to effect any arrangement which might be made for its introduction. He returned to England, and the fate which his application for a patent there met with is stated at large in a paper written by Professor Morse respecting Sir John Campbell.

On his return to America he applied himself occasionally to perfecting his invention, and as I occasionally called upon him at his office I was made acquainted with his improvements. He was also engaged at this time with the new discovery of Daguerre.[6] One of his improvements (so considered at that time) was the correspondent for the purpose of transmission by means of separate keys for each letter of the alphabet, by which he could, on pressing down a key, wind up a weight over a pulley, then releasing his finger from the key, the type for breaking and closing the circuit representing a letter would slowly return to its former position, producing the required marks and spaces for making the letter. He was also much engaged in producing some mode of marking, better suited to the purpose of marking on paper than lead pencils or pens supplied with ink. In this his modes were numerous, such as marking upon metallic plates, upon different kinds of prepared paper. All these were in turn thrown aside for some better device.

Being called upon by the American Institute to make an exhibition of his invention before them, Professor Morse prepared two instruments which were put up and exhibited at the Fair in the fall of 1842.

Alfred Vail

5. The wire was placed on two reels of five miles each. In the Capitol were used numbers entirely and a dictionary.

6. This discovery was the well-known daguerreotype process, of which all the modern photographic processes are the outgrowth.—[Ed.]

DISTRIBUTION BY ALTERNATING CURRENTS.[1]

BY M. M. M. SLATTERY.

REPORT OF COMMITTEE ON ELECTRICAL DISTRIBUTION BY ALTERNATING CURRENTS.

One short year ago the commercial success of the branch of electric lighting in which induction coils are used was by some of our best authorities considered very problematical, but practical use of the induction system has not only succeeded in commercially converting high tension

1. Read by Mr. Slattery, as Chairman of Committee on Electrical Distribution by Alternating Currents, before the National Electric Light Association, at Boston, August 9th, 1887.

Digitized by Google

electricity to low tension for electric lighting purposes, but also high tension theoretical opponents by practical demonstration of facts.

Upon the occasion of the last convention, the extensive use of the induction system received its first authoritative indorsement by our esteemed friend, Dr. Otto A. Moses, and although he was by some considered over enthusiastic in his statements, time has served to prove the correctness of his views and the realization of many of his anticipations.

We will go back six months, and, mentally, what do we see in this business from here. A few experimental plants scattered about in various parts of the country struggling for public recognition, and with the innumerable detail difficulties which dog the footsteps of every new departure; difficulties, the magnitude of which are usually in proportion to our ignorance of their nature, and therefore more frequently than not, unduly magnified.

Now, what have those difficulties been, and has the past six months' experience enabled the manufacturing companies engaged in this branch of business to eliminate them?

We find there were three factors in the induction system that required all the ability of the electrical engineer to work out and place upon a proper footing, namely, the dynamo machine, the induction coil, and the disposition of the external circuit to take the best advantage of the use of the induction coil.

Of course there were alternating dynamos in existence, as were also induction coils before this branch of business had acquired any prominence, but they were not such as would meet the new requirements.

We will first take the dynamo. It will be familiar to all of you, that no matter how intimately acquainted you may be with the construction of dynamo machines, when you start in to build a new type, your previous experience, however valuable it may be, does not enable you to foresee innumerable detail difficulties which will assuredly develop with practical use, and which take time to ascertain and remedy.

Well, so far as we have been able to learn the weaknesses which developed in this apparatus were first, the liability of the current to jump across the coils in the event of the field being excited with the armature circuit open. This open circuit sometimes happened by a dead cross occurring in some place in the mains, blowing the fuse at the dynamo, thus opening the circuit, and then the field being fully excited, the armature would generate an exceedingly high electromotive force for an instant; the current under the circumstances would be very liable to jump across the coils of the armature, and other hurtful effects to the machine would ensue; the remedy for that was inserting at every branch in the external circuit a junction fuse, and at various points along the mains and sub-mains section fuses to such an extent as to make an open main a remote contingency. It was also found that the armatures heated excessively owing to the presence of the plaguey Foucault currents. It was found that this evil could be almost wholly suppressed by building the armature without iron, and avoiding as much as possible the use of masses of metal in proximity with the armature coils. In this connection Siemens' early type of alternating dynamo, slightly modified to meet the new requirements, might read us a lesson.

It was a bold step when the alternating dynamos were constructed with iron cores, and those who make this class of machine for this high tension incandescent business might give us some interesting information. To my mind this iron core construction speaks of disagreeably high temperature. I do not say that they will not be able to present a rational theory why this evil may not be, or has been, greatly modified, but the fact existed in the past, and as far as we have been able to ascertain stands unrefuted at present. One thing, however, is pretty evident, that just now this type of machine appears to be finding a rather extensive use, evidencing that it must be doing good work. So much for the alternating current dynamo, a machine destined to play a most important part in the future electric lighting business, and in the light of the past experience no doubt should exist in the minds of anyone here that these dynamos in practical use are now almost, if not quite, as reliable as any other dynamo; while coupled with this is the important factor of a pretty close self-regulating property attainable in this system, without the necessity for any particular method of winding, that property following chiefly as the result of the use of the induction coils. It is satisfactory to know that during the probation of this system every accident of any importance which has occurred to the dynamos has been of a purely mechanical nature, and our mechanics have reduced them to a minimum.

No doubt the induction coils have been the source of considerable anxiety, not because there was any obstacle in the way of obtaining high electrical efficiency, as this latter appears not to have been by any means a difficult problem to solve. The source of greatest trouble has been, as far as I can learn, that of insulation. In what form will the weakness appear has been a question often asked himself by a timid electrician, and as usual the most unlooked for troubles developed. At one time an unaccountable defect in the insulation of the secondary coil would occur, cutting out a number of convolutions, thereby causing annoyance by reducing the incandescence of the lamp in its circuit; the remedy was simple—increase the insulation of the wire and exercise still greater care. The same accident would still more frequently happen to the primary coil; the same remedy applied overcame it; sometimes a number of the layers of the primary coil would thus be suddenly cut out, resulting in the passage of a much heavier current than the fuse in the coil box had carrying capacity for; the fuse would then melt and possibly draw an arc that you had a great deal rather do without if you could; the remedy for that was, keep on insulating the primary coil layers from each other until the trouble ceased, and increase the distance between the ends of the primary fuse to such an extent that when the latter melted, an arc, no matter how great its volume, would not be able to bridge over the distance which, after all, was calculable because the E. M. F. was constant. Then again metallic contact would take place between the induction coil and the iron box in which it was mounted, and if that box happened to be placed anywhere near a ground, possibly unpleasant electrical experiences might be related in wet weather. It was again only a question of looking out for the insulation to reduce such defects to a minimum; well, the insulation appears to have been looked out for, as the smooth and safe working of that branch of the business would now seem to testify, and to-day that part of the system can be made as reliable, simple, and as easily disposed of as any other part of an incandescent system.

Thus the two new and troublesome factors have gradually and surely been strengthened for their future work.

The next in the system, viz., that method of distribution which would enable you to utilize the induction coil to the best advantage, although apparently presenting the simplest problems at the outset, has required a great deal more thought than was anticipated. It was found that no particular rule, as in the case of low tension distribution, could be carried out, the methods of distribution varying with the condition of the district in which you had to distribute. In some cases the wires were run out from the central station through the centre of distribution, and tapped at any point along the route where lights were required. This was the earliest and simplest form of distribution, and answers perfectly well for comparatively small installations, it being desirable to keep the loss in the mains down to about two per cent. and perhaps about two or three per cent. in the induction coils, so that the incan-

Digitized by Google

descence of the lamps should not vary appreciably throughout the system—this arrangement of the circuit may be carried out in small and very scattered towns, where it has been found to answer admirably. In other cases, where the district is more densely populated and a large installation is required, the inductoriums are placed in the centres of distribution and used like so many stationary dynamos, the high tension primary current with comparatively small conductors feeding each of these centres, the secondary or distributing circuit being taken where lights are required; still other methods of distribution are carried out, but what has been stated in this connection will serve to show that again the past year's familiarity with the business has given an opportunity to perceive and profit by many advantages the system offers.

One of the last, but by no means the least, points that I shall touch upon in this interesting subject is the question of comparative cost of the main conductors required in installation of an induction and low tension incandescent plant. Not at all infrequently we shall find ourselves called upon to figure upon a plant like this:

From the source of generation to the point of distribution is one mile and a half, making a three-mile circuit; at the point of distribution you are required to distribute some 400 16 c. p. lamps, at say 5 per cent. fall of potential, which appears to be about the limit allowed the induction system. The conductors for this purpose in the induction systems now in use would be No. 2 Brown & Sharpe, which will cost about $230 per mile. In the case of the low tension installations upon the low tension system, you would require a conductor costing about $1,050 per mile.

Should you be required to distribute throughout the whole of the length of the circuit, the wire such as is used for ordinary arc lighting purposes would be amply sufficient for the induction, and of course a proportional reduction may be made in the low tension.

Now, a great many exaggerated statements are made with regard to the dangerous shocks to be expected from this alternating current, and while I am not prepared to say that the physiological experience of a shock from a thousand volt dynamo is the most agreeable thing in the world, I am prepared to say that the shock is by no means as severe as that received from a continuous current dynamo of the same voltage. A few weeks ago a man showed me his hands, which were horribly burned. He had received a shock from an eleven hundred volt dynamo, and he said with a visible tremor in his arms, as if the recollection of that shock was still vividly impressed upon his mind, that he experienced the effect of that shock for more than a week afterward. A friend of mine was testing a 400 light 1,050 volt alternating dynamo, fully loaded, only a few days ago, and going towards the machine his foot slipped and he fell quite close to it; in his confusion he quickly reached out his hands and unfortunately placed them directly upon the poles of the dynamo. He said from where he fell to the wall behind him was about fifteen feet, and it seemed to him as if that dynamo was suddenly converted into an electrical gun, and he got shot across the room until the velocity of his movement was interfered with by the wall. There was scarcely the appearance of a burn on his hands, merely a pin's head matter, while the effect of the shock was felt by him only for a few hours. It might be said that the difference of effect of the shock was owing to the difference in the temperament of the two men; that may be so, but I have received three pretty severe shocks from a 1,000 volt alternating machine, and however much I may have felt inclined to dispense with the shaking up it gave me, the experience has been of value to me—one cannot have everything.

One word more in conclusion. The induction system has evidently come to stay, not because enthusiastic advocates think or say so, but because the expert public, the central station public, have practically indorsed it, because it more nearly than anything else meets their immediate and anticipates many of their future requirements. More especially is its advent doubly welcomed just now with this misconducted overhead conductor warfare pressing on every side, and which is every day acquiring seriousness in proportion to the increase of copper wire in the air, and I think that this system, with its comparatively small mass of conductors, will postpone for a considerable time the necessity of going underground with the electric light wires until more extended experiments shall have given us the confidence in underground systems that experience in the past has materially shaken.

ELECTRIC LIGHT FOR THE NEW CRUISERS.[1]

BY LIEUT. J. B. MURDOCK.

THE question of how to best install the electric lights in the new men-of-war has been considered in detail, and it seemed advisable to bring the matter before the National Electric Light Association, that the manufacturers of the country might have the problem presented to their consideration in advance of the time when they would be asked to act upon it. In conversation with managers of various companies, it has been impressed on my mind that the peculiar conditions existing on shipboard are but imperfectly understood, and as a natural consequence they have not as yet been as satisfactorily met in this country as abroad. I am confident that American ingenuity and skill can fully meet our requirements, and hope that the number of dynamos, about sixty, which will be needed for the vessels already authorized by Congress, may be considered as meriting the experiments necessary for their successful installation.

I am authorized to present in a general way the views of the bureau of ordnance of the navy department on the peculiar conditions to be met and on the best method of meeting them.

In men-of-war the prime requirements of all kinds of apparatus are compactness and lightness. Neither of these is of any material consequence in electric light installations on shore, and both are generally ignored. Attention has there been given mainly to the question of efficiency of conversion, and a glance at the advertising columns of any of the electrical journals shows that the maximum efficiency and best system of electric lighting is possessed by each of a dozen companies. Our conditions, so far as the dynamo is concerned, may be summarized as wishing the greatest electrical output for a given weight and bulk, and although at first thought this may seem to be essentially the same thing as efficiency of conversion, it is widely different.

The following figures of well-known American dynamos illustrate this point. The comparison is made on the basis of "watts of output per pound of dynamo." The weight, speed and electrical output have been obtained in general from the manufacturers, and are given, of course, only approximately. In this comparison it is of course necessary to consider also the sizes and the number of revolutions, the watts per pound increasing with large machines and high velocities:

The next consideration is that of the connection of the dynamo to its engine. A starting point is afforded in the rule that belting should never be used on a sea-going vessel. Nothing so radically violates our condition of economy of space as the use of belting. When space is saved by the use of a short belt, the working conditions are comparatively unsatisfactory. Belts are liable to be thrown off by the sudden change of load to which our dynamos are subject, and become a source of danger to the attendants if the ship is rolling heavily. The adoption of friction gearing between engine and dynamo has been sugges-

1. Read before the National Electric Light Association, Boston, August 10, 1887.

ted, and is probably practicable, but its durability on shipboard, when the motion of the vessel must cause work-

ing of the two shafts, may not be great. In the navies of Europe, the practice of direct connection is universal, the dynamo shaft being coupled to that of the engine. This calls, of course, for either a great reduction of the speed of the dynamo, or a corresponding increase of that of the engine. It is easy enough to procure an engine running 1,500 revolutions per minute, but it is a very different matter to find one which will govern satisfactorily at so high a speed. So far as I can ascertain there is no automatic engine manufactured in the United States capable of indicating 30 h. p. which is designed for a higher speed than four hundred. I have been informed, however, that some of the type now in the market could be modified so as to operate well at five hundred. I am not aware of any dynamo in the United States absorbing 30 h. p., which would yield its normal output at even the higher speed. It is much easier to reduce the speed of the dynamo while preserving its electrical output than to raise the speed of the engine. Admitting the desirability of direct connection on shipboard, the problem proposed is the best method of obtaining the same output in watts per pound, at speeds below 500, that are now commonly obtained between 1,000 and 1,500.

The following figures of European dynamos obtained in the same way as those already given for American machines, and probably equally accurate, will show how this problem has been met abroad:

It is necessary only to refer incidentally to a few of the methods by which these results have been obtained. The principal are the elimination of all iron not needed for the magnetic circuit of the dynamo, and the adoption of a type in which the circuit furnishes a framework of necessary rigidity. The magnet core should be of the best wrought iron, this single condition frequently reducing the weight twenty-five per cent. while preserving the output. Armatures of large diameter give high peripheral velocity at low speed, and this seems to recommend the Gramme ring, a large drum armature being cumbersome. The Gramme form has another advantage for ships' use, that it can be repaired or even re-wound with the facilities existing on shipboard, although I believe a Siemens winding has recently been perfected, which admits of equal facility of repairs. The use of multipolar machines contributes to lightness, and the Siemens and Halske machine referred to in the preceding table has four field magnets inside a Gramme ring. Flattened ring armatures and multipolar magnets also give large output for the weight.

Every ship, aboard which the electric light is a necessity, should have two similar dynamos, that either may be used

at will. At present this precaution is not observed in the navy. The lighting of the ships by incandescent lamps is under the control of the bureau of navigation, and the installation for this purpose consists of an ordinary plant of an engine driving a dynamo by belting. The electric search lights, two of which are furnished to each large vessel, are supplied by the bureau of ordnance, the installation for this purpose consisting of a Brotherhood engine driving two "C" Gramme's connected direct on the same bed plate. In case of accident the incandescent dynamo will not work the search lights to advantage, nor will the Gramme's operate the incandescent lights well. This is of course most unsatisfactory, and the need of the service is for a dynamo which will perform either work well, and, if necessary, both at once. Our search lights require about fifty volts and fifty amperes for ordinary work, the current being sometimes increased to one hundred. The lamp is operated by hand in order to fully utilize the radiation from the crater of the positive carbon. The hand lamp and Mangin projector are in use in nearly every navy in the world, for projecting a condensed beam of light to a distance. Automatic lamps do not admit of continuous adjustments as readily as the hand lamp, and are not so thoroughly under the control of the operator. In any search lights the arc may sometimes fail, and it is sometimes advisable to cut the lights out without notice. Large and sudden variations of load are thus liable to occur, and these should not affect the dynamo. It is unquestionable that incandescent lights can be worked from a series dynamo, and search lights operated by a shunt machine, but most of these proceedings are make-shifts. It is undeniable that both search lights and incandescent lights can be worked satisfactorily by a compound dynamo. I have been called upon to work all these kinds of dynamos for each purpose, and the compound dynamo works incandescent lights as well as the shunt machine, and search lights better than does the series machine applied for the purpose. I have also worked two search lights and fifty incandescent lights simultaneously from one compound dynamo. Each search light had three-tenths of an ohm dead resistance in circuit to bring the difference of potential down to about fifty volts. There is nothing new in this, but I have so frequently been asked what advantage the compound dynamo possessed, that I have trespassed somewhat on

the time of the convention to give reasons for the opinion that all naval dynamos should be compound wound for a constant potential.

It is probable that many fine new vessels will require electric motors. Some of our gun carriages may be worked in this way, on account of the advantages that an electric motor offers in small weight and bulk, and in the important fact that it is so much easier to splice a broken main than to patch a leaky pipe when steam or compressed air is used for power. Electric motors will be useful for shell hoists and ammunition whips, reducing the number of men employed for these purposes. Here, also, light weight and compactness are absolutely essential, and nine-tenths of the motors in commercial use would be barred out as too heavy. A 10 h. p. motor, the largest we would probably use, should not weigh over five hundred pounds.

The potential at which the main should be kept, must be determined from the relative importance of the three uses to which our dynamos will be put. As we are not bothered by the question of long-distance transmission, we can well use a low potential for incandescent lights and motors, while search lights require only fifty volts, although it is advantageous with any dynamo to have a little dead resistance in the search light circuit. For these reasons I think seventy volts is about the best point for a compromise. This is the voltage used in the French navy, the English working at eighty. If two search lights can be successfully worked in series, the potential at the dynamo might advantageously be raised to one hundred and ten, or even one hundred and twenty volts. Experiments have been made to test this point, but it is not decided as yet. Should there, however, be any material advantages secured in the working of either incandescent lights or motors by the use of a high potential, the search lights could be operated with sufficient resistance to give them their proper potential.

The same requirements of small bulk and weight must control in the choice of engines. The adoption of a compound dynamo throws extra responsibility on the engine,

as without constant speed the advantages of the dynamo are not apparent. American automatic engines can easily meet this demand, but most of them are too heavy, rigidity of frame being secured by the use of unnecessarily large masses of cast-iron. One hundred pounds weight per indicated horse-power, with 80 lbs. steam, is a liberal allowance. In many European engines steel and phosphor-bronze have been largely used to obtain lightness.

It may be interesting to compare a few well known dynamos as to compactness, the comparison being made on watts of output per square inch of floor space.

The preceding show a general average of about forty pounds dead weight of dynamo and engine for each sixteen candle lamp, whether high or low speed dynamos are used. In the following special attention has been paid to the manufacture of light and compact apparatus:

As illustrating the advantages of direct connection in economy of floor space and also of weight when care is taken, I have a few statistics of ship installations.

TABLE IV.

PLANT.	Connection.	Total weight.	Floor space.	Weight per 16c. lps.	Sq. in. of floor space per 16c. lamps.
1-200 light Brush compound 1-8 in. Brotherhood engine	Direct.	5,500		27½	
Steam yacht "Restless." 1 Arnold dynamo (30 lights) 1 Vertical engine	Friction.	600	6 sq. ft.	20	29
1 Goolden-Trotter dynamo (75 lights). 1 Tower engine	Direct.	900	5¼	12	11
1 Victoria dynamo (60 lights) 1 Brotherhood engine	Direct. 765 revs.	800	4⅛	13	11
Italian cruiser "Dugali." 1 Parson's dynamo (150 lights) 1 Parson's steam turbine (8 plants like above.)	Direct. 9,000 revs.	900	6¼	6	6

It is noticeable abroad, that with the type of slow-speed dynamos established in the markets, the system of direct connection is adopted in many isolated plants on shore. The tendency throughout Europe is to reduce the speed of dynamos, preserving the electrical output by a careful study of details. Few recent machines built abroad are designed for higher speeds than 800, while an American

Digitized by Google

company, operating at and above 850 advertises slow speed as one of the advantages of its dynamos.

In this country the naval demand for slow-speed dynamos will be comparatively small, but if it serves to introduce the type into the market, I am satisfied from what has taken place in Europe that the system of direct connection will create a field for itself, as soon as the apparatus can be procured without the heavy expense attendant on special work. It recommends itself in any installation where either weight or floor space is be economized. I believe it can be successfully utilized in lighting railway trains, especially if, in the near future, railroad companies have to furnish steam for heating purposes. Plants could be furnished small steamers and yachts, in which a common installation could not find room.

There are one or two other considerations governing ship installations. The principal is the absolute necessity of high insulation. The bureau of navigation has, in its recent contracts, called for an insulation resistance of 1000 megohms per nautical mile, after twenty-four hours immersion in salt water.

Lead covering is also required as a protection against mechanical injury. We are so exposed to short circuiting and corrosion from salt water that the high standard called for is most wise. All switches, junctions and safety boxes, and in fact all parts of the circuit, should be thoroughly insulated. Difficulty has been experienced from salt water running along the wires into lamp sockets, short circuiting the lamps. The insulation of the whole circuit is sometimes required to be at least 1000 ohms for each volt at the terminals of the dynamo.

STORAGE BATTERIES FOR ELECTRIC LOCOMOTION.[1]

BY A. RECKENZAUN.

THE idea of employing secondary batteries for propelling vehicles is almost contemporaneous with the discovery of this method of storing energy. To Mr. Planté, more than to any other investigator, much of our knowledge in this branch of electrical science is due. He was the first to take advantage of the action of secondary currents in voltaic batteries. Planté is a scientist of the first grade, and he is a wonderfully exact experimenter. He examined the whole question of polarization of electrodes, using all kinds of metal as electrodes and many different liquids as electrolytes, and during his endless researches he found that the greatest useful effect was produced when dilute sulphuric acid was electrolyzed between electrodes of metallic lead.

A set of Planté's original cells was exhibited for the first time, in March, 1860, before the Paris Academy of Sciences; scientists admired and praised it, but the general public knew nothing of this great discovery, thus brought to notice. Indeed, at that period little commercial value could be attached to such apparatus, since the accumulator had to be charged by means of primary batteries, and it was then well known that electrical energy, when produced by chemical means in voltaic cells, was far too expensive for any purpose outside the physical laboratory or the telegraph office.

It was twenty years after this exhibition at the Academy of Sciences, in Paris, that public attention was drawn to the importance of storage batteries, and that Mr. Faure conceived the idea of constructing plates, consisting of lead and oxides of lead. At that time the advantages accruing through a system of electrical storage could be fully appreciated, since electrical energy was already being produced by mechanical means through the medium of dynamo-electric machines.

It was the dynamo machine which created the demand for the storage battery, and the latter was introduced anew to the public at large and to the capitalist with great pomp and enthusiasm. One of Faure's accumulators was sent to Sir William Thomson, and this eminent scientist in the course of experiments ascertained that a single cell, weighing 165 lbs., can store two million foot-pounds of energy, or one horse-power for one hour, and that the loss of energy in charging did not exceed 15 per cent. These results appeared highly encouraging. There we had a method of storing that could give out the greater part of the energy put in. The immense development which the electric transmission of energy was even at that early day expected to undergo, pointed to the fact that a convenient method of receiving large quantities of transmitted energy, and of holding it in readiness until wanted, must be of the highest importance. Numerous applications of the Faure battery were at once suggested, and the public jumped to the conclusion that a thing for which so many uses could be instantly found must necessarily be a profitable investment, and plenty of money was provided forthwith, not with the idea of commencing careful experiments and developing the then crude invention, which would have been

1. Read before the National Electric Light Association, Boston, August 11, 1887.

Digitized by Google

the correct thing, but for manufacturing tons of accumulators in their first and immature form.

I need not describe the disappointments which followed the first unfulfilled hopes, nor repeat the criticism that was heaped upon the heads of the early promoters. Those early hopes were untimely and unreasonable. A thousand difficulties had to be overcome — scientific difficulties and manufacturing difficulties. This invention, like most others had to go through steady historical developments and evolution, and follow the recognized laws of nature, which are against abnormal and instantaneous maturity. The period of maturity has also been retarded by injudicious treatment, but the ultimate success was inevitable. Great advances have been made within the last few years, and I propose now to offer a few facts and figures relating to the present state of the subject with reference to the application of storage batteries to locomotive purposes. It is not within the province of this paper to discuss all the different inventions of secondary batteries, nor to offer any suggestions with regard to priority, therefore, I will confine myself to general statements. I am aware of the good work that was done in the United States by Kirchhof 26 years ago, and of the more recent work of Mr. Brush, of Cleveland, Mr. Julien, and others, but I am more particularly acquainted with the recent achievements of the Electrical Accumulator Company, who own the rights of the Electrical Power Storage Company, of London. I have used the batteries of the latter company for propelling electric boats and electric street cars. The first of the boats was the "Electricity," which was launched in September, 1882, and which attained a speed of seven miles an hour for six consecutive hours. Since then a dozen electric boats of various sizes have been fitted up and worked successfully by means of storage batteries and motors of my design. The most important of these were the launch "Volta," and another similar craft, which is used by the Italian government for torpedo work in the harbor of Spezzia. On the measured mile trial trips the Italian launch gave an average speed of 8.43 miles an hour with and against the tide. The hull of this vessel was built by Messrs. Yarrow and Co., and the motors were manufactured by Messrs. Stephens, Smith & Co., of London. The "Volta," which was entirely fitted by the latter firm, is 37 feet long and 7 feet beam. She draws 2 ft. 6 in. of water when carrying 40 persons, for whom there is ample sitting accommodation. There are 64 cells in this boat; these are placed as ballast under the floor, and actuate a pair of motors and a screw coupled direct to the armature shaft running at 700 revolutions a minute. We crossed the English channel with this boat in September of last year, leaving Dover at 10:40 in the morning, arriving at Calais at 2:30 P. M.; stayed about an hour in the French harbor for luncheon, and floated into Dover docks the same evening, at 6:30, with full speed. The actual distance traversed without entirely discharging the cells was 54 miles, the current remained constant at 28 amperes until 5 P. M., and it only dropped to 25 amperes at the completion of the double voyage between England and France. Several electric launches are now being constructed in London, and one in New York by the Electrical Accumulator Co.

Mr. Trouvé exhibited a small boat and a tricycle, both worked by Planté accumulators, at Paris, in 1881.

The first locomotive actuated by storage batteries was used at a bleaching works in France in 1882. During the same year I designed an electric street car for the Storage Company, and this was tried on the lines of the West Metropolitan Tramways in March, 1883. It had accommodation for 46 passengers. This car had many defects, and I reconstructed it entirely, and ran it afterwards in its improved form on the South London Tramways, and also on a private track at Millwall, where it is now in good condition, and I have a similar car in Berlin. M. Phillipart exhibited a car in Paris, and M. Julien made successful experiments in Brussels, Antwerp, and Hamburg. Mr. Elieson is running storage battery locomotives in London. Mr. Julien has also been experimenting with a car in New York, and I believe one is in course of construction for a line in the city of Boston. Messrs. W. Wharton, Jr. & Co. have a storage battery car running at Philadelphia on Spruce and Pine streets, and this energetic firm is now fitting up another car with two trucks, each carrying an independent motor, similar to my European cars.

I have mentioned all these facts in order to show that there is a considerable amount of activity displayed in the matter of storage batteries for street cars, and that continued and substantial progress is being made in each successive case. The prejudices against the application of secondary batteries are being rapidly dispelled, and there are indications everywhere that this method of propulsion will soon take a recognized place among the great transit facilities in the United States. I feel convinced that this country will also in this respect be far ahead of Europe before another year has passed over our heads

There are several popular, and I may say, serious objections to the employment of storage batteries for propelling street cars; these objections I will now enumerate and endeavor to show how far they are true, and in what measure they interfere with the economical side of the question.

First objection: The loss of energy, which amounts in practice to 20, and sometimes 30 per cent. Now, every method of storing or transmitting energy involves some waste, but in saying this we need not condemn the system, for after all the term efficiency is only a relative one. For instance, a 10 h. p. steam engine consumes three times as much fuel per horse-power hour as a 1,000 horse-power engine does, yet this small engine must be, and is regarded as, one of the most economical labor saving appliances known to us. Considered as a heat engine the efficiency of the most economical steam motor is but 10 per cent.—90 per cent. of the available units of heat contained in coal being lost during its transformation into mechanical energy. Thus, if we find that the storage battery does not return more than 70 per cent. of the work expended in charging it, we ought not to condemn it on that account until we have ascertained whether this low efficiency renders the system unfit for any or all commercial purposes. It is needless to go into figures in order to show that, when compared with animal power, this objection drops into insignificance.

The second, more formidable objection, relates to the weight of storage batteries—and this involves two disadvantages, viz.—waste of power in propelling the accumulator along with the car, and increased pressure upon the street rails, which are only fitted to carry a maximum of 5 tons distributed over 4 points, so that each wheel of an ordinary car produees a pressure of 1¼ tons upon a point of the rail immediately under it.

The last mentioned objection is easily overcome by distributing the weight of the car with its electrical apparatus over 8 wheels or 2 small trucks, whereby the pressure per unit of section on the rails is reduced to a minimum. With regard to the weight of the storage batteries, relatively to the amount of energy the same are capable of holding and transmitting, I beg to offer a few practical figures. Theoretically, the energy manifested in the separation of one pound of lead from its oxide is equivalent to 360,000 foot pounds, but these chemical equivalents, though interesting in themselves, give us no tangible idea of the actual capacity of a battery.

Repeated experiments have shown me that the capacity of a secondary battery cell varies with the rate at which it is charged and discharged. For instance, a cell such as we use on street cars gave a useful capacity of 137.3 ampere hours when discharged at the average rate of 45.76 amperes, and this same cell yielded 156.38 ampere hours when worked at the rate of 22.34 amperes. At the commencement of the discharge the E.M.F. of the battery

Digitized by Google

was 2.1 volts, and this was allowed to drop to 1.87 volts when the experiment was concluded. The entire active material contained in the plates of one cell weighed 11.5 lbs., therefore the energy given off per pound of active substance at the above high rate of discharge was 62,225 foot pounds, and when discharging at the lower rate of 22.34 amperes the available useful energy was 72,313 foot pounds, or nearly 2.2 electrical horse-power per pound of active matter. But this active substance has to be supported, and the strength or weight of the support has to be made sufficiently great to give the plate a definite strength and durability. The support of the plates, inclusive of the terminals above referred to, weighs more than the active material, which consists of peroxide of lead and spongy lead; so that the plates of one cell weigh actually 26.5 pounds; add to this the weight of the receptacle and acid, and you get a total of about 41 pounds per cell when in working order. Seventy of these cells will propel an ordinary street car for four hours and a half, while consuming the stored energy at the rate of 30 amperes, or over 5.6 electrical horse-power. The whole set of seventy cells weighs 2,870 lbs., which is barely one-fifth of the entire weight of the car when it carries forty adult passengers, therefore the energy wasted in propelling the accumulator along with a car does not amount to more than 20 per cent. of the total power, and this we can easily afford to lose so long as animal power is our only competitor. From numerous and exhaustive tests with accumulators on cars in this country and abroad, I have come to the conclusion that the motive power for hauling a full sized street car for fifteen hours a day does not exceed $1.75, and this includes fuel, water, oil, attendance, and repairs to engine, boiler and dynamo. We have thus an immense margin left between the cost of electric traction and horse traction; and the last objection, that relating to the depreciation of the battery plates, can be most liberally met, and yet leave ample profits over the old method of propulsion by means of animals.

The advantages of storage battery street cars for city traffic are self-evident, so that I need not trouble you with further details in this respect, but I would beg those who take an interest in the progress of the electric locomotive to give this subject all the consideration it deserves, and I would assure them that the system which I have advocated in this brief but very incomplete sketch is worthy of an extended trial, and ready for the purposes set forth. There is no reason why those connected with electric lighting interests in the various cities and towns should not give the matter their special attention, as they are the best informed on electrical engineering and already have a local control of the supply of current needed for charging.

THE PRESENT STATUS OF THE STORAGE BATTERY.[1]

BY C. O. MAILLOUX.

In one of his masterly newspaper interviews, a well-known American electrician once said of the storage battery that it was chiefly remarkable for its power of stimulating the propensity for lying which is inherent in some natures. This sweeping assertion naturally makes me realize very fully the possible risk of compromising my reputation which I run in undertaking to make a few observations relative to the storage battery.

Under the circumstances an apology might seem to you to be a suitable preface, but I trust that a simple explanation will suffice to dispel all doubts on your part as to my good faith in the premises. This explanation rests upon the fact that the storage battery, like the dynamo, the arc lamp, the incandescent lamp, and many another thing, has grown and progressed. Only a year ago I would have hesitated, perhaps refused, to say anything before you in favor of the storage battery. My reason would not have been a lack of confidence, but rather a feeling that the era of the storage battery was not yet at hand. I felt that this youthful offspring of the great and powerful family of electrical applications promised to play as important an industrial role as any of its colleagues, but I also knew that it had already made one debut some years ago and failed to draw, because it was too young. I would have been sorry to see its chances of success forever spoiled by a second premature attempt. The child seems, however, to have now had sufficient time to mature and perfect its training, and after an interval of some five years it has reappeared upon the scene, this time with a fair and encouraging success. Within a few months there has been in America a great revival of interest in the storage battery, as you are aware. Many of us practical men, who were once disposed to be skeptical, begin to regain confidence. Certainly the applications which have been made of the storage battery in this brief period prove beyond dispute that this time the storage battery is coming to stay. In some cases it found a new and profitable field waiting for it, as for instance in railroad car lighting. In many other cases it opened an entirely new range of possibilities by its playing a secondary role. In a word, it has a wide sphere of usefulness to cover, through many devious paths, some of which it alone can tread over, and many of which it will compass with the help of other applications of electricity. It does not presume to fill all these parts at once. In the case of some of them it may prove wise to permit the process of evolution to go on for some time to come, before they are considered.

It is not necessary, however, for the storage battery to wait until it can accomplish *everything* before accomplishing *something*. There are many applications where it is now entirely competent to give satisfactory results; and while doing what it is at present capable of, it can learn what it does not know. The dynamo was not at first what it is now, nor was the lamp, nor indeed were the details of lighting systems. Electric lighting was limited at first to isolated installations. The range of adaptability compared with what it now is, was limited greatly. It was necessary to confine the applications of the light to isolated cases of fitness, since the apparatus was too limited in every respect to admit of doing more. But while we were doing what lighting could be done with these facilities—and making money too, even then—we were learning to do more. Invention, and the yet greater force, evolution, were hard at work to give us better ideas and more practical devices. In time came the central station, such as it was—and I might emphasize the *such*. Many are here present, doubtless, who were operating these pioneer arc light stations, with long rows of dummy lamps, to be shifted in or out of circuit for the purpose of balancing the work in the circuit itself. Then came the current regulator, and, following in its wake, a succession of devices and improvements, of methods, of systems. The evolution of the incandescent light is also of equal interest, and from the useless platinum wire lamp to the very useful alternating system of to-day, the steps are so numerous and strange that the mind finds itself in a regular museum in attempting to retrace them. I need not tell you that the evolution of the electric light is not complete. The very existence of our organization proves that, since our object is to promote and further the process of development. Each year we have found electric lighting advancing a few steps. Ten years from to-day we may have made so many of these steps that our present systems may seem obsolete, yet these very systems in their time were good enough to earn dividends with. This is precisely the case with the storage battery. Its application can even now play a brilliant part in electric lighting, but it can be very useful even if intrusted with a more modest part. In a word, it has arrived at that age and condition of development which fit

1. Read before the National Electric Light Association Boston, August 11, 1887.

Digitized by Google

it to enter the active service of civilization and begin the race for promotion. If I may judge by the very favorable attention which the storage battery has received from the public, and particularly from those who are dispensing electricity to the public, I think I can venture, like our very genial friend and learned colleague, Dr. O. A. Moses, to prophesy that the storage battery is going to be the next great step of progress. It has already taken its place in line, and I believe it will speak for itself inside of a year.

With regard to the storage battery itself, it may be said that in following its development since the days of Planté one meets with an already large and interesting collection of ideas and devices. It is outside of the scope of the present paper to enter into the study of the steps by which the art has arrived at the present stage. The number of patents relating to storage batteries in this country and in Europe is already quite large; nevertheless the number of good storage batteries is exceedingly small. In this respect history repeats itself. The large and constantly increasing number of patents on dynamos, lamps, regulators, converters, and what not, when contrasted with the small number of those inventions which are really useful, suggests that a large proportion of inventors must have been engaged too deeply in taking out patents, and pay altogether too little attention to the work of reducing their inventions to practice. Passing by the history of the secondary battery and the theories of its action, which properly have no place in a paper like this, it might be of interest to dwell briefly on the objections urged against the storage battery. The two chief objections are limited life or durability and low economy. I shall frankly admit at the start that in many cases these objections are sufficiently valid to throw the storage battery out of competition. The final commercial test of the storage battery, however, is the prospect of gain which it offers under the circumstances of any given case. Viewed in this light, the above objections to the storage battery lose some of their force. I can cite as an example the case of a Philadelphia hotel which it is proposed to light by electricity. A practical electric light man, who has been engaged in the business of establishing and operating central station plants ever since the beginning of electric lighting, went over the case very carefully and came to the conclusion that the storage battery would be preferable. So well satisfied is he of the fitness of the storage battery that he submitted detailed propositions for furnishing light. The present cost of lighting the hotel by gas is $7,500 per annum. For the sum of $6,500 per annum, this practical man is willing to assume the responsibility of furnishing light for a term of years. Being a careful and shrewd business man he has made a wide allowance in his calculation. He does not count upon the two years' guaranteed life of the battery plates, but assumes a necessity for their entire renewal in one year. He calculates, nevertheless, to make 15 per cent. on his investment, and I may say that he seldom makes mistakes in his ventures. In this case, the fact that light must be on "tap" for every moment of the 24 hours becomes an important consideration, and the evident advantages of the storage battery outweigh the questions of durability and economy. Now, taking up the question of durability by itself, I may say that it is greatly dependent not only upon the kind of battery, but even upon the use to which it is put.

Then perhaps one may neglect to put in more than the quantity necessary for a normal capacity. The result is that the battery is not fully charged, and to furnish the usual capacity it must be discharged by drawing upon its residual charge. He soon finds his battery giving symptoms of disease, and in a short time both the positive and negative plates will require doctoring.

It must be said, however, that improper care is not solely responsible for all the troubles that affect the life of the storage battery, Some difficulties, like the scaling off of the active matter, the buckling and stretching of plates, are largely inherent in the battery. They are natural consequences of the manner or method of making the battery. So it may be said here that the storage battery has a personal equation depending on the make, the care, skill and knowledge of the maker. This amounts to saying that some kinds of storage battery are more troublesome to keep in order than others.

The life of the storage battery plate must not be regarded as doomed to remain compassed within the term of a couple or three years. The limit is gradually being extended, and it may be said that each succeeding batch of the product of a factory is slightly better than the preceding. The same may be said of the cost, which, of course, is an important consideration, in view of the necessity for repairs or perhaps renewals at certain intervals. The cost of manufacture has been reduced 30 per cent. inside of one year, and it is even expected that it will be brought down to 50 per cent. before the year is up. The prices have not been reduced because the demand is great even as it is. This of itself shows that the storage battery has already a good field of usefulness, where it can command to a great extent its own price.

The weight of the battery is another of the objections to be met, particularly for street cars. This objection is one which is of particular rather than of general application. It depends on the battery. We know, however, practically, that with 27 lbs. of active matter, it is possible to provide a supply of energy for 6 lamp-hours or over 10 watt hours per pound of matter. This result will no doubt be improved upon greatly.

Last but not least among the objections used against the storage battery is that of reduced economy. My esteemed friend and colleague, Mr. Anthony Reckenzaun, whom you will have the honor of hearing after me, will give you very clear and precise information on this question of economy, more particularly as regards the use of storage batteries for power. I will leave this portion of the subject to him because I know he is a most competent authority. I will permit myself also to commend his very intelligent work in Europe during the last five years in the application of accumulators to electrical traction and propulson.

The question of economy considered in relation to the storage battery does not present such difficulties as might at first be supposed. Considered as an apparatus for transforming energy for electric lighting by incandescence, the storage battery has an efficiency so much below that of the dynamo, or the transformer, that it cannot hope to enter into direct competition with these in many cases. Of the electrical energy produced by the charging dynamo, probably not more than from 65 to 70 per cent. finds its way into the lamps. With direct lighting, as we know, we may obtain as much as 90 per cent. But just here there is a question of great interest and importance which arises, namely: the proportion of energy appearing in the lamp as light. In an incandescent lamp probably not five per cent. of the energy expended is utilized as light. This five per cent. of rays represents the proportion of heat rays which are visible. The other rays are invisible. Now it is also well known that this very proportion of the useful light-giving heat increases with the absolute temperature of the filament. This means that the higher we raise the incandescence of the filament, the more light it gives for a given amount of electrical energy. But when the filament is brought to an excessive temperature its life is not so great. Just here I will note the fact stated by authorities, that alternating currents have been found to increase the life of the filament as compared with continuous current. Now I can supplement this with the statement that the storage battery current gives yet much longer life to the lamp. It permits the raising of the filament to a higher degree of temperature, and consequently it leads to a gain in the economy of energy.

Digitized by Google

We have found in practice that we can obtain the same average life of 600 hours with a lamp of 2½ watts per candle-power, while direct currents would require lamps of 3½ to 4 watts per candle-power. In our early work, realizing the great disadvantage at which we are placed, we resorted to the use of lamps of higher economy, so called. The makers of these lamps refused absolutely to give any kind of life guarantee. They were themselves yet more surprised than we to learn of the remarkably long endurance of these lamps, even on board cars, where the filament is subjected to the wearing effect of mechanical vibration.

Of course I cannot pretend to say what is the cause of this increased life of lamps with the storage battery current. It is probably related in some manner to the fact that the current of a storage battery is continuous in the strict sense of the term, while the current of dynamos and transformers is wavy in character.

It would seem, therefore, that so far as electric lighting by incandescence is concerned, while the storage battery is open to the objection of wasting at the spigot, it can claim some saving at the bung-hole, which quite nearly equalizes the difference between the results obtained by the direct and the storage method. Taking our 65 per cent. of energy, or in round numbers 485 watts, we can obtain twelve lights per electrical horse-power of 746 watts produced in the dynamo, using lamps of 51 watts, which is the most economical yet heard of with a continuous current, we have the following results: Out of 746 watts, taking 90 per cent. as available at the lamps, which is a liberal proportion, we have 671 watts, or less than 12 lamps of 51 watts. If we consider the fact that in practice, lamps of 60 to 70 watts per 16 candle-power are the rule, the difference would be yet greater in favor of the storage battery. Taking another view of the question, we can calculate what is the lowest per cent. of efficiency permissible in the storage battery.

Taking 11 lamps as the result of the direct application from the dynamo, we find that the storage battery must, at 40 watts per lamp, supply 440 watt hours out of each 746 watt hours given to it, or somewhat less than 59 per cent.

I need not dwell at length upon the uses of the storage battery and the services which it can render in connection with electric light plants, for these are quite generally understood, and new ones suggest themselves all the time. The present rate of demand shows that the uses are at least equal to the rate of supply and sometimes in excess. One application of special interest in this connection, however, is that in connection with incandescent lighting, both from isolated and central station plants, the incandescent light is growing in favor so rapidly that where it is already in use for a certain number of hours during the evening, there is an objection to the use of gas at other times. In small installations it would evidently not pay to run constantly for a few lights. The storage battery would here be very useful, if not indispensable, and a number of local companies who could sell electricity for power in limited amount are also turning to the storage battery. Since they are compelled to run during the day to supply electricity for a few lamps and motors they find it would be as well to run to full capacity, using the balance of power to charge storage batteries from which the energy can be drawn later in the evening, to supply incandescent lamps.

In conclusion, I hope I have succeeded in making a fair presentation of the storage battery case, so far as it concerns the uses and purposes of electric light men. As I have intimated, the storage battery is as far from being perfect as were the first dynamos with which some of the enterprising men of this very body first paved the way to the great industry that now interests so many minds and enlists so much capital. But it is so far perfect, however, that it is ready to help enlarge this great industry to push further ahead in its wonderful development.

A SIMPLIFICATION OF THE NEW WEATHER SIGNAL CODE[1].

BY PROF. EDWIN J. HOUSTON.

In the new code of weather signal flags recently adopted by the United States Weather Bureau, approaching changes in the weather, as is well known, are indicated as follows, viz.:

The triangular black temperature flag indicates, by its position above or below the clear weather (a white square flag) or the precipitation flag (a blue square flag), a higher or lower temperature, respectively; thus, figure 1, indicates clear weather, higher temperature; while figure 2, clear weather, lower temperature; figure 3, rain or snow, with higher temperature; figure 4, rain or snow, with lower temperature. The cold-wave flag, figure 5, a square black centre on a white ground, is displayed whenever a

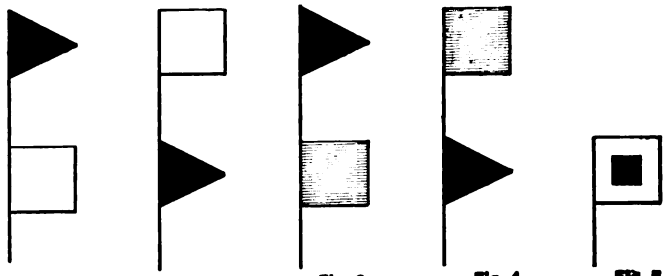

Fig. 1 Fig. 2 Fig. 3 Fig. 4 Fig. 5

decided fall in temperature is indicated. It is usually displayed at least twenty-four hours before the fall in temperature is expected to come.

The cold-wave flag, of course, is never displayed along with the temperature flag. The other three flags, however, may be displayed simultaneously. In this case, when displayed from poles, the indications of the upper flag are to be taken first. When displayed horizontally (see figure 6), the left-hand flag is to be taken first, indicating rain or snow, followed by fair but colder weather.

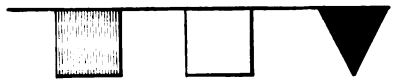

Fig. 6

The author proposes a simple modification of the above code, which, while it will do away with the cold-wave flag entirely, will, nevertheless, permit the indications both of a cold and a hot-wave when it is so desired.

This modification is, briefly, as follows: while the triangular temperature flag is employed as before to indicate warmer or colder weather, respectively, according to its position above or below the clear weather, or the precipitation flag, the extent of the change towards heat or cold is indicated by the distance it is placed above or below these flags.

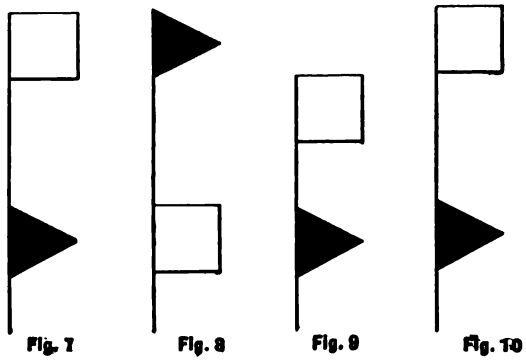

Fig. 7 Fig. 8 Fig. 9 Fig. 10

1. Abstract of Remarks made at the Stated Meeting of the Franklin Institute, held Wednesday, May 18th, 1887.

Digitized by Google

According to the code as now employed, the separate flags are displayed separated from one another a distance equal to once their diameter. In the code as modified, it is proposed to do away with the cold-wave flag and replace it by the triangular temperature flag displayed below the clear weather or the precipitation flag, a distance equal to at least twice the diameter of any of the separate flags. Thus, figure 7, indicates clear weather; cold wave.

In the same way the triangular temperature flags, when displayed above the other flags, at a distance equal to at least twice the diameter of a single flag, indicates an approaching hot wave. Thus, figure 8, indicates clear weather; hot wave.

Since the poles or horizontal supports for the signal flags, as now employed, provide sufficient space for the simultaneous display of three flags, no difficulty will be experienced in obtaining the distance of twice the diameter of a single flag as required by the proposed modification.

No difficulty need be anticipated in distinguishing between the lower temperature indicated, and that of a cold wave as indicated in the two flags (figures 9, 10), since whatever the distance of the observer, the apparent size of the flags will always readily permit a ready decision as to whether they are at a greater distance apart than once their diameter.

It is evident that, when so desired, the severity of the hot or the cold wave can be indicated by displaying the temperature flag a distance above or below the other flags greater than twice their diameter. Or, should such refinement become desirable, distances equal or proportional to the diameter of a single flag might be marked off on the support, to indicate differences of 5°, 10°, or 20°.

The author believes that the excellent code now in use would be greatly improved and simplified by the modifications he proposes.

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Continued from page 308.)

CHAPTER VIII.—FIELD MAGNET COILS.—(CONTINUED.)

SERIES MACHINES.

FOR the purpose of calculating the coils for the magnets, a series machine may be regarded as a separately excited machine whose exciter has a fixed, definite current and a potential which may be made as great as is required for the coils. Most of what was said above regarding separately excited machines in general, and this class in particular, applies, therefore, to series machines as well.

In making the test with temporary coils for determining the required ampere-turns, the magnets should be excited until the armature generates, not only the current and potential required for the external circuit, but in addition that which will be required by the magnets of the finished machine. This additional energy can readily be determined prior to testing the machine, it being a certain definite proportion of the whole output, as described above, depending on the size and desired efficiency of the machine. In a series machine the main current passes through the magnet coils, a certain amount of potential will therefore be absorbed in the coils; in making the preliminary test for determining the ampere-turns, the armature should therefore be made to generate this additional potential by increasing the excitation of the temporary coils. For instance, if the external circuit requires 1,000 volts. and 10 amperes, and if 5% of the energy be allowed for the magnets, the exciting with temporary magnets should be continued until the potential at the brushes is 1,000 + 5% = 1,050 volts. when the current is 10 amperes.

The number of turns, being the quotient of the ampere-turns and the current, is readily determined. The diameter of the wire is then calculated, as described from the limiting conditions, namely, the limited coil space, the heating, the desired efficiency and the cost of the wire. In shunt magnets certain values of the diameter of the wire would make it impossible to generate the required ampere-turns, and it is therefore necessary to guard against this in such cases by careful calculations and by assuming a comparatively large factor of safety in the allowable resistance or potential; but in series machines the whole current must pass through the magnets, no matter what the size of wire; therefore such impossible cases do not occur, and these precautions are therefore not as necessary, while the factor of safety may either be omitted altogether or taken much smaller than in shunt machines, the latter being preferable as it is always more satisfactory to the constructor to find the final results to be inside of the limit placed than beyond it. If for any reason the diameter of the wire has been taken smaller than it should be it will merely decrease the efficiency of the machine and increase the heating, but it will not prevent the machine from being used for generating the required output as would be the case in shunt machines.

The most important quantity to allow for in the factor of safety is probably the self-induction in the magnet coils, which acts to increase their apparent resistance. It is a question, however, whether this absorbs energy as a dead resistance would, or whether it acts more like a spring or a cushion, in which case no allowance in the factor of safety is necessary. With the usual solid iron cores it is probable that it acts like both. Its value depends on a number of quantities, such as the number of windings, the current, the number of armature coils, the speed of rotation of the armature and the nature of the iron cores; for ordinary machines 5 to 10% of the potential lost in the magnet coils will probably be a sufficient factor of safety to cover all contingencies in series machines.

As it is impossible to calculate such a complex machine as a dynamo with the same accuracy as is attainable in simpler apparatus, it may be found upon testing the finished machine that its output differs slightly from what was required. If the test described above for the empirical determination of the required ampere-turns has been made, almost all the errors and indefinite or indeterminate factors which enter into the calculation of a dynamo, have thereby been eliminated, as the chief elements of error occur in the calculation of the magnetism, (which depends, among other things, on the quality of the iron, on the relation of the ampere-turns to the magnetism induced, and on the magnetic leakage), also in the calculation of the induction in the armature, in the self-induction, and in the adjustment of the brushes to the position of least sparking. These chief causes of inaccuracy having been eliminated by the test for the ampere-turns, any differences which may be found to exist after the machine is completed, should be inappreciable or at least very small.

If it is desired to correct such differences, and if there is no regulator attached to the machine by which this can be done, the speed may be altered accordingly. To determine this correction for series machines, run the finished dynamo and adjust the resistance in the external circuit until the current is the required strength after the machine has been running with full load for a number of hours and has attained its highest temperature. Measure its speed, S, and the potential V, at the binding posts when thus running, then if the required potential is V^1, the speed at which it should be run, to correct for this potential, is

$$\frac{S\,V^1}{V}.$$

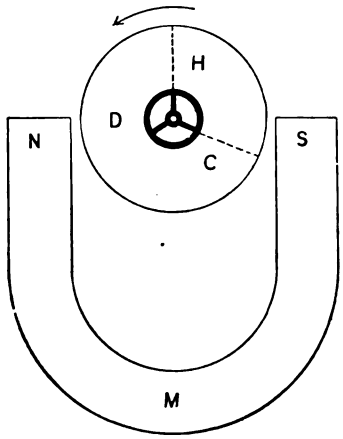
ABSTRACTS AND EXTRACTS.

A CURIOUS THERMO-MAGNETIC MOTOR.

BY PROFS. EDWIN J. HOUSTON AND ELIHU THOMSON.

DURING investigations by the authors, concerning the increase in the coercitive force of steel by changes of temperature, the following curious thermo-magnetic motor was devised. This motor, though devoid of practical value, will, no doubt, be of sufficient scientific interest to warrant a short description.

In the figure, a disc or ring of thin steel, D, is mounted on an axis, so as to be quite free to move. The edges of the wheel are placed opposite the poles N and S, of a magnet. In this position, the wheel of course, becomes magnetized by induction.



If now, any section of the wheel, as H, be sufficiently heated, the disc will move in the direction of the arrow. The cause of this motion is as follows: The section H, when heated, has its coercitive force thereby increased, and being less powerfully magnetized by the induction of the pole s than the portion C, immediately adjacent to it, the attraction exerted by the pole s on the latter portion is thereby sufficient to cause a movement of the disc in the direction shown by the arrow. If a constant source of heat be placed at H, a slow rotation in the direction shown is maintained.

To insure success, the disc must be sufficiently thin as to prevent its acquiring a uniform temperature. If the source of heat be at the same time applied at diametrically opposite portions of the disc, as at H and D, adjacent to the poles, the same effect will be produced. Since the amount of heat expanded in producing motion of the disc is so enormous when compared with the force developed, it will be readily understood that this motor is of no value as such, but must be regarded as an interesting example of the interconvertibility of force.—*Journal of the Franklin Institute*, January, 1879, p. 39.

EDISON'S PYRO-MAGNETIC GENERATOR.[1]

As a heat engine, the thermo-cell appears to follow precisely the law of Carnot, and hence can have at the most no higher efficiency than the reversible engine of this eminent philosopher. If, therefore, the result hoped for is to be attained at all, it must be looked for in some other direction. It has long been known that the magnetism of the magnetic metals, and especially of iron, cobalt, and nickel, is markedly affected by heat. Since, whenever a magnetic field varies in strength in the vicinity of a conductor, a current is generated in that conductor, it occurred to me that, by placing an iron core in a magnetic circuit and by varying the magnetizability of that core by varying its temperature, it would be possible to generate a current in a coil of wire surrounding this core. This idea constituted the essential feature of the new generator, which, therefore, I have called a pyro-magnetic generator of electricity.

1. Abstract of paper read before the American Association for the Advancement of Science, New York, August 15, 1887, by Prof. G. F. Barker, from Mr. T. A. Edison.

The principle of utilizing the variation of magnetizability by heat as the basis of electric machines, though clearly applicable to generators, was first applied to the construction of a simple form of heat-engine, which I have called a pyro-magnetic motor. A description of this motor will help us to understand the generator subsequently constructed. Suppose a permanent magnet, having a bundle of small tubes made of thin iron placed between its poles, and capable of rotation about an axis perpendicular to the plane of the magnet, after the fashion of an armature. Suppose, further, that by suitable means, such as a blast or a draught, hot air can be made to pass through these tubes so as to raise them to redness. Suppose it by a flat screen, symmetrically placed across the face of this bundle of tubes and covering one half of them, access of the heated air to the tubes beneath it is prevented. Then it follows that if this screen be so adjusted that its ends are equidistant from the two legs of the magnet, the bundle of tubes will not rotate about the axis, since the cooler and magnetic portions of the tube-bundle (that is, those beneath the screen) will be equidistant from the poles and will be equally attracted on the two sides. But if the screen be turned about the axis of rotation, so that one of its ends is nearer one of the poles and the other nearer the other, then rotation of the bundle will ensue, since the portion under the screen, which is cooler, and therefore magnetizable, is continually more strongly attracted than the other and heated portions.

This device acts, therefore, as a pyro-magnetic motor, the heat now passing through the tubes in such a way as to produce a dissymmetry in the lines of force of the iron field, the rotation being due to the effort to make these symmetrical. The guard plate in this case has an action analogous to that of the commutator in an ordinary armature. The first experimental motor constructed on this principle was heated by means of two small Bunsen burners, arranged with an air-blast, and it developed about 700 foot-pounds per minute. A second and larger motor is now about finished, which will weigh nearly 1,500 pounds, and it is expected to develop about 3 h. p. In both these machines electro-magnets are used in place of permanent magnets, the current to energize them being derived from an external source. In the latter machine the air for the combustion is first forced through the tubes to aid in cooling them and then goes into the furnace at a high temperature.

The generator consists of eight electro magnets, radially arranged around poles, connected with two discs of iron, through which pass, opposite these poles, eight rolls of thin corrugated wire. When the magnets are charged, these rolls are magnetized, and the current is generated in the coils. The apparatus being placed on a furnace, and hot air passing through these rolls, called interstitial armatures, they become non-magnetic by heat. Beneath the lower disc a semi-circular plate is made to revolve, so that it cuts off heat from one-half the armatures, four being heated and four cooled continually. The current of electricity being generated in them all, the direction in the four under the guard plate is opposite to that of the four without. The separate coils are then so connected that the currents so generated are given a common direction by a commutating device.

The entire machine now described is placed upon the top of any suitable furnace, fed by a blast, so that the products of combustion are forced up through those interstitial armatures which are not covered by the guard plate, and raise them to a high temperature. The field magnets, when charged, magnetize, of course, only those interstitial armatures which are cold; that is, those beneath the guard plate. On rotating this plate, the interstitial armatures are successively uncovered on the one side and covered on the other; so that continually during the motion four of the eight armatures are losing heat and the other four are gaining heat. But those which are losing heat are gaining magnetism, and vice versa.

The potential difference developed by this dynamo will obviously depend (1) upon the number of turns of wire on the armature coils, (2) upon the temperature difference in working, (3) upon the rate of temperature variation, and (4) upon the proximity of the maximum point of effect. No advantage will be gained, of course, by raising the temperature of the interstitial armature above the point at which its magnetizability is practically zero; nor will it be advantageous, on the other hand, to cool it below the point where its magnetism is practically a maximum. The points of temperature, therefore, between which, for any given magnetic metal, it is most desirable to work, can easily be determined by an inspection of the curve showing the relations between heat and magnetism for this particular metal.

The results thus far obtained lead to the conclusion that the economy of production of electric energy from fuel by the pyro-magnetic dynamo will be at least equal to, and probably greater than, that of any of the methods in present use. But the actual output of the dynamo will be less than that of an ordinary dynamo of the same weight. To furnish 30 16-candle lights in a dwelling house would probably require a pyro-magnetic generator weighing 2 or 3 tons. Since, however, the new dynamo will not interfere with using the excess of energy of the coal for warming the house itself, and since there is no attendance required to keep it running, there would seem to be already a large field of useful-

Digitized by Google

ness for it. Moreover, by using the regenerative principle in connection with it, great improvement may be made in its capacity, and its practical utility may very probably equal the interesting scientific principles which it embodies.—*Electrical World.*

CORRESPONDENCE.

NEW YORK AND VICINITY.

Electric Railways in New York.—Subway Work Down-Town.—Railroad Accidents and Electrically Actuated Brakes.—Necessity for Thorough Work in Electrical Engineering.—New Jersey Electric Railway Notes.

WHERE can I go in this vicinity to see an electric railway in operation, was the very natural question propounded by a civil engineer a few days ago. The gentleman thus accosted, who was considered pretty well posted in such matters, hesitated a moment, and finally replied that he could not positively name one nearer than Baltimore, although various experiments had been made on the elevated and surface railroads in this city. Some of these may be in operation, but the chances are that a visitor would find the car laid up for good reasons, and with all our agitation of this subject during the past three years there appears to be nothing for us to show. For this reason, every person having faith in the future of electrical transportation should hope for the success of Mr. Stephen D. Field's motor, which has just been placed on the 34th street branch of the 3rd avenue elevated railroad. Mr. Field has given this problem conscientious study, and was one of its earliest investigators since the advent of the successful dynamo. If there are any further obstacles to overcome he will strive to remove them; and his skill and ingenuity have already produced an electric locomotive which has at least the most business-like appearance of any yet brought out.

Down-town people are now being given an opportunity to inspect contractor Crimmins's "Subway Works," as the inscription on his new tool boxes designates the holes in the ground which are creeping up Broadway from Courtlandt street. The character of the work is the same as the conduit on Broadway above 14th street, and it starts from the new telephone building with 104 iron ducts, each 2½ inches in diameter. The disturbance of the soil has not given rise to such a variety of odors as characterized the up-town work, but the opening of Broadway at one of its busiest sections is quite an obstruction to traffic.

Recent railroad accidents in various parts of the country have attracted attention to the occasional failure of air brakes, and the use of electricity in combination with them will doubtless be considered of more importance now that practical tests have demonstrated its usefulness. Nothing that can be devised, however, should permit the slightest relaxation of vigilance in the care of passenger trains. An occasional unexpected call for brakes might be profitably indulged in for the sake of proving that brakemen understand the signal. There is an existing impression among all classes, that occasional failure is a weakness of electrical devices, but experience will show that careful construction and intelligent supervision will lead to the same reliability with the electric current as is popularly supposed to prevail in the use of steam, water, air or gas,

Temporary and careless work has been too prevalent a feature of electrical engineering, and now that the safety of life and property depends upon this new profession to such a great extent, every precaution should be used to raise the standard of construction.

There are some electric railway rumblings from various parts of New Jersey, which may settle down to the hum of business before winter sets in. The triangular fight for a franchise in Elizabeth has not yet ended; but the authorities in New Brunswick have granted permission to the street railway to use electricity if the property holders are willing. The Jersey City and Bergen horse railway continues its experimental trips with a storage battery car. The sea-shore railway at Asbury Park has received its first daft motor, and the indications are that the line will be ready for business by the first of September, rather too late, however, to avail itself of the summer traffic.

NEW YORK, Aug. 3, 1887.

PHILADELPHIA.

Comprehensive Plans of the City Authorities for Electric Lighting.—The Electric Railway Experiments of Messrs. Wm. Wharton, Jr. & Co.—Gathering of "Old Time" Telegraphers in Philadelphia.

THE entire city lighted by arc electric lights and the wires supplying the currents laid underground! The very suggestion will take the breath of Philadelphians. Yet this is the aim and object of chief Walker of the electrical department, and one that is looked upon favorably by director of public works, Wagner and Mayor Fitler, and in consequence its consummation is being pushed with all the energy that is desirable in so great a project and one so fraught with complications and weighty considerations. It is intended also that the lighting shall be done by plants owned and operated by the city and not by private corporations, as most of it is done now. For a long time chief Walker has been working on the project. He has made numerous experiments with underground wires, and has consulted the plans of the city with respect to the location of plants, the laying of conduits and wires, until he could almost draw a correct map of Philadelphia with his eyes closed. While he has been working long and hard, he has still been working secretly, and has given no sign to the public of the good things that are in store for them.

Although the main points of the great project have leaked out, the chief is still reticent. "Until I have completed all my plans and submitted them to my superiors," he said, "I will not give anything out. I can assure you that there will be a good deal in the way of news in this connection before long, but just now I do not care to give it out.

Some practical experiments that the chief has been making are seen on North Broad street. Ever since the scheme of placing the disfiguring and dangerous electric light and other wires underground has been broached, the companies owning such wires have set up as an excuse for not complying with the wishes of the people the statement that it is impractical to put electric light wires underground.

Chief Walker has been experimenting largely with underground wires and with complete success. On Broad street, between Fairmount avenue and Tioga street, he has laid conduits in which he has put wires, and has been operating with them for some time arc lights in all that territory. The light surmounting neat slim poles has filled that wide and pretty thoroughfare with the brilliancy almost of day, and there has been no hitch or halt of any kind. This clearly demonstrates what can be done with underground wires.

The gloom and darkness that has filled Front street from Vine to South, will very shortly be dispelled forever. That district will be lighted with twenty-four two thousand candle-power lights, the current for which will be supplied by underground wires. This portion of Front street will then be the best lighted thoroughfare in town.

It is no longer a secret that the city officials desire to secure the wharf at Otis street, Delaware river, which is now used as a pumping station to the Kensington reservoir, for the purpose of establishing there one of the electric light stations from which the entire city will eventually be lighted.

The conduit companies have obtained the right from the city to use at least 100 miles of streets in the best paying and most populous sections of the city, and to obtain control of these conduits the municipal government would be compelled to indemnify the companies in large sums of money. So far as Chestnut street is concerned, there is no room that is not already held by private concerns. One of these companies, and the principal one—the Penn—reserves one compartment in its conduit for the use of the city.

The electric storage battery motor, as applied to an ordinary street car, under the direction of William Wharton, Jr. & Co., had a practical test a few days since in the presence of a number of gentlemen, who made a trip on one of the new motor cars from the Wharton works to Third and Walnut streets and return to Gray's Ferry, and thither to the works again, the trip having been again repeated later in the afternoon. Among those present were president Fox, of the Second and Third streets line; president Noblit, of the Fifth and Sixth streets road; president Parsons, of the People's line, and president Brooks, of the Spruce and Pine streets line; superintendent Cooper, of the Thirteenth and Fifteenth streets line; G. W. Blabon, E. C. Knight, councilman John Bardsley, Samuel R. Shipley, president Tyler, of the Fourth street national bank, and Wharton Barker. William Wharton, Jr., was master of ceremonies, and was assisted by his superintendent, G. Herbert Condict, who ran the car, and Anthony Reckenzaun, C. E., who has run cars with the same accumulators, or storage batteries, in London, Berlin and Vienna. Eighty-four accumulators are used in each car, being ranged along the side and on the bottom under the flooring, which is slightly raised to give the needed room. Sprague motors were used.

On Wednesday and Thursday of the present week a very interesting convention is to be held in this city, that of the Old-Time Telegraphers' Association. Many of the delegates will be telegraph operators who were in the military service during the war. Their headquarters during this, their seventh reunion, will be at the hotel Lafayette, with parlor C as the office and reception room. The officers of this body are: William R. Plum, Chicago, president, and George C. Maynard, Washington, vice-president, of the United States military corps, while the "Old Timers" are officered by Charles C. Hine, president, of New York, and Charles E. Taylor, vice-president, of Frankfort, Ky.

Digitized by Google

The Old-Time Telegraphers' Association was organized seven years ago. Charles E. Taylor, of Frankfort, Ky., a veteran Morse operator, seems to have been the originator of a reunion of Old-Timers at Cincinnati, on September 7, 1880. The association was formed there, and the custom of holding annual reunions is one of its principal features. The members to be eligible are required to have been in the business of telegraph operating twenty years prior to their application for admission, and to have been connected with the business at least two years.

There are quite a number of old time telegraphers in this city, and the man who is generally accredited with being the oldest Morse operator in the United States is captain Louis Chasteau, of the Park Guard. He was engaged on the earliest telegraph line between Baltimore and Washington, in the days when they had electro-magnets to work the current almost as big as a man's body. Among the old Philadelphia telegraphers are Henry Bentley, president of the Philadelphia Local Telegraph Co., Samuel A. Plush, general manager and George W. Snyder, superintendent of the Bell Telephone Co., and David R. Walker, superintendent of the electric bureau of the city.

The Bell Telephone Co. has raised its price for connections from Camden with South Jersey towns from 25 to 35 cents. To several towns this is in excess of the railroad fare.

Philadelphia, Aug. 19, 1887.

BOSTON.

Midsummer Dullness.—Business Reports of Telephone Companies.—Lighting Private Carriages by Storage Batteries.—Electric Railway Privileges.—Severe Damage by Storms in New England.—The Electric Light Association.

THIS is the season of the year when the local correspondent, with two or three rivals in the field, contending in the search for early worms, almost despairs of picking up fresh information. Moneyed men are out of town, so that the busy middleman or promoter who sets up a "syndicate" on the "ground floor," for the poor inventor of electrical apparatus, is out of employment; the "lambs" are out on mountains or fields, or are listening to what the wild waves are saying, at the sea-shore. The manufacturing concerns have had their little say, in the cooler months of the year, and wait over the heated term, before they bring out new devices, notions, or advertisements.

The American Bell Telephone Co.'s statement of the output of telephones for the month ended July 20, and the year to date is as follows:

July—	1887.	1886.	Increase
Gross output	4,345	3,279	1,066
Instruments returned	3,196	1,382	1,814
Net output	1,149	1,897	*748
Dec. 1 to July 20—			
Gross output	33,008	24,914	8,094
Instruments returned	14,310	10,644	3,666
Net output	18,698	14,270	4,428

*Decrease.

The usual quarterly dividend of 75 cents a share, was declared by the directors of the New England Telephone Co., July 27. The gross receipts of the company for three months ending June 30, were $251,781.99; expenses, $178,587.72; net receipts, $73,194 27. The comparative statement for the quarter ended June 30, is herewith tabulated:

Quarter ended June 30—	1887.	1886.	Increase
Gross receipts	$251,782	$228 043	$23,739

*Decrease.

Mr. John G. Low, of the Chelsea Art Tile Works, is probably the first man in these parts to utilize the storage battery for lighting a carriage. He has a small battery and two incandescent lamps of five candle lights each. The cost is trifling and the convenience very great. He gave the Boston agent of the Julien storage battery quite a surprise, by springing the lights on him when calling on him at his cottage in Winthrop, the other evening. It is likely that this use of the storage battery will soon become general, being particularly convenient for hacks and other city vehicles.

The Edison company are extending their underground system through Boylston street, to the Back Bay residence district.

The following was presented to the board of aldermen, July 25th:

CORPORATION COUNSEL'S OFFICE,
14 Beacon Street, Boston.
June 30, 1887.

J. H. O'Neil, Esq., City Clerk:

Sir—I return herewith, without approving them the agreement and bond of the American Conduit & Construction Company. As the Board of Aldermen cannot authorize the company to lay and maintain pipes and conduits in the highways for the purposes named in the order referred to in said agreement and bond, the city would be liable to indictment for any obstruction of the street by said company. Very respectfully,

E. P. NETTLETON, *Corporation Counsel.*

The matter was referred to the committee on bonds.

The aldermen passed an order to allow the Cambridge Horse Railroad Co. the right to experiment with electric street cars on North Harvard street, Brighton, between Western avenue and the Cambridge line.

During the past six weeks, nature has been actively engaged in electrical business in New England. On the 25th ult., at Great Barrington, Mass., a striking feature of the storm was a cloud burst, accompanied by electrical phenomena, a huge gaseous ball descending and bursting with a loud report, the explosion blowing out a huge hole in the ground, and scattering debris in all directions. The appearance was sudden and startling, only a few rolls of thunder preceding the burst. Rain fell in sheets and the rise of water was unprecedentedly rapid. In Alford, Egremont, Great Barrington and Sheffield, selectmen were out with gangs of men endeavoring to save the roads by turning the swollen streams that dashed down the hillsides. The torrent that rushed through the banks of Green river and then swelled the Housatonic was terrific and destructive, tearing embankments, stone walls and bridges along its path. A reconnoitering locomotive on the Housatonic road was cut off by washouts before and behind, and ignominiously stranded. At least twenty-five bridges were swept down the stream, while cattle were caught in the overflowing tide and drowned.

The semi-annual convention of the National Electric Light Association, held at the Parker House, August 9th to 11th, was largely attended by representatives of electric lighting interests in all parts of the country. Five sessions were held. The papers read and discussed were upon topics of immediate interest, and brought out much interesting and useful information. The members of the association were handsomely entertained by the city authorities, the Boston Electric Club, and the Thomson-Houston Electric Co., in an excursion to Lynn via Nahant, an inspection of the Thomson-Houston works, and a banquet at Point of Pines.

BOSTON, August 16, 1887.

CHICAGO.

Lively Trade and Short Vacations.—The Electric Light Convention at Boston.—Electrical System for Directing the Movement of River Traffic.—Successful Forgery in the Office of the Central Union Telephone Co.—The City Contract for River Front Lighting Plant Awarded to the Western Electric Co.—Trade Notes.—The American Cushman Telephone Co. Sued for Injunction and Damages by the American Bell and Central Union Companies.—The Chicago Electric Club.

BUSINESS in Chicago this summer is so active that, in spite of hot and disagreeable weather in the city, short vacations are the rule. Fortunately there are within a few hours ride of the city a number of delightful resorts, on the shores of great and small lakes, where a day or two of rest may be spent. The longest trip is that made by Mr. E. M. Barton, president of the Western Electric Co., who for health and pleasure is making an extended tour in the Northwest. We understand that he is now among the glaciers and perpetual snows of Alaska.

Speaking with some of the gentlemen who represented western electric light interests at the Boston convention, we find them unanimously of the opinion that this was one of the most profitable conventions that have been held, and that the time there was spent most pleasantly too. Every one was delighted with Boston and with the courtesies shown there to the visitors.

Within the past month there has come into practical use in Chicago a system for controlling the movements of vessels in the river, by means of electrical communication, that has already shown itself to be a remarkable success. There are twenty-five bridges spanning the river, bridges over which myriads of people pass daily, and through which vessels, empty and loaded, must be constantly passing on the way between their docks and Lake Michigan. Heretofore the custom has been for a vessel moving in the river to whistle at each bridge, as a signal for it to turn and let her through. This simple plan caused considerable inconvenience for several reasons. In the first place, the noise was a public nuisance, the shrill whistles of tugs and lake steamers sounding almost without cessation. Then the delay on the streets was aggravated by the continual turning of the bridges, and the fact that they were often kept open for an unnecessary length of time; for instance, a bridge-tender instead of closing his bridge

Digitized by Google

after one vessel had passed would wait for another that he saw coming in the distance. But the noise and the unnecessary delay have been almost entirely done away with by the simple system planned and put into execution by city electrician Barrett. Telephones on each bridge are connected with a switch-board in a small building at the foot of LaSalle avenue, where a vessel despatcher is always present, who alone is responsible for the turning of the bridges. The bridge-tenders are in constant communication with him and act only by his instructions. He does not allow two large boats to block the river by trying to pass each other in a narrow place, and he reduces the number of turns of the bridges about one-half, by holding vessels until he has several bound in the same direction. When the fleet moves it moves without delay and without noise, the bridges opening one after another at the vessel despatchers' request. This seems to be the best solution of the bridge problem, as it is much more just to the shipping interests than the plan proposed of allowing vessels to move only at night.

The Central Union Telephone Co. have had an adept forger among the employés in their central office. It was recently discovered by accident that A. J. Whitman, a young man who has held a position of trust with them for several years, has been in the habit of taking blank checks and forging the names of president Phillips and treasurer Chapman so skillfully that he was easily able to obtain money on them. He collected some $18,000 in this way and squandered the money.

The Brush, Western Electric, American, Fort Wayne Jenney, Excelsior, Ball and Sperry electric light systems were represented in the competition for the city contract for river lighting mentioned in last month's letter. When the bids were opened by the commissioner of public works they were found to range from $39,840 down to $29,295, the Western Electric Co. putting in the lowest bid, and the Ball Electric Light Co. the highest These figures include the steam as well as the electric plant, with some six miles of armored submarine cable. The Chicago Arc Light and Power Co. offered to rent the lights at 45 cents per night, but it was deemed desirable for the city to own its own plant, and so the contract was awarded to the Western Electric Co. as the lowest bidder. It is expected that the lights will be burning in about 60 days.

The Western Electric Co. have a number of other large arc light contracts; they have orders from the Grand Pacific hotel, Chicago, and for street lighting at Lawrence, Kansas, and Stevens Point, Wis. They will also furnish about 280 lights for the illumination of the large buildings in which the Chicago and St. Louis expositions will be held this season.

The Central Electric Co. have established a factory at Columbia City, Indiana, where white oak timber of the finest quality abounds, and are making pins and brackets which they claim to be the best in the market. They call this branch of the business their specialty; but they also handle almost everything electrical, and have a growing trade. The Messrs. McKinlock say that they made no mistake in coming to Chicago to establish their new enterprise.

The Electrical Supply Co. are giving particular attention to the requirements of the multitude of electric lighting companies in the west. They keep on hand a large supply of insulated wires and carbon points, the wire being of their own make, and the carbons those manufactured by the Standard Carbon Co. of Pittsburgh. Manager Terry reports business this summer as most satisfactory.

The American Bell Telephone Co. and the Central Union Telephone Co have commenced action against the American Cushman Telephone Co. by suing for damages and perpetual injunctions against 40 users of the infringing instruments at Findlay, Ohio.

The next meeting of the Chicago Electric Club is appointed for Monday evening, August 22d, at the club rooms, 225 Dearborn street. Dr. Badt will read a paper on "Dangers to Human Life from Electricity."

CHICAGO, August 19, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

THE REIS "BORED-BLOCK" TELEPHONE.—A CORRECTION FROM DR. THEO. STEIN.

[73].—I have just received No. 67, July, 1887, of "THE ELECTRICIAN AND ELECTRICAL ENGINEER," which contains a translation of my open letter to Prof. Houston, sent you in German. An erroneous rendering of one paragraph therein, would give rise to misunderstanding. The passage mentioned was written by me in German as follows:

"Ich will zu Ihren Gunsten und zu Ihrer Ehre annehmen, dass Sie selbst von jenen, an dem von mir durch Vermittelung des Herrn Silvanus P. Thompson, in London nach den Vereinigten Staaten gekommenen Original Bored-Block Telephone, vorgenommenen Veränderungen Keine Kunde gehabt haben."

Owing to the German method of placing the words your translator did not apprehend the correct meaning of this sentence and has given it an entirely different significance. Below I give you the same sentence in German, arranging the words differently to make it more easily intelligible.

"Ich will zu Ihren Gunsten und zu Ihrer Ehre annehmen dass Sie selbst von jenen vorgenommenen Veränderungen an dem von mir durch Vermittelung des Herrn Silv. P. Thompson, in London nach den Vereinigten Staaten gekommenen Original Bored-Block Telephone Keine Kunde gehabt haben."

The sentence in the July No. (67) of the ELECTRICIAN AND ELECTRICAL ENGINEER, reads as follows:

"I will in your favor and to your honor believe, that you had no knowledge of the changes which *I made* on the original Bored-Block Telephone, which went to the United States through the agency of Prof. Silvanus P. Thompson, of London."

Changes I have never made on the apparatus; in fact the apparatus reached America through Mr. Thompson, as originally made by Reis. The mistake of the translation can be seen from the context following it. The passage in question (on page 282 of your July No.) should read as follows:

"I will in your favor and to your honor believe, that you had no knowledge of the changes which WERE *made* (in America) on the original bored-block telephone which went to the United States, through Prof. Silvanus P. Thompson, of London."

Begging you to make this correction if at all possible in the August number of the ELECTRICIAN AND ELECTRICAL ENGINEER, under the heading of "Letters to the Editor," I am, very respectfully, Yours truly, DR. THEO. STEIN.

Frankfort-on-the-Main, July 25th, 1887.

[Dr. Stein's letter reached us too late for insertion in August number.—EDITOR.]

THE ALTERNATING SYSTEM OF ELECTRICAL DISTRIBUTION.

[74.]—The publication of the interesting series of articles by Mr. Rankin Kennedy in the current volume of THE ELECTRICIAN AND ELECTRICAL ENGINEER, urge me to relate my own part in the development of the transformer system in the United States.

While Mr. Kennedy's articles are admirable expositions of the art, yet it would appear from them that all the credit of developing this system has been due to our English friends, and I question whether he is fully informed respecting the work which has been done in this country. It is not my purpose to write of the electrical problems which have been solved, but simply to narrate the practical developments in which I have been interested. Nor do I wish to claim for myself all the credit for what has been accomplished.

In August, 1884, while measuring the vacua of my incandescent lamps with an induction coil, I noted the relation between the quantity of current absorbed by the primary circuit, and that abstracted from the secondary coil, when the external resistance of the secondary circuit was varied. I found that the ohmic resistance of the primary coil (a thick short wire) was insufficient, in itself, to account for the difference of potential maintained at its terminals, and that the *apparent* resistance of this coil varied coincidently with variations of resistance in the secondary circuit.

As these phenomena were analogous to the counter E. M. F. developed by an electric motor, and as they varied in a precisely similar way, I used the term counter E. M. F. at that time to express the reactive effects observed. The relation of this counter effect to the applied E. M. F., and particularly its value as an immaterial variable resistance, I explained at the time to a number of my friends, and shortly afterwards undertook the formation of a system of distribution, having a high difference of potential in the main circuit and induction coils, or converters, as I called them, with which to reduce this difference of potential. My first endeavors were to apply a direct current to a converter wound with a double primary circuit, having an automatic switch to shift the applied E. M. F. from one coil to the other, together with various short-circuiting devices, intended to produce a variable field around the primary and secondary circuits; all these devices proved to be impracticable. My next endeavor was to employ an alternating generator and converters arranged in series in a manner similar to the system of Messrs. Gaulard and Gibbs, of which, however, I knew next to nothing. These coils at first caused much trouble from want of regulation, but I found that, *by saturating the core*, that is, by making the number of ampere-turns sufficiently great and the self-inductive capacity relatively small, I could obtain excellent self-regulation on a constant current circuit. This system, however, wasted a large percentage of the energy applied, and was, therefore, abandoned.

In my next experiments I used the parallel system of distribution, and immediately found all the previous obstacles removed.

Digitized by Google

The parallel system, the usefulness of which appears to have first been suggested by Mr. Kennedy (although his experiments were unknown to me when I began work in the same direction), is the natural sequence of any experimental work with the series system; for, as I found, if all the converters had their primary circuits in series, and their secondary circuits connected in parallel. then applying a constant E. M. F. to the primary circuit, a constant difference of potential was obtained from the secondary circuit. The experimental proof of this proposition at once developed the utility of such a system, and the construction of the necessary apparatus for generating and transforming currents of high potential required but the application of previously acquired knowledge.

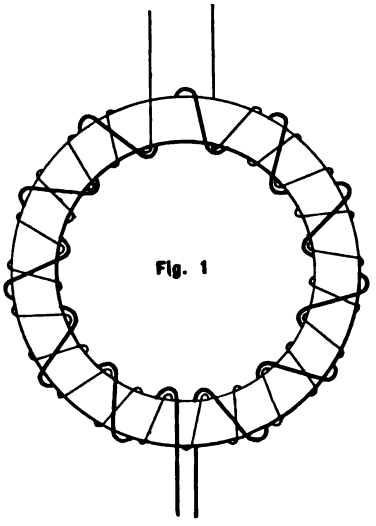

Fig. 1

In working out a commercial transformer, I began with the Faraday ring type, figures 1, 2 and 3. By adding projecting lugs or teeth, as in a Gramme armature, figure 4. I somewhat reduced the magnetic resistance. I then applied internal and external rings (see figure 5), to reduce the length of the magnetic circuits; this form, however, was inconvenient to construct, and was abandoned almost immediately in favor of the type at present used, figures 6 and 7, which is a development of the Gramme ring type of converter, for it is simply one coil of a Gramme ring with its inner and outer sheathing of iron.

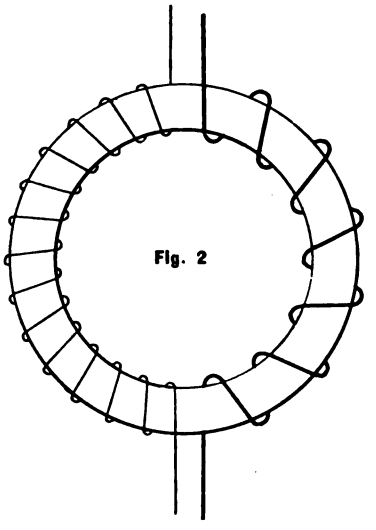

Fig. 2

Figures —— show one of my converters as manufactured by the Westinghouse Electric Company, and figure —, the outer case, for protecting it from the weather.[1] In the fall and winter of 1885 I established a central lighting station, employing these converters, at Great Barrington, Mass. This, I believe, was the first station in America operated on the induction system. We fed about 150 incandescent lamps on a circuit of No. 6 (B. & S.) wire, the circuit being nearly a mile in length. The lamps were largely used in the village stores and for general lighting. So successful was this attempt, that the Westinghouse Electric Company immediately undertook the construction and installation of a large number of stations upon the same general plan.

The advantages obtained by a double conversion system are very great. In such a system the cost of the conductors and, more important still, the loss of potential in the line, even for very long distances, may be substantially disregarded. In order to do away as nearly as possible with the loss in conversion that

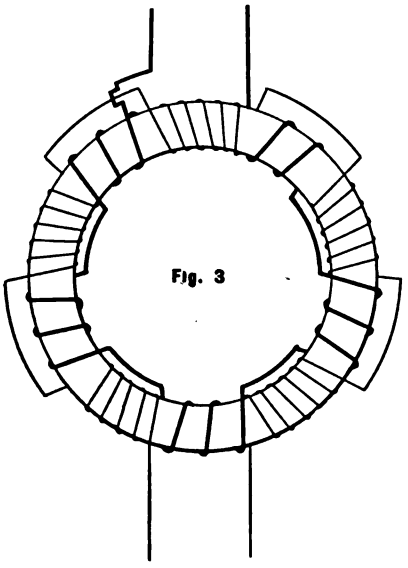

Fig. 3

is due to what may be termed magnetic friction, I have designed a system, which, I believe, to be entirely novel. In this I employ what I term "auto-converters," viz.: converters or transformers, each consisting of a single coil only.

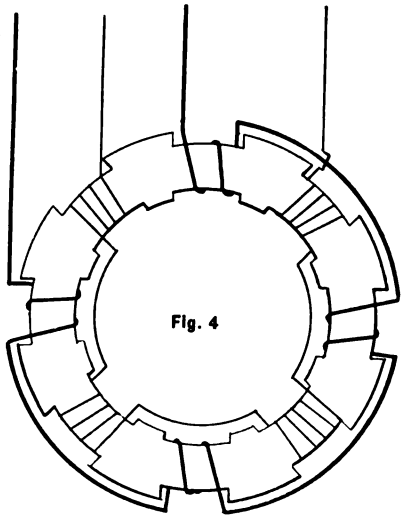

Fig. 4

Figure 8 shows one method of raising the potential by means of the "auto-converter." A-B is a converter consisting of a single coil. It is evident that one-half of the coil acts to the other half

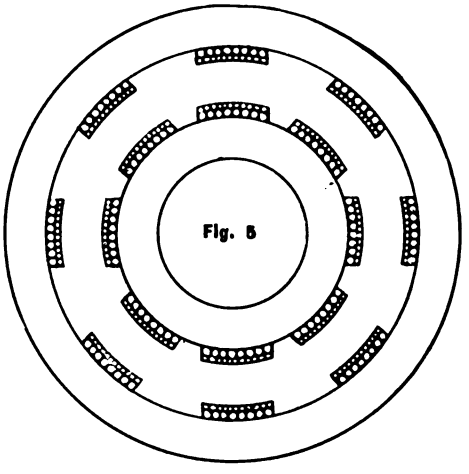

Fig. 5

as the primary of an induction coil to its secondary, and the potential between A and B is constant and is double that of A-C. Figure 9 shows an auto-converter for reducing the potential

1. These figures, being essentially the same as figures 7, 8, 9, 11, 12 and 13, on pages 336 and 337 of the present issue of the ELECTRICIAN AND ELECTRICAL ENGINEER, are not repeated here, but will serve to explain fully Mr. Stanley's reference.—[ED.]

Digitized by Google

economically, *i.e.*, with less loss than with a double coil transformer. At intermediate points, C′ D′ E′, of the single coil, A′ B′, loops are left out from the coil, and from these loops service wires are run, between which translating devices are connected in parallel in the usual manner.

Fig. 6

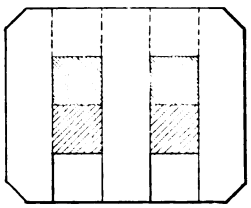

Fig. 7

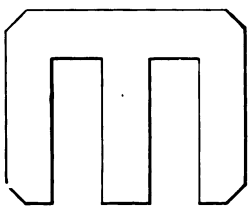

It is evident, that if the resistance between adjacent loops is equal, the arrangement becomes a series multiple coupling, and the coil, A′ B′, has no work to do, and consequently there is no loss due to conversion. If, however, the resistance between any two adjacent loops is varied, say for instance, increased, then that portion of the coil, A-B, included between those loops acts as a primary to the rest of the coil, and the potential difference between all the loops remains constant. From this it will be seen

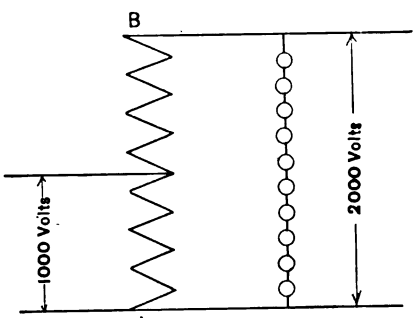

Fig. 8

that the coil acts to supply an induced current only to such resistances in any loop as are less than the resistance of the neighboring loops, and, therefore, the loss due to conversion is simply that due to the conversion of the current flowing through the algebraic sum of the resistances of the separate loops.

This form of converter possesses the same merit in potential distribution that the three-wire system does in the direct system. The real value of the induction system lies in the fact that by it

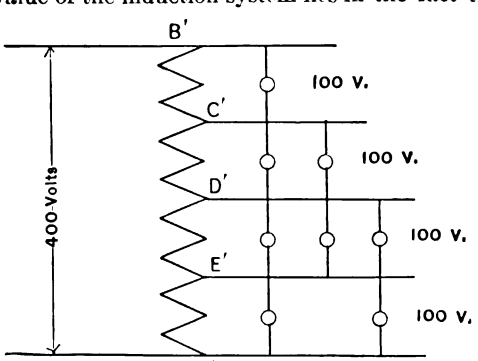

Fig. 9

potentials may be varied, raised or lowered at will, in the majority of cases with an accompanying loss of less than 2 per cent., and in many cases with no loss at all. If it were generally understood that the potential applied to a coil is simply distributed over its entire length at an equal voltage per unit of length, and hence that to obtain any desired E. M. F., it is simply necessary to tap off an equivalent length from the coil, the practical applications of the self-induction coil would be far more numerous than they now are.

There is a general misunderstanding to the effect that the alternating system of distribution in this country is, in its details, the invention of Messrs. Gaulard and Gibbs. None of the apparatus now used, however, was either designed or invented by them, nor is the system of distribution employed in connection with two or more converters, the series system employed by these gentlemen.

But while the credit of the alternating inductive system, which has now become a commercial success in the United States, cannot be given entirely to Gaulard & Gibbs, their labors have, nevertheless, been most valuable, in that by their persistent efforts toward the practical application of induction coils in electric lighting, they have drawn the attention of electricians generally to the subject, and thus paved the way for the new departure in electric engineering.

WILLIAM STANLEY, JR.

Great Barrington, Mass., August 20th, 1887.

THE REPORT OF THE COMMITTEE ON INSULATION AND INSTALLATION OF THE ELECTRIC LIGHT ASSOCIATION.

[75.]—I notice in the reports of the sixth meeting of the National Electric Light Association, several statements concerning the report of the Committee on Insulation and Installation, to which as chairman of the committee I take exception.

Not having been able, through press of business engagements, to attend the meeting of the association, I desire through your columns to call attention to the following statements made concerning the above committee, viz.:

1st. The statement made by Mr. De Camp that he understood the committee did not wish to be responsible for their report.

I am unable to comprehend how anything in the report itself, or anything I may have said personally to Mr. De Camp could be construed into an expression of unwillingness to assume the responsibility for anything to which I was willing to append my signature, and this I am sure can be said for the other members of the committee who signed the report.

What the committee did wish understood, as they stated in their report, was that they recognized the fact that some additions or alterations would probably be necessary in the code of tests proposed, when such code came to be subjected to actual trial.

2d. The statement made by the president, Col. Morrison, that "this committee, either all six, or one of its members, perhaps more, wrote to me asking, &c.," for an appropriation to meet expenses in carrying out tests. If Col. Morrison will refer to the letter in question he will find that it was written by the secretary of the committee, at the request of the committee itself, all of whom were present with the exception of Mr. Robinson.

The letter referred to, contained the following phraseology in reference to the expenditures; viz.: that the committee be authorized "to expend a sum for express charges. stationery, incidentals and alterations, not to exceed $1,000; and, further, that the responsibility of accidental injury to the machines or instruments be assumed by the National Electric Light Association."

3d. The statement of the president, that from the date of receipt of the above letter "nothing more was heard from the committe until this paper, with quite a column of printed matter, was sent in yesterday or the day before to the National Electric Light Association."

As chairman of the committee, I notified Mr. F. A. Gilbert, chairman of the executive committee, some ten days or two weeks before the meeting of the association, that the committee on insulation and installation would submit an incomplete report. This information does not appear to have been communicated to the president of the association by the chairman of the executive committee.

In conclusion, permit me to express my regrets that the earnest effort of the committee to give to the association the best of what they had been able to accomplish should not have met with a more courteous treatment than that of having their report laid on the table.

Very respectfully yours,

EDWIN J. HOUSTON,
Chairman of the Committee.

PHILADELPHIA, August 22, 1887.

THE LATE ALVAN CLARK.

THE advancement of science has probably received no greater impulse in this country than has been given by the genius of Alvan Clark, the celebrated telescope maker, who died at his home in Cambridgeport on August 19th, at the advanced age of 84 years. For more than thirty years that home and the unpretentious building in which he has done his famous work, has been a place of interest and the Mecca of pilgrimage to the astronomers of every nation of the world who wanted better instruments than they could obtain elsewhere; and it is safe to say that

Digitized by Google

none ever made the visit without carrying away a feeling of the highest admiration, not only for his genius, but for his simple and lovely character. In exceeding modesty, in love of truth, in his infinite patience to arrive at perfection, he closely resembled the greatest of English astronomers, and he should be called the Herschel of America.

Each of these men was about forty years old, when he was led, with no idea of the ultimate result, to undertake the construction of telescopes. Herschel, the musician of Bath, having found great enjoyment in reading a book upon music, was led to read another by the same author upon optics. A new interest was thereby awakened, a new field opened to his imagination, and from the book he looked up to the heavens; then he wanted a telescope. The loan of a small one from a friend whetted his appetite; the cost of a larger one was beyond his means, and he resolved to make one for himself. Then followed years of labor, but at the end the king sent for him to bring his telescope to London and show the new planet which he had added to the solar system.

Clark, the artist, while painting portraits in Boston, often passed his leisure hours in rifle shooting, his fine mechanical genius enabling him to make the most perfect weapon, while his accuracy of eye probably justified his claim to being the "best shot" in his native state. While thus amusing himself he wanted a better telescope for his rifle than any one could make for him, and he determined to make it for himself. The almost minute lenses for this instrument were the natural precursors—for there his spirit found its work—of the enormous glasses, the work of his hands and which have revealed siderial objects far beyond the ken of Herschel's mirrors.

The successive increase of the size of his glasses was achieved only during years of patient toil; nor did recognition begin at home. Having once finished a fine glass, but one that would now be considered of very moderate size, he set himself the task of plotting down all the stars it could reveal to him in the great nebula of Orion. He desired to verify some of his observations, and craved permission to look through the large telescope of a venerable institution situated not far from his home. The request was granted with some hesitation, and probably some indications of annoyance on the part of those having charge. A little time passed, and the director of the same institution learned that the great "Fraunhofer" which was under his charge had been surpassed, both in size and in definition, by a telescope made by his modest visitor, and that by means of it the long suspected companion of Sirius had been discovered. And so the director asked permission to come and look through Mr. Clark's telescope, a request not only granted but followed by a life-long friendship.

The first recognition came from England. The Rev. W. R. Dawes, a lover of telescopes, and a keen sighted observer, learned of his work, and ordered a large glass. He found it better than the best work of the European artists, and the publication of its performance fixed the fame of Clark.

When he began working it was difficult to obtain glass of sufficient purity to make a telescope of even eight inches in diameter. It is probably safe to say that the remarkable progress of the glass makers of Europe in producing pure discs, finally up to 36 inches in diameter, is in part due to the avowed ability and willingness of this American artist to work to a perfect figure, object glasses of any size that could be produced.

Clark went to England in 1858, and visited his patron Dawes. While there he called upon old Admiral Smyth, the Nestor of amateur astronomers, who said of him, "There is no end of the findings of such an ardent gazer as this American is; divers proofs of his prowess will be found in the monthly notices of the Royal Astronomical Society."

Herschel's name is popularly associated with the "forty-foot telescope" which he erected at Slough, under the patronage of the king; but astronomers well know that this was far from a perfect instrument, and that his fame and his discoveries were due to the delicate precision of his smaller telescopes. So Clark's genius is probably more generally recognized by astronomers on account of the great beauty and perfection of the telescopes he has made of moderate size, than of the gigantic and almost unwieldy tubes that look upward from the antipodal regions of Russia and California.

It would be too much to say that Clark leaves no successor. His sons are possessed perhaps of all his marvelous practical skill; still there are those who affirm that object glasses by his hands will command a premium in time to come on account of their intrinsic merit—that "something" which the touch of genius only can give—which steers the light aright and makes them instruments of discovery.

LITERATURE.

REVIEWS.

Die Wrkungsgesetze der Dynamo-Elektrischen Maschinen. By DR. F. AUERBACH. Published by A. Hartleben, Vienna, Pesth and Leipzig.

THIS little book on the laws of the action of dynamos, constitutes the 38th and latest volume of the electro-technical library issued by the same publisher. It treats chiefly of elaborate mathematical and physical theories of the dynamo, under the latter term in German, being understood self-exciting machines only. The author compiles, compares and discusses the various theories advanced, chiefly by German physicists, and among these more particularly the theories of Clausius and those of Froehlich, to which he adds experimental data and theories which are presumably his own. The theories of Clausius and Froehlich, which have been published within the last few years in the *Elektrotechnische Zeitschrift*, are given here more concisely; in which form they will no doubt be better appreciated by the average reader. To students and others who are interested in purely mathematical discussions, this book no doubt presents a fair and brief summary up to its date of publication; but for those who are practically engaged in designing and building dynamos there is little that will assist them which is not contained in any good work on the subject. For example, after discussing the theories the author concludes from them that for low external resistance series machines are the best, and for high external resistance shunt machines are best; this, as is well-known to any one practically engaged with machines and plants, is exactly the reverse of what is found best in actual practice, shunt machines being almost invariably used for incandescent lighting in multiple arc, and series machines for arc lighting in series.

The theories as advanced here are in general based on the action of the dynamo as a whole. Although this may be a safe way of attacking such a problem, we venture to predict that this is not the way in which it will ultimately be solved, at least not if the theory is to be in such a form as to enable the designer to deduce therefrom the best and most economic proportions of all the parts. A dynamo consists of two separate parts, the armature or inductor, and the electro-magnet or field, and as these may be of such widely different forms and combinations, general formulæ applying to all alike, would naturally be too complicated, and would contain too many unknown and widely varying "constants" to be of much practical value to the designer. The problem will probably be solved most satisfactorily when the armature is considered alone as an inductor pure and simple, and the field alone as a magnet, the best combinations will then no doubt present less difficulty than if both are considered together. It is gratifying to be able to say that a departure in this direction has already been made.

The book contains 84 neat illustrations, mostly diagrammatic representations, characteristics of dynamos, and curves showing tabulated results. Among the most interesting and instructive of these, are some of the apparently original ones in chapter ii, showing very clearly the induction in a loop moved in different parts of various fields, by the number of lines of force cut. He describes the measurement of magnetism and magnetic intensity by the unit lines of force, and states that the latter evidently make complete circuits closed in themselves, as an electric current. In several chapters are contained numerous tabulated results of series of experiments on dynamos. Neither alternating current nor unipolar machines receive particular mention. The volume concludes with a chapter of "special problems."

On page 245 there is a numerical error; to reduce volt-amperes to kilogram-meters per second, the former must be multiplied by .1019 and not 6.12 as stated; the latter number reduces them to kilogram-meters per minute.

ELECTRICAL NEWS AND NOTES.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

SIXTH SEMI-ANNUAL MEETING.

THE sixth meeting of the National Electric Light Association was held in Boston, Aug. 9–11, in the large dining room of the Parker House.

The meeting was called to order by President Morrison, at 10.30 A.M., on August 9th.

The President read an opening address, as follows:

Gentlemen of the National Electric Light Association:

I have again to congratulate you upon the success of your organization, which the large attendance to-day from all over the country evidences. Inventive ability and irrepressible energy of the most pronounced character still farther encourages us in the belief that if electrical business does not achieve a phenomenal success, it shall not be for want of intellectual activity, energy and integrity.

Great progress has been made in the last six months in electric lighting generally, but especially in the development of incandescent systems. The induction system, which permits of low tension lamps, at a great distance from the station, is a branch of lighting that has greatly increased since the last convention, and is now successfully conducted in numerous places. This system, more than any other formerly in use, is designed to find its place in the illumination of private houses. Its flexibility is very great. Its farther development is encouraging.

Lighting by storage batteries has also received a great impetus within the last three months, and while there are still some difficulties to overcome in certain branches of illumination, it is fast superseding the dangerous oil lamp on railway trains.

Dynamos have been perfected so as to give greater efficiency per pound of metal used, and our electricians are constantly working to reduce the cost of the machines, and thereby insure a large market for the same.

The perfection of the arc lamp has increased, and the demand for the same in the last six months exceeds the output of the previous eighteen months.

Mill owners and others are beginning to realize the enormous advantages of the electrical illuminant, not only in the more healthful condition of the operative, but also in the greatly decreased fire risks. The underwriters throughout the country recommend the introduction of incandescent lights to their patrons in all factories where inflammatory fabrics are made.

Abroad, the introduction of electrical installations has been slow and unsatisfactory, but of late our brethren across the ocean have taken up the subject with vigor, and to-day are becoming formidable rivals in the enterprising spirit of this country in the adoption of electric energy for all uses.

The patent office question, perplexing and unsatisfactory as we are well aware it is, is now receiving attention through the agitation of the subject by the association, and we intend to keep this matter before the world until legislation shall be compelled to furnish what is needful.

As suggestive of the multiplicity of uses to which electricity may be put, Lieut. Murdock submits a paper setting forth and explaining the electrical requirements for the new government cruisers; and although this especial electrical application would necessarily be limited, it would no doubt be useful, and still farther evidences the desire and demand for the applications of electrical devices in every branch of industry.

The perplexing wire gauge matter will again be placed before you, and if the work of the past six months of the committee on this subject corresponds with the exhaustive and excellent report made at the last convention, we may expect something definite enough this time to decide the attitude of this association in relation thereto.

I regret to have to announce the absence of the report of the committee on insulation of wire and the proper installation and construction of plant. This committee requested the association to provide the necessary means to enable them to carry out their investigation. But, as the association was in no condition to render them the pecuniary aid they required, they determined not to pursue their work any further. I believe this to be a loss to the association; as from the statements they have made or what they intended to do, if they only had the means, I can easily foresee the loss of a great deal of valuable information to ourselves and to the world at large.

I have now the honor of introducing to this association one of the most popular mayors that the city of Boston has ever had, a gentleman who represents public interests more than the interests of any particular party or clique, and who under the most trying circumstances has shown his fidelity as a public representative to such an extent as shall make his official administration one of the most memorable landmarks in the history of Boston's progress.

On the conclusion of his address Mr. Morrison introduced the Hon. Hugh O'Brien, Mayor of Boston, who said:—

Mr. President and Gentlemen of the National Electric Light Association: You almost overcome me, Mr. President, by your very flattering remarks; but it gives the Mayor of Boston great pleasure to welcome so many distinguished gentlemen to the city who are engaged in a very important work. I hope your visit will be a pleasant one, as well as a profitable one, and if you can show us any way whereby we can light our streets and dwellings better than the work is now done, we shall be very thankful to you, Mr. President, and your association.

I read in the papers a few weeks ago that immense fortunes were made in the electric lighting business. It must be a very attractive business, and I suppose now that I am addressing not only men engaged in electric lighting work but millionaires of various degrees (laughter). Our experience in Boston does not, I am sorry to say, corroborate that supposition. Electric lighting so far has been introduced by the energy, the ability and the intelligence of men who have been engaged in local lighting. I believe it is their intelligence that has scattered the electric light over the country in such large proportions in every city and many of the country towns. So far, I believe, profits have not been very equally divided. Some few men, I have no doubt, have grown rich in the electric lighting business; but I am satisfied that every man who has started a local company either in this city or in any other city of the country has been more a public benefactor than a successful money maker through his work. I do not intend, gentlemen, to advise you or say anything about the work which you are engaged in. I have no doubt your discussions will be interesting, and I hope that your visit to Boston will be a pleasant and agreeable one. I know it must be very satisfactory to many of you coming from cities and towns where the thermometer ranges up to the hundreds to visit so delightful a city as we have here in Boston where you can enjoy good fresh air at about 65. And if you have time, it would give me pleasure to take you down our beautiful harbor and into our beautiful suburbs, and I hope you will not leave Boston before you visit these attractions.

If you can give us any advice about the electric motor we should be very much obliged to you. We have street car lines running in all directions and we would like to run them by electric motors; but the experience of electric lighting men in these parts shows that experiments are very expensive, and we hope that some of you who are running electric railroad motors in other sections of the country will give us some intelligent advice on that subject. We also believe in the motor business here. Boston has neglected small industries. I believe if you establish a motor that will do the work that you will enable us to build up a great many small industries that have been neglected in our city.

I will not detain you any longer, gentlemen, but I again hope that your visit to Boston will be a pleasant one to you all. (Applause.)

The secretary made a brief report, embracing the treasurer's account which was referred to the executive committee for verification.

The president then called for the report of the Committee on Patent Legislation.

Mr. Arthur Steuart—I have the honor to make the report of the Legal Committee as well as the report of the committee appointed at the February meeting in Philadelphia—a special committee on patent legislation. At that meeting I had the honor to read a paper upon necessary reforms in the patent system, particularly with reference to those reforms that were needed in the patent office, and I pointed out at that time numerous changes that were thought necessary in the patent office. The principal among them was the establishment in the patent office of a court that would embody in itself the jurisdiction that is now divided up among half a dozen different officers all of whom are acting to a greater or less extent at cross purposes with one another. The second subject which was considered was that of an increased calibre of the personnel of the office, and some systems were suggested. The third was the increase of space in the patent office and the establishment of a laboratory for the conduct of experiments, principally electrical, which are very much needed, and we had the pleasure of having a few words from Mr. C. J. Kintner, who was at that time the examiner-in-chief of the electrical division—since resigned—in which he set before you very clearly the very great need of the office in that particular, there being absolutely no laboratory or any apparatus of any consequence—he said not over five hundred dollars worth, in all—to test the inventions which are constantly increasing in number, and which require to be tested in order to be understood. The committee now submit the following report:

REPORT OF LEGAL COMMITTEE ON U. S. PATENTS.

At the February meeting of this association, your legal committee made a report in which were set out some of the present needs of the United States Patent Office; and suggested a means by which the needs might be met and the defects remedied.

The subject being one of great importance, a special committee

Digitized by Google

upon patent legislation was appointed, consisting of Mr. J. F. Morrison, Baltimore; Mr. Walter C. Kerr, New York; Mr. Frank Ridlon, Boston; Mr. F. J. Sprague, New York, and Mr. Arthur Steuart, Baltimore, the chairman of the legal committee, to further consider the questions presented, and make a full report to this convention. Your committee has given the matter careful consideration and report that they are convinced that that branch of the patent system which relates to the granting of patents is based upon a law which was formulated at a time when the mass of business to which it was applicable was one-fiftieth part of what it is at present, and that the law needs revision in the following particulars among others:

I.

The statute law of the United States relative to the granting of patents has very few provisions which determine the rights of the applicants. The result is that nearly all the vital questions both of law and fact by which the rights of applicants for patents are to be determined now lie within the jurisdiction of the various branches of the patent office. The examiners have nearly all questions of fact to determine primarily as well as many questions of law, and their jurisdiction is divided up among a number of junior examiners who are overburdened with work. The examiner of interferences sits as a court to determine the question of priority between contestants for patent on the same invention. From the primary examiners cases go on appeal to a board of examiners in chief and from there to the commissioner, and appeals from examiner of interferences go to the commissioner. The personnel of the office is constantly changing, the commissioners more often than others. Then too, the persons who are appointed to the position of commissioner are generally chosen from some reason that has no connection with patent law, so that as a general rule the highest appellate tribunal knows less about the law and practice of the patent office and the rules by which patent cases are to be decided than the examiner from whom the first appeal is taken. This being true, it is not surprising that the examiners pay comparatively little respect to the decisions of the commissioner, and also that one green commissioner following another in quick succession should make rulings which result in a hopeless chaos in the practice. In addition to this fact the commissioner is burdened with executive duties which demand so much of his time, that with the greatest experience and power of work it is impossible for him to properly consider the numerous important cases presented for his decision.

In order that the legal rights of the patentees may be fully defined and secured, it is necessary that those rights should be understood and a settled method of obtaining them established; for this reason it is desirable that some means should be adopted to make clear and uniform the practice of the patent office.

All authorities seem to agree that the best method of accomplishing this result is to establish a strong court in the patent office that shall have jurisdiction of all legal questions arising in relation to the issuance of patents as well as all questions of fact which arise in interference proceedings, and on appeal from the examiners.

II.

The work required of the examiners in the patent office is of such a technical nature and so important to the public, that it seems to be desirable that the patent office should be put on the same footing as the army and navy. That the examiners should be educated for the service, should receive compensation equal in corresponding positions to officers of the army and navy, should have the same system of admission and promotion upon examination, and retirement on pay equal to that of those departments of the public service.

III.

The patent office is now cramped for space, the employés are crowded into quarters half large enough for them, and the patent office building, built with money paid the government by patentees, is more than half occupied by the interior department, which should have separate accommodations Additional space would enable the patent office to have a laboratory, so much needed, for the demonstration of electrical and other scientific discoveries and inventions.

To accomplish these reforms, the most cautious, expeditious, and at the same time intelligent way, seems to be a creation of a commission to be appointed by the President which shall carefully examine these and all other questions relative to the subject and report an act to Congress which will provide for their solution. We suggest the following bill which we propose shall be submitted to Congress this winter for passage:

A BILL CREATING A COMMISSION TO EXAMINE AND REPORT TO CONGRESS NEEDFUL REFORMS IN THE PATENT LAW.

Whereas, The Patent Laws of the United States are deemed to be in such a condition as to require revision; therefore,

Be it enacted, by the Senate and House of Representatives of the United States, in Congress assembled:

Section 1. That a commission be, and the same is hereby created, to consist of three suitable persons to be appointed by the President of the United States, who shall hold office until a final report of this commission is submitted to and accepted by Congress, and who shall receive for their service a compensation of $5,000 each per annum.

Sec. 2. It shall be the duty of this commission to examine thoroughly the patent laws of the United States, and those of other countries, and their practical operation and effect, in meeting the needs of the public and fulfilling the purposes for which they were created; to formulate a report to be submitted to Congress which shall set forth the results of this investigation and their conclusions therefrom, with reference to changes in, or additions to, the present law, pertaining to patents The report shall also contain a draft of an act which will provide for the changes found necessary by the investigations of the commission.

Sec. 3. The commission is authorized to employ such clerical force as may be necessary for the proper conduct of its work and to incur such other expenses for stationery, printing, etc., as may be found expedient.

Sec. 4. The salaries of the members of this commission as well as all expenses legitimately incident to its work, shall be paid from the surplus in the United States Treasury to the credit of the patent office. All expenditures by or for said commission, other than the salaries of the members, shall, however, be under the control of and authorized by the Secretary of the Interior.

And now a duty devolves upon the members of the association. It is one thing for your committee to make this report, but a totally different thing to have it passed by Congress. That result can, however, be accomplished if the members of the association will intelligently and faithfully support the hands of their committee, by themselves, each one of them, doing the part of the work assigned him to do. This association represents twenty-four states, and members of this association are fellow townsmen with eighty members of the House and Senate, while the members of the House and Senate from the states represented in the association are 61 per cent. of all the members of Congress. The committee have divided up the members of Congress among you, and assigned to each the duty of seeing the members of Congress from his state, and urging upon them the importance of the passage of this bill. Its passage lies in your hands.

The committee think it very desirable that the next meeting of the association be held in the city of Washington. The location is central and Congress will be in session at that time. The members of Congress will have an opportunity of seeing how large and important an interest is calling upon them for action, and the members of the association can take the opportunity of waiting upon their representatives in Congress and urging the passage of the bill we present for the appointment of the commission.

Present at the meeting of committee, July, 21, 1887, New York:

J. F. MORRISON,
FRANK RIDLON,
WALTER C. KERR,
F. J. SPRAGUE,
ARTHUR STEUART, *Chairman.*

Mr. Steuart supplemented his report by remarks as follows:—

I have only one other word to say and that is to submit the written report of the legal bureau. I shall not read it. It simply gives a statement of work being done by the legal bureau, of which I have the honor to be the custodian, in reference to a digest of the literature of electric lighting. We have at our command at present a set of journals and books which I suppose are not to be found anywhere in this country save in Baltimore, and we are now preparing an analytical digest of the literature of the subject, which we feel sure will be useful to the association.

Mr. Frank Ridlon offered the following resolution:—

Resolved, That the report of the Committee on Patent Legislation be accepted and the committee continued and authorized to take such steps not involving expense to the association that they may find necessary to have the bill as presented passed by Congress.

The resolution was seconded by Mr. Lynch, and adopted.

The President—The report of the Committee on Revision of the Constitution will be presented by Mr. DeCamp.

Mr. DeCamp—In looking over the reports of the various meetings it appears that several amendments have been made to the constitution, as printed, that change it entirely. Therefore we have thought fit to submit an entirely new constitution as a substitute for that which was originally adopted, and I now lay it before you.

The report of the Committee on Revision of the Constitution was read by the secretary:—

After some discussion on the propriety of making the office of secretary and treasurer one of appointment with the president, the report was recommitted, with instructions to the committee to report at a later session. Mr. Duncan was added to the committee.

REPORT OF WIRE GAUGE COMMITTEE.

The committee on wire gauge, Mr. Allan V. Garratt, chairman, presented as its report a carefully prepared table

Digitized by Google

of "Mathematical Properties of the Metric Wire Gauge," printed and distributed among the members of the association. In presenting it, Mr. Garratt said: A year ago in Detroit, a committee was appointed to consider the matter of wire gauge, which at that time was in an almost hopeless condition. After six months of constant correspondence with the largest users and makers of wire in this country and abroad, and the leading scientists in the speciality of electricity, I reported at Philadelphia that this association should do two things—first, that it vote that the British standard gauge be no longer the recognized gauge of this association, and secondly, that the metric system be made the basis of measuring wire. Both of those propositions were accepted. The honor conferred upon me in accepting my report was not less than the honor I received in being again placed at the head of the committee to elaborate this subject. The committee was considerably increased by the addition of some valuable members. During the six months we have taken up the subject of measuring wire in simple diameter in tenths of a millimeter, and have elaborated it into a mathematical table. This table is not of necessity a gauge, although the first column to the left represents a series of even numbers—integral numbers, which agree with the tenths of millimeters which appear in the next column or column No. 2. The object of doing that, is this: in sending telegraphic messages I find it is almost impossible to make a telegraph operator use a decimal point. It is almost impossible also in hasty writing to get the decimal point in the right place. For common purposes, in speaking of wires in ordinary business parlance a simple number is more convenient than a number with a decimal point, for this reason, a column of figures is used with simply the decimal point removed. That, however, is not the gauge, if there is any gauge. The gauge, if there be one, is simply the measuring of wires in diameter of tenths of a millimeter. That appears in column 2. As we have in this country a unit which is much more familiar—the inch—it seemed wise to this committee to convert those diameters into inches for the purpose of referring to tables which are already constructed, and with which many electricians are thoroughly familiar For that reason, table No. 2 was multiplied by a constant which represents tenths of millimeters in the denomination of inches. That converts the tenths of millimeters into inches, so that though unfamiliar with the metrical properties of wires, one can readily refer to these tables and see just what they are. There are three properties of wires which enter into the work which we have to do—the tensile strength of the wire—that I shall not touch upon; it is a subject by itself and does not directly interest us; the static capacity of wires—that I shall not touch upon, because in electric lighting wires it is entirely a negligible quantity in the present state of the art. The third property, is the conductivity, and it is necessary for us to know the ratios of conductivity to weight, to size in diameter and to length of conductor. The first thing we want to know about a wire to determine its physical properties is its sectional area. In this particular table, to insure almost absolute accuracy, the mathematical work was done independently by two members of the committee; Mr. P. Keilholtz, of Baltimore, independently calculated tables 4 and 5. Mr. Herbert H. Eustis, calculated the same tables. They were both submitted to me; I compared them and found some differences. Where differences occurred, I independently made two calculations upon different days, and if those two calculations agreed, I submitted them to the other gentlemen and the alteration was made in their calculation. Virtually then, columns 4 and 5 have been independently calculated by three persons. The likelihood of error has been reduced to a minimum by not calculating by ordinary arithmetic, but by logarithms, and the logarithm used was that employed in fine astronomical calculations—the seventh place logarithm compiled by Vega. I will say that carries the accuracy so far that even in calculations as to the solar system very slight errors are found. In that calculation comes in the property of the π ratio. The section area was calculated by these two gentlemen from different formulæ. Mr. Eustis calculated it from the square of the radius multiplied by this ratio ($r^2\,\pi$). Mr. Keilholtz calculated it by the square of the diameter multiplied by π and divided by 4; $\left(\frac{d^2\,\pi}{4}\right)$ two entirely independent calculations. Probably the tables here of area in square millemeters and square inches is about as correct as it is possible to make a table of figures.

Before I go on to the other details, I will say here why we put this question of sectional area so conspicuously on this table and so near the beginning. The conductivity of wire is directly proportional to the sectional area. It is, however, proportional to another property, which is entirely independent of the π ratio, and which is extremely simple in practical use. The conductivities of wires are directly proportional to the squares of their diameters. You will find, in column No. 16, squares of diameters. Wires have to be used by a great many men who are too hurried in life to familiarize themselves with mathematics and electrical formulæ, and who want to get quickly at what wires may be expected to do. From this simple table, No. 16, by simple arithmetic, you can arrive at almost any physical or electrical property of a wire. For instance, if I have a small wire or if I have 20 small wires, and I wanted to have a large wire of the same conductivity, I would simply have to take that square of diameter multiplied by 20 and look in the table and find the nearest corresponding number in column No. 16, and I would have the wire which would give the same conductivity.

All the columns in the table were figured independently by two members of the committee. The units were taken from Matthiesen's last determination—the British Association unit—multiplied by the constant which converts that resistance into the legal ohm. Hence that resistance, and also the physical properties against the resistance, such as feet per ohm, and pounds per ohm, correspond to the legal ohm.

Many gentlemen will take exception to the fact that the calculations are made at zero centigrade. This convention, if it sends out this circular, commits itself to the scientific world as doing a thing which no trade body in the United States has heretofore done. It is a scientific matter. It will be studied. Those calculations will be gone over by scientists and mathematicians. Zero centigrade is now recognized the world over as the unit of temperature. There is no probability of its being changed in the immediate future. I have corresponded with leading professional electricians in this country and without a single exception they replied to me—by all means determine your gauge on zero. The zero centigrade is that on which all scientific work is based when the question of temperature is involved.

As to the question of making these determinations of resistance, etc., on commercial copper or on pure copper, the committee found it utterly impossible to determine what commercial copper was; hence, this table has been calculated upon the basis of chemically pure copper. If any manufacturers adopt and use this, it will be very easy for them to append a constant at the bottom of their tables, which you can multiply into any one of these properties and convert your weight, your resistance, etc., directly into the degree of purity which they claim to put out commercially.

There are two other columns here which may not be of much interest, but which this committee has seen fit to tabulate to enable electricians generally to make calculations in fine electrical work; that is, a table of logarithms of area. We have appended seven place logarithms which have been calculated by three members of the committee—a logarithm of the square millimeter and a logarithm of the square inch. That, of course, is not a commercial figure; I don't know that it will ever appear in a trade statement; but it is valuable for us to use and put out.

Columns 17 and 18 contain the numbers nearest corresponding in the Birmingham, and Brown and Sharpe gauges. The Brown and Sharpe gauge I have taken from a manuscript copy sent to a member of the committee by Messrs. Brown and Sharpe, and I will say here that very few of the wire drawers who publish Brown and Sharpe tables, agree as to the actual size of Brown and Sharpe numbers. I examined one table in which, out of 40 numbers of Brown and Sharpe, 28 were wrong, and that was from one of the best wire makers in the country.

In regard to the Birmingham gauge, I will say there are 14 independent Birmingham gauges in use at the present time. I have taken Mr. Gordon's figures of the Birmingham gauge for the purpose of comparing it with the metric. Mr. Gordon has spent a great deal of time upon the question of the physical and electrical qualities of wires. He has compiled the largest tables on the properties of wires which have ever been made, expressed in the old ohm.

This committee has been very glad to do this work. All of the work other than the first five columns has been calculated by Mr. Eustis and myself. It has occupied every evening for three or four weeks until past midnight most of the time. We have put our best work and energy into this. We have based it upon the best information that we could get inside and outside of this association, and we have not failed to consult with any one from whom we could get assistance. We have corresponded with the Smithsonian Institution at Washington, and although they were unable for want of apparatus to give us any direct aid, they gave us their most hearty assurance that the deliberations of this assembly should receive proper recognition before the government of the United States, and if in their opinion it was wise, it would be adopted as the governmental measure of wire. I will say here that by act of Congress the metric system is already the legal system of measuring of the United States government. Every scientist works in it and every chemist, and it is simply a question of time, no matter whether we adopt this particular gauge or whether we discard it as useless—it is simply a question of time when the properties of everything that can be measured will be determined in the metric system. We have this now in this form. It is useless for any body of men to attempt to legislate what other men shall do. If this association should vote to adopt and use any other gauge than the metric gauge they never would be able to enforce it among their members unless those members found it for their advantage so to do.

Digitized by Google

Personally, I do not anticipate that everybody is going to lay aside thousandths of an inch, the Brown and Sharpe gauge and the Birmingham gauge and immediately take this up. I know, however, it is only a question of time when some such system of measuring will be used that will do away with all arbitrary numbers, which in themselves convey no idea as to the quantity which you are expressing.

The question of bringing this commercially before this country is a very grave one, and one to which I have not given the attention that I have given to the mathematical properties of the gauge. Of course I have corresponded with all of the wire makers in regard to it, and at the last convention I read a voluminous correspondence from them, the majority approving of this and hoping that it would be carried out.

I propose this afternoon to have this table electrotyped. It will then be the property of the association in electrotype. It can then be cut up, and such portions of it furnished to manufacturers as is thought fit. This gauge goes from the tenth of one millimeter to 10 millimeters which means from about a 38 wire to a No. 00 or No. 000 wire of Brown and Sharpe. It gives a much finer division than either of the other gauges in the larger sizes; in the finest sizes it does not give nearly so fine divisions. In the sizes which would be used in incandescent wiring, it gives much finer properties, and electricians are getting to work finer and finer on the properties of their wires all the time. It is a tendency of the times to do so. As you go up into the larger wires it becomes very marked. In the larger portions of this gauge there are seven, eight or nine numbers instead of the single number of Brown and Sharpe or the Birmingham gauge. I received a number of letters from well meaning persons calling attention to the fact, that in a small portion of this gauge there is too great a variation between the numbers. That is very true; but nobody can tell just what size of wire anybody wants in those small sizes. To tabulate it would be to make a book as big as the dictionary almost; but from the figures given any electrician can calculate the electrical and physical properties of any wire varying in hundredths of a millimeter. All of the data here is necessary for making such computations. I presume in those fine wires if this system is adopted, you will find in the course of a short time that manufacturers will be publishing odd numbers; instead of No. 2 gauge it might be 2.23, which might meet the particular requirements of somebody. Those first 10 numbers will probably receive considerable addition. This will be the basis for determining their physical and electrical properties. In the use of expensive wires—in platinum for example—no man drawing expensive wires can afford to adhere to any particular gauge, because the requirements are so nice in regard to it; but from these tables there is no difficulty in any one determining just what the resistance will be, or the size shall be, or the weight of any wire he wants determined in terms of a hundredth of a millimeter, which is about three times as small a difference as you will find in the thousandth of an inch

I don't know that I have anything more to say. I have made myself extremely disagreeable to a great many people by making them work so much. I have troubled a great many people in regard to it. I called in the best expert testimony which I have been able to get in this country. I have worked the members of the committee night and day. I have put the matter in type. I bring the matter to the association. What will you do with it, gentlemen?

Mr. Eustis—In order to give the association some little idea of the work that has been undertaken by the committee in tabulating this gauge I would mention that on a rough estimate of the number of figures necessary to calculate, it comes out in the neighborhood of 30,000—probably rather more than less; that is, for each separate calculation. Now, as the whole thing has been done three times it would make a nice little figure, very close toward a round 90,000.

Mr. Mailloux—A few friends of mine I see beginning to smile as I get up to say something on the wire gauge question, and probably what makes them smile is the remarkable slowness with which we have been arriving at any sort of conclusion relative to any wire gauge. The committee of the American Institute of Electrical Engineers has had the subject of wire gauge under consideration for a long time—it must be two or three years. There has been more or less interest taken in it by the members of the committee, and efforts to arrive at a determination as to what is proper and expedient. I was very much interested, as being a member of another committee, in the report made by Mr. Garratt, and I think that we should appreciate the care, the precision and the assiduity with which that committee has carried on its work. But at the same time I feel that I must emphasize a point which he himself has alluded to. I am brought to this consideration by remembering that while a gauge may be particularly suited to the requirements of one individual or set of individuals, yet it is of the utmost importance that a gauge in order to become universal, should have the elements of usefulness to all parties who are using gauges. I notice that between the size corresponding to No. 38 of Brown and Sharpe gauge and No. 32, he has only one number; there is only a difference of a tenth of a millimeter. Now, those who are in the telegraph business and the telephone business and many other cognate industries would see at once a very grave objection. It is true, as Mr. Garratt proposes, that we may have several sizes—smaller sizes in tenths of a tenth of a millimeter; but if we begin to introduce the sub-division of the scale it seems to me that we might just as well have no scale at all and revert to the principal of determining the diameter by the thickness in the first place, irrespective of any number or of any gauge for that matter. As you all know, it is a common practice in this country and there seems to be a large preponderance of sentiment in favor of determining the size of wire by thousandths of an inch. The difference in the use of systems of measurement is one which has full weight, of course. At the same time we must not forget that in this country we are, so to speak, married to the old system of the inch, and that there is only a very small proportion of the people who really understand the metric system or could use it intelligently; and therefore it looks to me, that while the system is very well adapted indeed to the requirements of the electric light industry insomuch as it affords a long range of sizes differing from each other by very much smaller differences than the gauges at present in use, yet, as we get to the small end of the scale it is as far deficient as it is redundant at the large end.

After due consideration of all these points, the wire gauge committee of the electrical engineers, which include a celebrated engineer, an officer of the United States army, in the engineering corps, a trained mathematician, has come to the conclusion that no gauge in which the sizes are defined by equal increments of diameter can ever hope to meet the requirements of the general body of electrical industry, and if we look into the matter closely, we shall find that the gauges at present in use have after all a great deal of convenience, and that a rational gauge based on the principle now imperfectly carried out in existing gauges would at least be entitled to some consideration before voting to adopt definitely and inflict upon the community another gauge of any kind. I say inflict, not because I wish to disparage the very able work that has been done by our committee, but because to add another official gauge to the number already existing would be to increase the perplexity with which we are now so greatly troubled in trying to make calculations regarding wire.

The basis, I think, of a proper gauge would be an asymptotic one—a gauge in which the sizes of wire vary with the resistance or the sectional area as a function, as a variable quantity, so that the ratio would be represented by a curve which is hyperbolic, somewhat like the curve of the present Brown and Sharpe gauge. In that case, as it will readily appear, it would be possible to represent all the numbers of gauges by formulæ.

Mr. Garratt—Will the gentleman kindly give an example in gauge calculation which an unintelligent man could make on the Brown and Sharpe gauge or the Birmingham gauge, which he could not make by measuring wire by the diameters in tenths of a millimeter? He made the statement that the metrical system was unfamiliar to the general run of people, and therefore they could not use it with the facility with which they could use the Brown and Sharpe gauge. Will he kindly give me such an example, or will he state one off the board himself.

Mr. Mailloux—I think that in practice the men that Mr. Garratt refers to, the linemen, would not go to the trouble of multiplying, because a great many of them could not multiply two quantities of two figures each.

Mr. Garratt—I will say in regard to an asymptotic gauge that I corresponded as far as I could with every maker and user of wire in this country and abroad, and I found just one gentleman who advocated it, and he was a distinguished mathematician in the United States army—Captain Michaelis, of Troy. I corresponded with him on the subject and we could not come to any very good understanding. The asymptotic curve is the property of a tangent to a parabola at infinite distance. I did not find any other man in the United States—I have now found another—who advocates such a gauge.

Mr. Mailloux—I think the question bears more on what people have been doing and on what we can make them do. I have no doubt it is easy enough to make a far more scientific gauge than people could use. We have the experience of this country in the slowness with which it has adopted the metric system. I prefer the metric system to all others and use it a great deal. I believe that in chemical work it is the only system by which satisfactory work can be done. But at the same time I note that it is not going into use with very great rapidity. I note on the other hand that it is being adopted in this country with great slowness, and I doubt if the present generation will ever see the metric system in use in this country. What I have reference to is that as people are accustomed to gauging thickness by a certain method we must not give them something which is so radically different that we shall make people object to it

Mr. Garratt—I did not understand that the work of this committee was to consider the peculiarity of men's minds. I was instructed six months ago that the reports of the last committee

Digitized by Google

was accepted. That report embodied the proposal that we lay aside the British standard gauge and accept the metric measuring of wire. The work of this last six months has simply been to put that into a suitable mathematical shape. I understand that that is the report of this committee. I am not reporting on what I think people will do. I am reporting on the mathematical properties of the system of measuring which was adopted six months ago. As I say, the United States government has adopted the metric system. As a professional chemist I agree with Mr. Mailloux in his statement that it is the only system for use in chemistry. If he had calculated as much in connection with wire as I have he would realize the extreme facility of making such calculations. The unit of a hundredth of a millimeter seems peculiarly adapted to fine instruments of precision. The ten thousandth of an inch is too fine, but the hundredth of a millimeter seems to be just about the limit of ordinarily fine measuring apparatus like the micrometer screw, which all electricians use in their calculations.

Dr. Moses—I feel a certain diffidence in speaking on this subject from the fact that my name appears on that committee as a member of it. I would say that though I am a member all of the credit of the work is due in varying proportions to the other members on the committee. The honor of being put there was one that I appreciated, and when called upon to do my share of the work I was unfortunately sick, and since then I have been abroad and have not been able in the last few weeks to participate in the labors of the committee. I feel, too, as if I ought to give the meed of praise to my co-members on that committee for the very comprehensive and laborious work that they have accomplished. I also feel as if I should say in view of the probable adoption of the report, that the metric system is one so well known and so generally used at present that there is no necessity for us to advocate it as a standard. The government has done so already. Other governments, even the German government, opposed as they are to the French, have in a certain disguise adopted the metric system; they were forced to do it; so that we must for the present not consider the advisability of adopting the metric system, because it forces itself upon us, and if we acknowledge it we simply acknowledge the inevitable. But there is some weight in a remark made by Mr. Mailloux that I would like to call attention to, and Mr. Garratt sounded the key-note for it when he said it was impossible to consider any standard of conductivity because it was something that varied with all of the commercial makers of wire. It is a very important thing that there should be some standard always, but where you have the essential standard always varying it is very difficult to fix it. But we have in the use of the units themselves the adoption of the metric system. We are employing them constantly for all the varying moods and tenses of the current, and why may we not adapt them to the uses of the consumers of wire since, ultimately, what is to be determined is the resistance of the wire—since it is the resistance of the wire, entirely independent of the material, that has to be calculated by the electrician, it is of the utmost importance that we should be able to calculate the resistance rapidly. Now the resistance varies in any two specimens of wire. I take a wire; it measures such and such resistance; I twist it accidentally—it measures a different resistance. So we have to take something as we find it and determine what we have or what we want. Now I do not like to speak always in prophetic mood; but I think the day is not far distant when we shall have measures of resistance that will be as portable as a Brown and Sharpe wire gauge. I think that we will be able to take an ordinary lineman and give him this instrument and let him say such and such is the resistance measured on a dial, if you please, of such and such a length, measured for him and in the nature of the instrument itself constant and independent of his erroneous observations. He takes a certain resistance of a certain unit, and if he can multiply—and he has probably been taught how to multiply, though he has not a very extended mathematical knowledge—he can multiply that, and let the unit be an inch a yard a metre—anything you please, he simply multiplies it by the number of units that he wishes to multiply by, and he has his result accurately given. Now I do not say that that machine is invented, but I say that it is possible to invent such a machine and to make it most exact and very portable. Now it is immaterial to me whether my wire is iron or gold, or silver, or whether it has a conductivity of A, B, C or D, as long as I get the greatest amount of conductivity for the least amount of resistance reciprocally for a given weight in hard cash. That is all I want to determine. When once that is determined, why, I give my order to Tom, Dick or Harry, and the man who gives me the most conductivity for the least money gets my order. It is quite immaterial to me whether it is No. 38 or No. 32. The question is—What is the resistance and what is the cost? Now those things will settle themselves the instant we have a little piece of apparatus by which we can take a unit of length and determine its resistance, and let that be done by the most uneducated person.

Mr. Mason—If I understand Mr. Garratt rightly, he states that one matter was decided at the last annual meeting of the association—namely, that the association adopt this system.

Mr. Garratt, accepted it.

Mr. Mason accepted this system—I would like to ask the chair to inform us where it leaves us now. As I understood from Mr. Garratt the committee was continued to perform certain clerical work. If that is so, it is simply for us to determine whether or not they have done their work. If I understood him correctly, we are not called upon now to discuss the question of this or that gauge, but of the quality of this work and whether we will accept these tables.

The President—(Reading from the minutes of the last convention). "Mr. Powers, of Troy, made a motion that the matter should be left in the hands of the committee for a further term, and that the committee be increased to five, with instructions to report further at the next semi-annual convention, and that in the meantime the report of the committee be accepted (the report was accepted and placed on file), and such suggestions as they made be carried out in regard to printing copies, so as to enable the members of this association to familiarize themselves with the new gauge in case it should be adopted at the next meeting." Now, is the case thoroughly understood? The fact is, the matter was referred back to the committee, and it has come up in the shape of a report.

Mr. Lynch—I would like to suggest that Mr. Garratt add to his already very excellent report a column showing the safe current carrying capacity of the wires at different temperatures. It would be a feature for our country members that would be very acceptable to them.

Mr. Garratt—I would simply say it is necessary to multiply the figures in the table of areas by a sinple constant. I believe that Sir William Thomson found that in the British navy the safe limit should be one-and-a-half amperes to the millimeter in section.

Mr. Steuart—I have heard what has been said for and against the report of this committee, and I would add my voice to what Dr. Moses and others have stated in commendation of the admirable work done by the committee. They have gone into the subject most laboriously and intelligently, and I think the least we can do under the circumstances is to adopt the report of the committee. They were appointed a year ago; they have gone through the subject as thoroughly and laboriously as possible; they have given us the benefit of the work done, and they have produced it here in a most intelligent and thorough way, and I would, therefore, move that the report of the committee be adopted.

Mr. Lynch—I second the motion.

Mr. Phelps—I would like to ask what the significance would be of adopting the report. Will the association be committed to promulgate this as a wire gauge and recommend its adoption as a wire gauge or not? Much has been said, but too much can not be said, of the value of this work. Mr. Garratt and his co-adjutors have completed their——

The President—I will answer that question of yours first. If this report be adopted, then this association pledges itself, and its members pledge themselves, or each one pledges himself individually, to carry out the law laid down by this report. You may call it whatever you please; but this committee reports a method for measuring wire which we will adopt if we adopt the report.

Mr. Phelps—The key to what I was going to say was furnished by Mr. Garratt in his remarks a little while ago when he said, "There is no gauge." It is an infinitely useful compilation. A useful system is here provided for ordering wires by diameter, and a great step, in my judgment, is taken and gained in using metric diameters instead of inch diameters. But I should hesitate to assist in promulgating a wire gauge I think if we look the matter well over, in view of Mr. Garratt's remark that there is no gauge, unless you choose to call it so, but an almost infinitely useful aid to the manufacturer and orderer of wire, that if the association can promulgate this information in a way to make it useful to everybody having to make, buy or use wire, and by so doing put a peg in towards the further use of the metric system, that, it seems to me, will be a useful thing to do; but do not let us call it a new wire gauge. We have more wire gauges than we want. You see my idea, Mr. President? I would like to hear from Mr. Garratt.

Mr. Garratt—There is no wire gauge about it. If I understand the matter right, the electric arc light men will use a definite number of wire, perhaps; the incandescent men will use a certain other definite number; the men who make hairpins will use another number. They will have those sizes, and it doesn't make any difference whether you express them in tenths of a millimeter, in thousandths of an inch, or any other measure you see fit. All that I advocate is that we express the size of the wire we use in the metric system and not by an arbitrary number which means nothing.

Mr. Phelps—It is very gratifying to know that the practice of ordering wire by diameter has been constantly growing of late years. It has been found a sort of a necessity by people who require wire of any accuracy. Part of the work has already been

Digitized by Google

done. We are accustomed to ordering by diameter, but mostly use thousandths of an inch. This information will enable people to use a better unit of diameter, and that is the main function of it, and the information supplied here of the mathematical properties of wires, based upon their diameters in metric units, is something we have not had before, and should prove infinitely useful.

Mr. Garratt—If you introduce an asymptotic curve, you are introducing the question of high mathematics again, you are plunging us again into a new gauge, you are plunging us into something that is purely arbitrary. It will be a laborious thing for thousands of people in the United States. We measure ground by feet and rods; we measure length by thousand feet; why not express our wires in diameters and by the metric system.

The President—I suggest to the association that you make this the special order for a fixed hour on Thursday, and that will give the gentlemen an opportunity of studying the details and coming intelligently up to the work again.

Mr. Mason—I move that this matter be laid on the table and be the special order for the opening of Thursday's session.

The motion was carried.

The President—In the absence of Mr. Slattery, who was to have read a paper on electrical distribution by means of alternating currents, we will take up the partial report made by the committee on insulation and construction of plant.

Mr. Robertson—I would like just a word here in reference to that report as a member of that committee. I have read a rough draft of the partial report the committee has made, and not being able to endorse the report before it is presented to the convention, I would say that the committee as a whole have resigned from the work, and as I could not endorse what they said, I would not resign with them. Finding myself in a small minority, not even a fighting minority, I would ask you to accept my resignation.

The President—Gentlemen of the association, you have the verbal resignation of Mr. Robertson before you. He begs to tender his resignation as a member of the committee on proper insulation of wires and proper installation and construction of plant. The reason he gives for that is that he is unable to subscribe his name to the contents of this partial report. Therefore, he tenders his resignation. What will you do with the resignation?

A Member—I move that the resignation be accepted.

The president put the question, but no one voted.

The President—Gentlemen of the convention, you are here to perform whatever duty is assigned to you in the regular order of the work. No man need be ashamed to vote on anything. Every man should have an opinion of some sort, and he should be able to express that fearlessly. Again I put the question.

Mr. Garratt—We do not understand what Mr. Robertson resigns from.

The President—He offers his resignation from the committee on proper insulation of wires and proper installation and construction of plant.

Mr. DeCamp—Mr. Robertson is in a very awkward position. He is in so small a minority that he feels it would be presumptuous for him, I suppose, to make a report——

Mr. Robertson—No, sir; I would like to reply to Mr. DeCamp in that matter, and say that I received a rough draft of the partial report late on Monday, and therefore could only study through it hastily, and supposing they were going to make a report, until yesterday I was totally unprepared to make any report whatever. I beg that you will accept my resignation and let me out of the scrape.

The President—I think it is only fair that the resignation be accepted or rejected. Again I place the question before you.

The motion to accept Mr. Robertson's resignation was then carried.

The President—Before placing this paper in the hands of the secretary to be read, I beg to say that on a date which I am unable to find in the correspondence this committee, either all six or one of its members, perhaps more, wrote to me, asking that the National Electric Light Association furnish them with a fund of $1,000 to carry on their investigations, guaranteeing the cost of repair to any apparatus that might be damaged in the course of their investigations—apparatus which was to be supplied to them from the University of Pennsylvania—also, that an assistant be furnished at $3 a day. I laid that correspondence before the executive committee which met in Boston on June 9th. The committee found only one course open to them. The funds of this association are applied to its running expenses, with which you are all familiar. There was no such sum on hand to be turned over to the committee. Nothing more was heard from the committee until this paper, with quite a column of printed matter, was sent in on yesterday or the day before to the National Electric Light Association. Now, this paper is signed by Edwin J. Houston, chairman, William D. Marks, Carl Hering, and M. M. Garver, and is not signed by Mr. Robertson, and the reason he gave for his resignation, independently of this paper, was that he could not subscribe to the subject-matter contained in this report.

The report was then read by the secretary as follows:

REPORT OF THE COMMITTEE "ON PROPER INSULATION OF WIRES AND PROPER INSTALLATION AND CONSTRUCTION OF PLANTS."

The committee appointed by your honorable body hereby respectfully submit the following report:

The rapid growth of the electric lighting interests during the last decade, the large investments already made in such interests, together with the still greater growth that is probable in the near future, have strongly impressed your committee with the important nature of the work entrusted to them.

Your committee fully recognized the fact that any report to an association that represents the leading electric interests of the country, would naturally be expected to be of a thorough character; they therefore determined as far as lay in their power to spare no labor in the performance of their work.

The duties charged on the committee naturally divide themselves into two general classes, viz.:

First. The proper insulation of the wires or leading conductors.

Second. The proper installation and construction of the plant as far as relates to the insulation and protection of the machines, lamps, conductors and accessories, and to the safety of consumers, attendants and buildings

The first branch necessitates an exhaustive and carefully planned series of practical tests as to the insulation of the leading wires; the second, the preparation of a code of rules, based on actual experience for the general installation of the plant, both so far as concerns the insulation thereof, and for its protection, as well as that of the consumers, attendants and buildings; or, in other words, to provide for such an installation of the plant as will best insure the protection of life and property.

Referring to the first branch of its work, your committee appreciate the fact that a mere theoretical discussion of the subject would prove of but little value to an association composed of men practically engaged in electric lighting.

They are aware that considerable valuable data have already been accumulated concerning the high insulation required for telegraphic cables, especially submarine. They are also aware that laboratory tests have been made of ordinary electric wires. These data, however, either refer to conductors not included in the scope of your committee's investigations, or though referring to electric light conductors, have been made under conditions that would render them of but little practical value in this connection.

Your committee therefore planned to make a careful series of practical tests under conditions as nearly as possible similar to those to which the conductors are actually subjected in existing installations.

The committee determined to limit the investigations chiefly to the leads that are ordinarily used in arc and incandescent lighting, subjecting them during such tests, as nearly as possible, to the various disturbing or other conditions that are met with in actual practice. They hoped by these means not only to obtain data by which the relative commercial efficiency of the different wires in the market could be determined, but also possibly to lead to the determination of the best conditions to be observed in the manufacture of insulated wire, in order to insure the production of the most serviceable material.

Tests, such as those contemplated, and of necessity required by the character of the work, not only called for excessive labors on the part of the committee, but also for the use of specially designed apparatus. Although the committee had the use of the well equipped electrical laboratory of the University of Pennsylvania, kindly placed at their disposal by Prof. Marks, one of the committee, and the use of valuable apparatus belonging to other members of the committee, additional apparatus was required, which, if specially designed, must be purchased, or if of existing types, must be borrowed. Then, too, the services of an assistant were required to start and look after the fire for the steam engine, clean out the boiler, run circuits, and do such other work as the committee could not be expected to do.

In order to obtain for these tests currents similar to those used in actual practice, various dynamo-electric machines would necessarily have to be borrowed. In view of these facts, the committee deemed it but fair to request the association to guarantee a sum sufficient to meet actual expenditures; and, further, to assume responsibilities for apparatus loaned to the committee, feeling sure that the association could hardly expect the committee to assume such expense in carrying out work of the character intrusted to them. This request, the committee were informed by your representatives, could not be entertained. The committee are therefore forced to resign.

Desiring, however, to give to the association such incomplete parts of their work as represented the results of their labors up to this time, they beg leave to submit the following incomplete report:

1st. On the preliminary code proposed for the tests on insulation of the conductors, etc.

2d. On an incomplete draught of a preparatory code of rules and regulations for the installation of an electric plant intended

Digitized by Google

to serve as a basis of experiment by the committee, and to be sent in printed form to the various electric companies and insurance interests for comment and criticism, before finally being submitted to the association.

As regards the preliminary code of tests, however, your committee wish it to be distinctly understood that they recognize the fact that preliminary tests on such code would, in all probability, show the code to be impracticable in certain portions, or at least to need modifications or additions.

In the preparation of the following preliminary code the committee bore in mind that leads possessing the requisite durability and efficiency for electric work should possess as far as possible, the following requisites, viz. :

1st. High insulation.
2d. Impermeability to moisture.
3d. Incombustibility.

In this view we submit the following preliminary code for tests, subject to the changes, modifications or extensions already referred to.

PRELIMINARY CODE.

(1.) *Leakage Tests.* (*Arc Wires.*) A definite length of insulated arc light wire to be immersed all but the ends in water. The water is connected to one pole and the copper to the other pole of a machine giving 3,000 volts, which is assumed to be the highest electromotive force ever used in practice. The leakage from the copper through the insulation to be continuously measured by a suitable ampere meter, the measurements beginning immediately on the immersion of the wires, and the tests to be stopped when the leakage reaches a certain definite amount. The greater or less rapidity of increase of leakage may then be assumed to indicate the less or greater value of the insulation.

(*Incandescent Wires.*) Incandescent wires will be subjected to similar tests, differing only in the voltage to which the insulation is to be subjected which will be in the neighborhood of from 100 to 150 volts, since, as it is known, at a voltage of say 60 volts moisture does not seriously interfere with ordinary underwriters' wire, while a somewhat higher voltage will set fire to wood through underwriters' insulation.

(2.) *Absorption Tests.* Coils of wire of definite length are immersed in water, and their ability to resist penetration or absorption thereof, will be measured by the increase in weight after equal duration of immersion.

(3.) *Frost Tests.* The ability of the insulation to resist the disintegrating effects of frost, on the alternate freezing and melting of the absorbed moisture, will be tested by the similar effects produced by the alternate absorption and crystallization of a solution of some chemically inert salt, such as magnesium sulphate. After the wires have been subjected to the frost tests (3), the leakage tests (1), and the absorption tests (2) will be repeated.

(4.) *Flexibility of Insulation.* A definite length of wire will be wound around a small cylindrical rod, say one inch in diameter, after which the leakage and absorption tests (1) and (2) will again be repeated.

(5.) *Abrasion Tests.* A definite length of wire will be bent in the form of an inverted U, having a given radius of curvature, and will be hung over a wheel, such for instance as a gear wheel having polished teeth with rounded edges, and heavy weights will be attached to the two ends of the wire. The wheel will then be turned and the number of turns noted before electrical contact is made between the copper of the wire and the metal wheel.

(6.) *Adhesion of the Insulation.* A definite length of wire is bared of its insulation at one extremity, and the bared end passed through a closely-fitting hole in a die plate. A measured pull is then exerted on the bare end of the wire until a definite length of the insulation is stripped off the wire.

(7.) *Refractory Qualities of the Insulation.* The current will be passed through given specimens of the wire and increased in quantity until the insulation is destroyed and the nature of the destruction noted, whether in the form of flame, charring, etc., etc.

(8.) *Igniton Tests.* The ability of the insulation to resist ignition by some external source of heat similarly applied to all the wires, and the rapidity with which the flame, started at one point, travels along the wire, will be carefully noted.

Besides the foregoing tests as to the quality of the insulation, the committee also proposed testing the conductivity and flexibility of the copper, as follows, viz. :

(9.) *Conductivity Tests.* The conductivity of the copper will be measured, assuming the wire to have the diameter claimed by the makers.

(10.) *Flexibility Tests.* A given piece of wire will be bent repeatedly backwards and forwards around a templet, curved to a quadrant of say one inch radius, the number of bendings required to break it being noted. In order to procure wire of the same quality as that commercially sold in the open market, it was proposed to purchase the specimens tested in the open market direct from the makers.

The second duty charged on the committee was, as already stated, the preparation of a code of rules, based on actual experience, for the general installation of plants, both so far as concerns the insulation thereof, and for the protection of the plant, consumers, attendants and buildings. The importance of a code of rules of this character, relating as it does to the better protection of life and property, is generally recognized, both by electric lighting and insurance interests. It is to the true interests of the electric lighting companies to assure the public that not only can they through electricity furnish a steady, reliable and cheap illuminant, but that such illuminant if intelligently employed under certain well considered regulations, is as safe, indeed far safer, than any other artificial illuminant. While, therefore, electric lighting companies should not hesitate at the adoption of the most stringent regulations that experience has found necessary for the protection of either life or property, it is of course advisable that all arbitrary and meaningless regulations should be carefully considered before their adoption by the National Electric Light Association. It has, therefore, been the aim of your committee to obtain a code acceptable alike to electric lighting and insurance interests.

As preparatory to the framing of such a code of rules, the committee planned the following work, viz.:

1st. The preparation of a compilation of existing rules.

2d. Obtaining the opinions of the principal electric light and insurance companies, as to the practicability of existing rules, and requesting suggestions of such changes or additions, if any, their experience might suggest.

3d. Conducting a series of experiments so as to determine, as far as practicable, reliable data on which a code could be deduced affording the widest latitude to electric light and power companies consistent with absolute safety to life and property.

4th. From the above to deduce a code to be regarded as a preliminary code.

5th. To have printed copies of such preliminary code sent to all electric light and insurance companies for comment and criticism.

6th. To prepare, finally, a code to be submitted to the National Electric Light Association of America.

In carrying out this branch of its work, the committee has addressed letters to electric lighting and insurance interests, asking for copies of existing rules, etc. To a certain extent these letters have been answered and copies of existing rules and regulations (though by no means complete), have been received, and the committee had commenced a compilation of the same. In the desire of aiding the association, they hereby respectfully submit such incomplete collection and compilation.

Being forced to abandon their work by reason of the failure of the association to make the appropriation necessary to carry out the same, the committee hereby submit the above incomplete report, and respectfully offer their resignations as members of the committee, and request that they be relieved from any further work in the matter. Respectfully submitted,

EDWIN J. HOUSTON, *Chairman.*
WM. D. MARKS,
CARL HERING,
M. M. GARVER.

The President—No exhaustive tests were made by this committee at all. They had completed their work to a point where they required financial aid to carry it on. They applied to the association for that aid. The association was unable to give it, and the committee present this report and resign. It is put in plain and unmistakable language, so that you may know that if you want any further work done you will have to pay for it. The paper is open for discussion or for whatever disposition you choose to make of it.

Mr. Eustis—We have had some little experience in wire. A good many years ago, when I was with the Bell telephone company, I decided to test a wire there, and made out a report of the wire. It tested splendidly after soaking for about two weeks. I made out my report, but fortunately it was not handed in. I put the wire up on the shelf, and glancing at it, I saw that the insulation was cracked from one end to the other, showing that while the wire might test perfectly well while still wet, after it had dried out a trifle it was absolutely useless. For practical working that of course is a strong point—that a wire should last and not become oxydized and cracked. There is also the other question, which I think should be brought up here, and that is the question of mechanical injury to the covering—abrasion. We all know wires are strung where they are liable to swing against awnings, the fronts of houses, trees, and so forth. That I think is also a question which should be brought up here.

Mr. Mason—I suppose we must decide this question now, whether money shall be appropriated for such an object. I do not suppose, Mr. President, that another committee could be found who would undertake the work which this committee has declined to pursue, and undertake it at their own expense. It seems to me that we should bear the necessary expense of making tests, the results of which would be so valuable to the members of this association. I move that the resignations of this committee be accepted and that their partial report be also accepted, proposing to move later the appointment of a new com-

Digitized by Google

mittee and the appropriation of a suitable amount of money to enable them to carry out such plans as they shall deem wise for the determination of the end sought by the committee whose resignations are now offered.

The motion was seconded.

Mr. Leggett offered, as an amendment, a motion that the report, which is admittedly incomplete, and for which the committee would not probably want to make themselves responsible, or the convention desire to adopt, be laid on the table.

The motion was seconded and carried.

The President—The Boston Electric Club have extended an invitation to the members of this association to attend a banquet to be given on Wednesday night at Point of Pines, and they request that the members of the association call at room No. 14, to notify their acceptance of this invitation.

The convention adjourned until half-past two o'clock P.M.

AFTERNOON SESSION.

The President—The first business of the afternoon session is the report of the committee on electrical distribution by means of the alternating currents.

Mr. Slattery—I regret to have to announce the absence of our very able chairman who had to report upon this important subject, secondary generators. In his absence, that duty devolves upon me and I feel the onus of the obligation involved of doing justice to a subject which is fraught with a great many perplexities.

Mr. Slattery then read the report of the committee. (See page 344.)

The President—Gentlemen, Mr. Slattery's paper is now before you for discussion.

Mr. Slattery—If I might make a suggestion, sir, we have our old friend Mr. Duncan present, who is fully charged with alternating effects this afternoon, and we shall be very pleased to receive a shock from him.

Mr. Duncan—I am not very well charged to-day. It has been a very fatiguing day for me, The atmosphere of this room is not such as was represented by the Mayor of Boston. In regard to the alternating current system, I have simply to say that there is no question about the practical and efficient working of that system. There have been some things which required a practical demonstration to bring them out, and there are some things about the system yet which are not fully solved, but which are being rapidly evolved. There is no question about the covering of a given space and the distribution of a large number of lights much more economically than by a direct system. Now in regard to the difficulties suggested by Mr. Slattery, those are questions which are gradually working themselves out, as he stated in his excellent paper. One of the difficulties which was first encountered, as he says, was the induction box itself, but practical experience of four months in the use of that box has been such as to show that in every respect it is entirely efficient, entirely satisfactory, and that it can be relied upon, placed in any position, to do its work effectually and efficiently.

In regard to the dynamo, he has gone through that part of it. Some heat is naturally generated in any dynamo. I do not know that I can say that we get any more heat from the alternating current dynamo than we do from the regular arc light dynamo; I do not think we get much less; I know we do not get a great deal more. In the heating of the parts in the original machines that were made there was considerable difficulty. Insulation has been provided from time to time, and at the present time I know of machines which have run successfully for three months to which nothing has ever been done. Some of those machines will average in a week's run 24 hours per day, except Sunday, and they will be shut down on Sunday for about two hours.

Mr. Smith (Allegheny City Light Co.)—Mr. President, I would say that I have had some experience with the alternating system in the same company with which Mr. Duncan is connected, and also with another company in Philadelphia, where we started first with the direct system and changed it to the alternating. Some of the points on which Mr. Slattery has asked for information I may be able to give some light upon. We have found that where we are using the converter system its enormous flexibility enables us to apply almost any system of placing the converters. In one of our stations in Pittsburg where we rent lights in a poor neighborhood where the majority of places would take but three or four or five lamps, we found it cheaper to place the converters on the poles, using either 50 volt or 100 volt lamps, as we pleased. In other parts of the town, where we found buildings taking ten, fifteen or twenty lights, we found it better to take the high tension right into the building and place the converter in the cellar or the garret. In some cases, we have a mixture of the systems. For watchmen's lights we have both the secondary main outside and the converters directly in the building. In very large buildings we carried the high pressure through the building and tapped to our converters wherever convenient. In the case of hotels, we have a high pressure wire down to the centre of the corridor, and in the case of a large parlor being lighted, we would put a converter into that parlor. In the case of a row of bedrooms requiring twenty lights, we would put in a twenty light converter. Without the slightest trouble we change buildings having three or four hundred lights from one system to the other without cutting off the lights for a moment, by cutting up the existing wires as they exist in sections and tapping in the converters one after another as we needed them. Whenever we wished to change a section we would substitute our 50 volt lamps for 100 volt lamps. When we had all the lamps changed in a building we would splice up where we had cut. In a building having 300 lamps we only put in converter capacity for 200, knowing that no more than 200 lights would be burned at one time.

As regards the danger of shocks I have had a little experience on both sides. I have had a full share of the arc light shock. I opened circuit on 1,500 volts, which was sufficient for me. I have also taken a thousand volts alternating, and there is no comparison between the shocks at all. If I may be allowed to give my own experience, I should say that the Thomson-Houston machine gives about the most tremendous blow I have ever felt. It is a peculiar dead stroke which you do not find in the Brush machine. But the alternating machine seems to throw you off instantly; you do not have time to take hold. We had a case in Philadelphia the other day, which I think will be interesting to Mr. DeCamp, as I believe he feared it was one of his men. We had been changing a building from direct to alternating, and while the building was still on the direct current, one of our wire men went into the cellar and put an ordinary key socket on to the mains to give him light. After the building had been changed to the alternating system one of these wires which had been used originally, became a dead wire and the lamp having been taken out of the socket there was no current passing through the wire. One of our men went down stairs to make some changes and our foreman cautioned him particularly to look out for those alternating current wires, as one of them was grounded. Two of the men went down together and one of them forgetting that the thing had been changed to alternating went feeling around to get hold of this socket, and he found it and he laid down on the wet ground and the other man stumbled over him and spoke to him but received no answer and spoke to him again. He stooped and looked at him and finding that he was growing black in the face ran off to call for help. He ran down to the station and while there learned that the foreman had gone to another building and he ran after him. By the time he found him and got back the foreman told him that the moment he heard something was wrong there he knew what it was. He ran down to the cellar and found this man lying on his back perfectly still and blue in the face. He stooped down and shook him and got a terrific shock himself. He saw that he still had hold of the socket, and using his coat so that he would not get the shock himself, pulled the wire out of the man's hand and then they picked him up. He had been then on the current, as near as we could estimate, four minutes, taking the full benefit of a thousand volt current. The men did not know what to do, but fortunately treated him for asphyxia. The man was blue in the face. They cut his clothes open and dashed water on him and tried artificial respiration, and in the meantime sent for an ambulance. By the time the ambulance got there, he was sitting up and refused to get into the ambulance and seemed to be very much disgusted that an old arc light man like himself should be keeled over in that way by an alternating current. The next day he expressed himself as perfectly well and ready to go to work. We had some difficulty in getting him to go and see the doctor, but we insisted on it. We were more afraid of the nervous shock than anything else. The man told us that for two minutes at least, of the time he was on the wire he was perfectly conscious, that he knew his companion was there and he tried to tell him to pull the wire away, but he could not speak, and that when the man went away he knew perfectly well he had gone for assistance and then realized that it would be three or four minutes before he got back, and he thought to himself that he could not stand it that length of time, and then he forgot everything. He said that he felt no particular pain. He got a shock that he would get from any electric current, when he first laid hold of the socket, but after that he felt nothing. The sensation seemed to be like that of drowning. As soon as we got him to gasp and breathe, his color came back again. This incident has given me quite a new hold on the alternating current system—to know that you can take 1,000 volts of it and stay on it that length of time. I know I should be very sorry to take a direct current, one quarter of that time.

As to the question of heating up machines, the newer machines, such as we are using now, I may say that we run them for a week, starting on Sunday afternoon and running until Sunday morning. A machine runs from nothing—an amount which you cannot read—to 35 or 40 amperes, and in all that time, it never gets so hot that you cannot bear your hand upon it with comfort. As to the larger size machines that we are using in Pittsburg—we have one there that has been running

Digitized by Google

two months—a 1,300 light machine—running 22¾ hours a day; we only stop for ten minutes and if the engineer does not feel like it, he doesn't stop then. The load on that varies from nothing up to 65 or 70 amperes. You can always bear your hand on the machine, and as long as you can bear your hand on it it is certainly not hot enough to injure any good insulation. The converters we know absolutely nothing about. We put them in and that is the end of it. I think we had to take two out on account of the blowing out of the plugs. The secondaries were short circuited, the effect of which is generally to blow out the primary plug. It does not injure the converter as far as we have been able to find. We have never had a case of a converter short circuiting either in the primary or the secondary. We have occasionally had a converter terribly overloaded, when it will heat up and finally blow the plugs through another converter which is tapped in on the secondary wire. It is hard to get linemen to understand that where two converters are coupled together and one of them gets hot it is usually the other converter that is at fault. I am a little of an enthusiast on the subject of alternating currents, as in Pittsburg we are using the direct system multiple arc and we have been struggling with 0000 wire, pulling our poles out of line, and the direct current machine burning armatures. In Pittsburg we put them to very severe duty, owing to the suddenness with which storms come up there. I have known a current in our station to jump from 300 to 2,000 lamps inside of fifteen minutes. Taking the two systems into account, the ease of distribution and the ease of handling, I say that the alternating system is bound to come, if for nothing else for the enormous reduction it makes in the cost of running your station.

Dr. Moses—I am very well pleased to hear some of the details Mr. Smith has mentioned. I feel myself a little responsible for the success of that system, inasmuch as I formerly *thought* it would succeed, and now I *want* it to succeed. The alternating current machine which I saw at Pittsburg was running very well and had only been running for one month when I made that report to the last convention, six months ago—as my neighbor facetiously remarks, that very extraordinary report. However, I have just returned from abroad and thought that before coming here I could not spend two days necessary to get over the *mal de mer* better than in going to Pittsburg and seeing how that machine was running. I am very happy to say that the same machine is running in that station in South Pittsburg that Mr. Smith speaks of, with this additional fact, that they have doubled up all around in their capacity—not doubling, however, that solitary man that Mr. Weeks saw there when he meandered through Pittsburg and looked at the alternating current system. The same man was there. They had doubled up the capacity, but that same one man was running it, and I did not see that he had any more work to do then he had before. They were running 3,000 lights where before they had been running 1,500. While wandering through Pittsburg and seeing thousands and tens of thousands of incandescent lights which they have about in all directions, I noted the progress that had been made by the principal company there engaged in the alternating current system, and I saw one thing there that I would like to call to the attention of this convention as being one of the most important things in connection with the development of alternating electric lighting that I have yet seen or heard of. When I went there six months ago they were making machines of 500 to 1,000 lights. The other day when I went up there, I saw a 2,500 light machine running and doing its work admirably well.

Mr. Kimball—In regard to the alternating system of supplying incandescent lights, since the last convention in Philadelphia, there has been a marked advance, and from the various installations which are at present in operation, we have been able to get data which are not only interesting, but useful, and the question of insulation of the high potential wires is one which appeals to every one in every part of electric lighting stations, whether in the lineman or the central station manager. In one case it is life and limb; in the other it is property.

The question of the insulation between the primary and the secondary of the induction coil is one which is governed by a variety of causes. Where converters are placed out of doors, moisture will get in and grounds will develop on the high tension wires, no matter how carefully the poles may be wired, or, possibly, we may have ground wires, and this bold expedient of grounding the inside wiring by heavy metallic lines to the ground has been brought to the attention of this convention before and has been published in some of the electrical papers, and it seems to me that opens a field for discussion. The fact must be appreciated that each system of incandescent wiring from a converter inside a building is entirely separate and completely isolated from every other piece of wiring in the city or town, and that running a metallic ground from one wire to the earth is not to be compared with grounding a positive wire by distribution from 75 or 100 volts, and in such cases should danger develop, being only on one wire, the lead fuse can give way to an excess of current on either positive or negative that in any way affected the other installation, and in such way give warning of danger whether in the converter or in defective wiring.

Mr. DeCamp—In the report read by Mr. Slattery, he speaks very positively about the difficulty of insulating for this current. On the other hand he notes that the effect of the current upon a person – and he is corroborated in this by Mr. Smith—is not as great as it is on the direct current. That struck me as being a little inconsistent. The electromotive force, as I understand it, is a very strong element to guard against in making installations. It is what affects the human body. I would like to have an explanation of that.

There is another thing I would like to know. The peculiarity of this current is such that the close proximity of conductors to each other is going to affect the currents or going to affect the insulation, making it more or less difficult to insulate. As an explanation of why I want to know that, I would say that we are about to run an alternating circuit underground in the city of Philadelphia through an iron conduit. Those are things we have got to contend with. Now, shall we make that conductor of an insulation that requires a second metallic covering such as lead? Do we lessen or do we increase our difficulties by so doing?

Mr. Slattery—Upon that point I would beg to refer to Messrs. Westinghouse, who are in that line, and who can give us some valuable information with regard to these special methods of insulation, and I defer to them as having a far greater experience in that direction than I have.

Mr. Smith (Allegheny County Light Co.)—I would state that I am not in any way a representative of the Westinghouse people, though using their apparatus, but being in the same city as the manufacturer I have had exceptionally good opportunities for observing their work. In Philadelphia we are using lead and copper cables. We use that because it seemed to us in underground work that the first thing we had to look out for was moisture. We satisfied ourselves that we ought to get a good metallic covering. Our conduit in Philadelphia is made of a common pine box, in which the cable is laid, and the box is filled with pitch. In that we have iron boxes for connecting our feeder into our mains. The outside covering of the cable is not insulated in any way from the junction box. In some parts of the street where we found it difficult, owing to water pipes, the cable car conduits, and so on, to lay a wooden box, we used iron pipe through which we pulled these cables and then filled them up with pitch, We filled them up with pitch simply as a mechanical protection. We have not had the slightest trouble, or loss of current, or induction, or anything else. Our men handle the outer covering of this cable with perfect impunity, and as long as your dielectric is in good shape it seems to me you have something that is perfectly safe. I understand that some experiments have been made by the Westinghouse company with regard to this very question, and when I put to them the question their answer was that we could use any kind of cable we wanted to as long as the covering was good, but for practical use they would recommend us in this particular instance a lead covered cable having both conductors in the one light covering; that is to say, two separate cables soldered together through their whole length. And that is the form of cable I have been advocating myself for mechanical reasons. They made the test for us. They tested it thoroughly in every way and told me I would get perfect satisfaction out of it. When we turned the alternating current into our Philadelphia lead covered cable, where the cables are run in separate boxes but grounded througout their whole length, the question was raised whether static charges would not come into effect and our men get shocks. But we did not find that there was any effect whatever. As I say, I have had no experience with long conduits of iron; but it seems to me that if you run your wires close together that any effect you get on one wire would be neutralized by the other.

As to the inconsistency of the statements that very high insulation is necessary for alternating currents and that they are at the same time less dangerous to life than direct currents, I have only practical experience. In an ordinary arc light machine you have an immense mass of iron in the field magnets, and when you open the circuit you discharge the field magnets into the line. That is the reason I think that the Thomson-Houston machine gives a so much heavier blow than another. I have taken these discharges from the field magnets from an ordinary incandescent machine. It is a dead blow and there is a large quantity of electricity discharged at once, but in the armature of the ordinary alternating machine there is so little electricity in it that not much harm is done We never think of shutting down the machine for the linemen to splice up. They climb up the poles and make the connections on live wires. We have had no case of a man being hurt with it at all. We had one of our men short circuit a thousand volts on our switch-board with his plyers. It scared him somewhat and burned the plyers, but it did not damage either the machine or the man.

Mr. Slattery—I would say that I think the object of this report has been creditably obtained through the very valuable information elicited from representatives of the companies that

Digitized by Google

take a large interest and care in the introduction of this induction system throughout the country. The candid spirit in which the information is given is extremely gratifying. It is almost magnanimous in the manner in which it is given, and I cannot express my appreciation of it in too strong terms.

Mr. Kinsman—I would like to mention that I have succeeded perfectly in burning an arc light with a 50 volt converter from the alternating system of the Westinghouse company. We get twelve hours from two carbons and a light that is perfectly steady.

Mr. Smith—I would like to ask Mr. Kinsman what is the style of the arc lamp.

Mr. Kinsman—It was the Simplex lamp, 2,000 candle, 55 volts.

The next paper was on the subject of "Electrical Education," and was read by the author, Mr. E. R. Weeks, of Kansas City, as follows:

ELECTRICAL EDUCATION.

Few questions of the day are so important as the applications of electricity, and there is none upon which exists such a lack of general information

The telegraph business is so extensive that people think no more of sending a telegram than of posting a letter; we are beginning to depend upon the telephone as an every-day necessity; the electric railway has demonstrated its financial basis; and the electric light, though a creation of yesterday, is so largely used that about $200,000,000 are invested in its manufacture in America alone. In fact, so many are the practical every-day uses to which electricity is put, that we have not time to enumerate them. Yet the public has more knowledge of almost any other instrument of its convenience than of this one force that first inspired the fear and curiosity of man. Not only is the general public almost wholly ignorant of the principles, uses and modes of application of electricity, but there has been such a scarcity of those who have made a special study of these new branches of industry, that it has been well nigh impossible to secure the intelligent service that many of them require. A man of average education may easily gain the mechanical dexterity, the sensitive hearing, and the rapidity of thought necessary for telegraph and telephone service; but some applications of electricity require thorough, special training for efficient work, and we cannot hope for satisfactory service in the direction of traction and lighting till this training is furnished.

Electrical engineering is undoubtedly the occupation of the future for the young man who does not care to enter the already over-crowded professions, but whose education fits him for a broader field than that of the trades. It holds out the highest inducements financially, and it is a service in which the intellect can never rust out, as it offers a continually widening horizon of thought; indeed, the possibilities of this profession are as yet practically unlimited. In most fields of labor the best has been accomplished; here the work is in its infancy, and the demand is not only for skilled hands, but for trained and progressive minds. The property involved in the applications of electricity is already immense, and is rapidly increasing; much of the machinery used is most delicate—no unskilled hands should destroy its value or make it render less than its best service. "Electricians" to whom Ohm's law is "Greek," and "experts" who "adjust," but never *clean*, should not be allowed to multiply.

But how can the special education which shall produce true experts and electrical engineers be obtained? Several colleges have given this department some consideration, but not so much as it deserves. Its training should be both theoretical and practical. A thorough understanding of the theory of electricity is absolutely necessary to enable one to keep pace with the rapid progress in this branch of applied science; and without an intimate knowledge of the apparatus used, commercial success is impossible. Colleges and universities should have well equipped laboratories, and should add to their curricula complete courses in electrical engineering, laid out after consultation with those few eminent electricians who have had experience in the class room, the laboratory, the factory, the station, and who know better than any school recluse what theoretical training is of value.

To receive the greatest benefit from such special course, it would be well for the young man, after completing a thorough basic high school course, to spend some months in an electrical station doing the practical, every-day work there required, and thus gaining a more nearly adequate idea of the information he will need to give him skilled control of the forces with which he is to deal. With this preparation, he will be enabled to take hold of the theoretical work with a zest that can come only from an understanding of what it is to do for him and what he is to do for himself. Having finished his college course, he is not yet to consider himself a graduated expert; but some time spent as a learner in factories and stations should be a regular part of his electrical education.

After fully carrying out such a plan, the young man will be in possession of a theoretical and practical knowledge of the work he has chosen, that will give him access to the most desirable of positions.

The more complicated electrical industries are of such recent date, and their growth has been so rapid, that school-trained workmen could not be obtained. Schools had not time to adapt themselves to the new order of things. Only unskilled labor could be employed, and only such can be had for some time to come. Much of this work has been performed by uneducated men, many of whom have shown that good results may be accomplished without school training or higher mathematics. Thoughtful observation and practical experience have done well for them, but always at the expense of costly mistakes and delays, and at best such labor is limited in its possibilities. Only the trained mind can attain the highest places.

But something should be done to assist the vast army of halting hands that in the near future—nay, in the very present—must do the work, while the schools are preparing for this new field of labor. Ours is not an industry with long years of experience to draw upon, yet it is one in which the unexpected, the unprovided for, is constantly occurring. Therefore, interchange and comparison of thought and experience are more necessary here than in other industries of greater age or slower growth. Had this been fully realized in the earlier history of electricity, much of the bungling work of the past might have been avoided; for there can be no doubt that the progress in intelligent service has been greatly retarded by the narrow policy which refused to impart information to the "new man," but which is giving way before the broader influence of our associations. Members of the electrical fraternity are beginning to recognize the truths that knowledge given away is the more securely possessed; and that, as all know more than one, all may be benefited by an interchange of ideas, and employers are awakening to the fact that they must also be educators.

The National Electric Light Association is doing much, and should do more, not only for the mutual advancement of its members, but to bring the business which it represents before the public in an intelligent way, not at all as an advertisement, but because it is safer, pleasanter and more profitable to serve a people well informed upon our work than one whose fears are multiplied through ignorance. The Edison Association and the Institute of Electrical Engineers are also exerting an influence in an educational way, and the clubs that are springing up in all electrical centres, cannot fail to accomplish a good work in the same direction.

But such organizations, however valuable they may be, can effect but indirectly the large body of men who handle machines and lamps, run lines or serve in any of the branches of a business that needs intelligence even in its firemen. Yet these are the men upon whom the success of the new industry must largely depend.

As intelligent service is the most profitable, employers can afford to spare no expense to obtain it. Every station should possess a pleasant reading room, well stocked with papers, magazines and standard books on electrical and kindred subjects, and employés should be made to feel it part of their daily duty to inform themselves upon all matters connected with their work. From time to time they should be questioned upon important points; and if they cannot be led to do the necessary reading in any other way, they might have monthly grades and ranks determined by the information they have gained from their work in the reading room. All large stations should have mutual improvement societies of the men, furthered and assisted in a personal way by employers, in which the problems of daily work may be discussed, and directions given for useful and telling study by employés who do not well know how to help themselves.

Municipalities should appoint boards of examiners, whose duty it should be to inquire into the competency of electrical employés, especially those of light and power companies, as ignorance and poor workmanship here endanger both life and property. Line and station foremen should be licensed, as their duties are fully as responsible as are those of stationary engineers.

By such legal measures, faulty construction will be prevented, and cities will secure safe and efficient service for the public; they will further the interests of workingmen; will protect electrcal investments, and assist in the education of the people.

Mr. Smith (Jamestown, N. Y.)—I would like to ask if Mr. Weeks could recommend to the convention any practical text books which could be put in the hands of linemen for use in their every day duties.

Mr. Weeks—Yes, sir, I think there are a number of books which are sufficiently popular in their style to be of great use to employés. We have a society of our employés in Kansas City on the plan that I have pointed out here, and we have made it a complete success. I think that if Mr. Smith will get a list of electrical works from any one of the electrical papers, that he will be able to select from 30 to 40 books, sufficiently simple and elementary to form a nucleus for a library of this kind.

Mr. Garratt—I would say in that connection that I found a little work by Sylvanus Thompson, known as "Elementary Lessons in Magnetism and Electricity." It is a very valuable little work, and an inexpensive one, and contains enough material to keep the average workman busy for a long time.

Digitized by Google

Mr. Mason—There is handed me, sir, the following resolution which I have been requested to read. I will read the resolution and append another:

Resolved, That the work that was assigned to the committee on insulation and installation is of such importance that this convention cannot allow the subject to escape their earnest attention.

I add this resolution, sir:

Resolved, That a committee of five on insulation and installation be appointed to report at the next meeting, and that Dr. Otto Moses be the chairman of this committee.

The first resolution was then adopted.

Dr. Moses—That is a very high compliment paid by Mr. Mason, but I must beg to decline.

Mr. Mason—Does Dr. Moses refuse to serve on such a committee?

Dr. Moses—I do not refuse to serve but I refuse to be the standard bearer when others are more competent than myself.

The motion to appoint a committee of five was then carried.

The President—I will appoint the committee, and I will endeavor to induce Dr. Moses to serve on the committee, if not as chairman, as one of its members.

With Col. Leggett's consent I will place him on the committee on revision of the by-laws. There are two points which he made this morning, and which I concede to be of the greatest importance—first, that the convention should decide where the next meeting of the association should be held; next that they should elect for president of the association some one in the locality selected for the meeting, believing that rotation in office is a good thing. I have passed the time when I am seeking particularly after glory, and would be very glad to resign the glory and labor to some more competent hands. In making up these by-laws I think it would be well to consider that part of the proposition. The business of the association can be better handled if the president of the association is chosen from the location in which you intend to hold your next meeting. I assume, Col. Leggett, that you will serve on that committee.

Mr. Leggett—I think inasmuch as I was cut off in my remarks this morning, that it would be fair for me to say that as far as I am aware, there could have been no better service rendered to our association than has been rendered by our present officers, and especially our present chairman; but it seems to me that it is a matter of considerable importance that the offices should be rotated, for the special reason which has just been mentioned by the chairman. The meeting in a certain locality ought to carry with it as nearly as practicable the election for that year of officers of the association residing in the same immediate vicinity, and then again we might at some period be burdened with certain officers whom we do not like, and through sentimentality be burdened in a manner which we might not care to relieve ourselves of; while I am very happy to say—and I know I reflect the sentiments of every member of our society—that the present officers have served us with great ability, yet I think that we should change the constitutional ground work of the association, so that no difficulty or embarrassment may arise hereafter in the organization of our society or in its meetings. It was my purpose in speaking this morning to suggest that it be made an element of our by-laws, that the tenure of office of the president and vice-president be limited to a single term—that nobody be eligible to those offices for two successive terms. I think it ought not to apply to the secretary and treasurer, because their duties are of such a character that they may properly, with great benefit, be retained in the same hands for a considerable period. I want to add that this same matter was talked over by our present chairman and myself prior to the meeting in Detroit, and it was his own suggestion and desire that the convention should take the course now proposed.

The President—A thorough discussion of this question took place between Mr. Leggett and myself, and I believe that it is better that the officers of the association should be subjected to some system of rotation. There is an honor connected with the holding of the office of president at least, and we all should be eager to fill that office. I have served my time over and over again, and I would be very glad to hand the gavel to some one else next year. I hope some gentleman will suggest a committee on nominations and place of meeting.

On motion duly carried, a nominating committee was appointed, the president naming Mr. Mailloux, Mr. Leggett, Mr. Robertson, Dr. Moses and Mr. DeCamp.

The convention adjourned until 10 A. M. Wednesday.

SECOND DAY'S PROCEEDINGS.

The convention was called to order at 10.30 A. M. Wednesday, August 10th, by Mr. Ralph W. Pope.

Mr. Pope—I have been requested to call the meeting to order in the absence of the vice-president, and it will be proper for you to nominate a temporary chairman to conduct the business of the meeting.

Mr. Frank Ridlon was chosen, and took his seat as temporary chairman.

Lieut. Murdock, U. S. N., read a paper on "Electric Lighting for the New Cruisers." (See page 346.)

Lieut. Murdock—One or two things occurred to me while reading the paper. Things which are necessary in marine installations are measuring instruments, both ammeters and voltmeters, which are independent of both gravity and magnetism. We want some kind of an instrument that would be independent of the earth's magnetism and would not be affected by the local magnetism of the ship. Another thing which is necessary is the independence of the needle from the effect of the rolling of the ship. This has been already met by Sir William Thomson in his marine galvanometer, and I think in some recent instruments which I have not yet seen. The simplest way, apparently, is to suspend the magnet or needle, or coil, by a suspension which passes through its centre of gravity. If this is accurately done, of course the force of gravity has no moment to act upon, and the rolling of the ship does not affect the needle at all.

I was requested to present these facts to the consideration of the convention, and I have to express my thanks for the courtesy extended in affording me the opportunity to do so.

Dr. Moses—I listened with great pleasure to that very interesting paper, and as there are some points in it which are of very great interest to a large class of our nomadic population, I would like to ask some questions of Lieutenant Murdock in regard to some statistics which he has omitted. Would he kindly let us know whether he has gathered any information as to the methods of laying wires on board ships; that is, are grounds used? Is the hull of the ship used as one of the conductors, or is there a tendency to have the circuits entirely independent of the ship itself?

Lieut. Murdock—In England, I know, they use what they call the ship return, or, as they prefer to put it, the one wire system, but I do not think anything of the kind has been used in this country, and I should think it highly objectionable. All the installations are required to be protected by the highest attainable insulation—a double circuit, and every part insulated. The system of earth connections has been used for quite a long while in torpedo service. Much of the torpedo apparatus in the navy has until within the last few years been arranged to work with the earth, but premature explosions have taken place, and that has been discarded. To-day, as far as I know, all plants are installed with two wires and high insulation.

Mr. Kinsman—I would like to ask the gentleman if he knows anything about the experience of the steamship Alaska. They were at one time giving the one wire system a test.

Lieut. Murdock—No, sir. I know they are using the one wire system on Mr. Vanderbilt's yacht, the Alva.

Dr. Moses—I was crossing in the steamer Bourgogne of the Compagnie Transatlantique, and we had made a very rapid passage, and everything was very lovely when about four hours from Havre people began to be disturbed because the previous ship, the Champagne, had been run on the rocks at about that distance from Havre. We were talking of the matter and suddenly we saw a stir about the ship and observed the captain and one or two officers disappear, when we all made a start to find out what was going on. We found about 20 feet of the molding smoking heavily, and firemen at work tearing it down. We found there was the beginning of what might have been a serious fire; it was started by the defects that Lieut Murdock spoke of in the insulation. It is the hardest thing in the world to keep an insulation on a ship at sea. All of you who have houses at the sea shore will have noticed that where the verandah or piazzas are painted with metallic paints, that there is a tendency to decomposition by the chlorides of the sea air attacking the carbonates, you have the bare wood towards the sea, and the rest nicely painted. If you want to make a good paint for a sea house use the worst paint you can get—that is, carbonate of baryta, which would not be decomposed. All these insulations are affected by the chlorides that come from the salt breeze. In this particular case I took occasion to inquire into the subject. The hull of the ship was used for the return wire, and when I inquired into it—although the crew and officers were very well disciplined and very reticent, I found they were always on pins and needles for fear fires would break out. On further investigation I learned that there had been a previous accident of the same kind. It is a highly dangerous method of wiring, and we ought in some way to protest against it.

Mr. A. Reckenzaun (of London)—I should like to ask Lieut. Murdock whether he has ever tried Ayrton & Perry's meters on board ship. These meters are protected by an iron shield which renders them independent of any magnetic influence. There is no necessity for the meter to be put perfectly level upon any table on any particular spot where the measurements are taken.

I should like also to point out in connection with this subject that in British men-of-war it is the tendency to use the double wire system, because, by using the ship's side as a return there is a large liability for leakages, as pointed out by Dr. Moses.

Lieut. Murdock—I have not been able to use the spring meter on board ship. With a Cardew voltmeter the needle would vibrate about four volts, and with the Perry ammeter it seemed

Digitized by Google

to vibrate about the same number of amperes. I don't know of anything in the market to-day better. I believe in the British navy they have been using a portable form of Siemens' dynamometers, and some of them have been ordered here in order to test them.

Dr. Moses—I am sorry to trouble you again, but there is some further information I would like to elicit. Signaling, I presume, is a very important thing on war ships, and it is very necessary that you should be able to use both small and large lights. Now, is it your experience that a 100 or 110 volt circuit is adapted to the use of arc lights, or would it not be preferable to have a 50 volt circuit on board ship so as to be able to use your arc lights directly in multiple arc?

Lieut. Murdock—I have recommended in the paper 70 volts. Of course our experiments with these search lights have been going on a great many years, and the general tendency seems to be that at least a tenth of an ohm dead resistance has a very steadying effect on the light, no matter whether we use a hand lamp or an automatic lamp. A little dead resistance seems to give us better working. The search lights are used so seldom and our general method of working is so economical, that we do not care for the energy we waste in these dead resistances. The search lights themselves are of French manufacture, though I think the Brush company, of Cleveland, have made essentially the same apparatus. I must confess, perhaps, to a little disinclination to use an incandescent lamp at 50 volts. I would rather take a little higher potential and work a lamp about 4 watts per candle.

Dr. Moses—Have you ever visited the installation on board the United States fish commission steamer Albatross?

Lieut. Murdock—I am familiar with the details, but have never been on board the vessel. They use the old Edison B lamp. Of course, if we want to take a B lamp with 55 volts, we can do it better than with a 10 candle lamp of the same potential.

Dr. Moses—On a recent visit to Pittsburg I saw everywhere an installation of 50 volt lamps. It appears that the Westinghouse company, of Pittsburg, have adopted that as a standard. Their reason for adopting it, as I am told, is on account of the economy of the lamp. They use less watts per candle power. It also permits of the use of arc lights directly in the circuit. Incandescent light people, as a rule, neglect the arc lamp, and arc light people neglect the incandescent lamp. It seems to me there should be an imitation of the harmony that prevails here, and they should unite in one system the advantages of all. Arc lights should be used with incandescent lights, and yesterday some one, I think Mr. Smith, of Pittsburg, suggested that an arc light can be used direct from converters. If Mr. Smith is present he will confirm or deny it, but I presume it must have been on a 50 volt circuit.

Mr. Smith—It was Mr. Kinsman, of New York, who mentioned that. It was news to me.

Mr. Kinsman—Some seemed to question the ability to run on very high voltage. They asked me if it was possible, after the adjournment. I have run them equally well on 100 volt converters. Fifty volts are, however, more desirable.

Dr. Moses—I happen to have made the first experiments on board the steamship Albatross that I spoke to Lieut. Murdock about, with the use of an arc light on incandescent light circuits. It was a 55 volt circuit. It was a lamp directly in the circuit, and one that was operated by a function of the current, and the lamp was invented to run on incandescent light circuits. While there it was found, after a great many experiments, that there was a normal length of arc. You may, of course, make lamps for any voltage, but it is found by experience, taking carbon in its chemical composition and the tendency to an extinguishment of the arc, that a certain length of arc is best adapted to arc lighting. For that reason it is necessary to have about 45 volts between the terminals of the lamps, and if you are running a 55 volt circuit it gives you that limit of loss which enables you to run out to any length right from the incandescent circuit on the ship. In this particular case there was about one-eighth of an ohm put in. It worked very satisfactorily. There was no winking of the lamps at all. The lamp itself was invented for a 55 volt circuit; for the difficulty of putting lamps in series on a multiple arc circuit is so great that it is not advisable. Therefore, the adoption of a 50 or 55 volt standard enables us to harmonize the arc and incandescent light in a most remarkable way. You can use your lamps directly from the circuit, and there are places, of course, no one will deny where an arc light is far superior to an incandescent light. It gives you five times as much light per pound of coal burned, and for large spaces it is very much more useful; so that it will be very desirable to adopt some general system in which arc lighting and incandescent lighting could harmonize.

Mr. Kinsman—The lamp that I have mentioned has been wound so that we have successfully burned two lamps, that is, multiple series, on a 110 volt current. I have not the slightest doubt but that can be successfully done by the lamp in a very short time. That brings the thing down to a commercial basis and under all conditions.

Mr. Wright—Lieut. Murdock speaks of one of the requisites for ship installation being the settlement of the voltage. I think that difficulty is entirely overcome with the alternating current system, as we can supply a converter to give you any voltage you please from our primary wires.

Lieut. Murdock—I am very glad Mr. Wright suggested that. I think there is one objection to the alternating current on board ship, and that is for search lights. Our hand lamp is rather a peculiar affair. The carbons are inclined at an angle and placed out of the line. The positive carbon being uppermost, so that the crater is turned toward the mirror. As most of the light is given off from the end of the positive carbon in a continuous current I fear that in an alternating current system we lose this advantage. As we are trying to get a system in which we may use both arc and incandescent lights from the same dynamo, the alternating current in this respect does not seem so good. I do not know that I fully comprehend Dr. Moses, but in the system I speak of we work our arc lamps parallel with each other, just as we put in incandescent lamps.

Dr. Moses—I would state more fully, then, that it is desirable of course to run an arc lamp exactly like an incandescent lamp. The arc is a constant for every voltage, so that if you use a multiple arc arrangement and you have a 50 volt circuit, since the arc for a 50 volt lamp is best adapted for arc lighting, it is advisable to use the 50-volt circuit for that purpose. You may use two lamps in series or throw in a considerable amount of resistance if you use a 70 volt circuit as you suggested.

The Chairman—I am very sorry to inform you that I hold in my hand the resignation of Mr. Morrison, president of the National Electric Light Association—something that I did not expect.

Dr. Moses—I move that it be indignantly refused.

The motion was numerously seconded, and carried unanimously.

The Chairman—The next business before the meeting is the report of the Committee on By-Laws—Mr. A. J. DeCamp.

On the request of Mr. Camp, the report of the committee on by-laws was deferred and made a special order for Thursday morning.

The Chairman—I have an invitation here from Mr. Meigs, of the elevated railway, East Cambridge. I have also an invitation from the New England Telephone & Telegraph Company to visit their works, and asking us to designate a time when any or all the members will make this visit.

Mr. DeCamp—Mr chairman, I would like to lay before you a communication which is a matter of information. It is not information growing out of any official action of this association, but it is a matter with which you are all more or less familiar, and several questions have been asked me in reference to it. The secretary will please read it.

The secretary read as follows:—

"The Committee of the Association of Electric Light Companies for mutual protection against exorbitant prices of carbon, after careful deliberation on the subject, desire to announce that in view of the collapse of the late carbon combination and the unsettled condition of the market, it is not deemed advisable at present for the association to take further action towards establishing a manufactory or the concentration of a large number of contracts for carbon, believing fully that the individual companies will experience no difficulty in placing their orders at fair and satisfactory prices. W. S. FREER, Secretary."

The secretary read the resignation of Mr. Charles Cooper as treasurer of the association.

Dr. Moses—I would like to repeat the same resolution that was offered with regard to our president were I not forbid from doing so by Mr. Cooper himself, whose great good sense suggests—and I should lay it before the convention in his words—that the treasurer should naturally be in the neighborhood of the president.

On motion the resignation was accepted, and the thanks of the association offered Mr. Cooper for his services.

Dr. Waldo then addressed the meeting on the subject of instruments for the bending test of line wire, as follows:—

In looking over some specimens of wire which were sent to the Baltimore & Ohio Telegraph Company, Mr. Maver and I were very much impressed with the uncertainty of the bending test of line wire. Very simple devices are oftentimes very advantageous in use, and I thought it might be of interest to tell the convention of a simple tool which will give more or less uniform results in the bending tests. The objection to taking a piece of wire in your hand and bending it, as is ordinarily done, is this—that a piece of wire bent at an angle here (illustrating) will break, not in proportion to its strength or its value as a wire, but in proportion to the diameter of the wire and its crystalline structure. A very hard drawn wire, for instance, will break with much less bend around a sharp angle than around a curve of its own diameter. I noticed that in all the tests described by the division of postal telegraphs in England, Mr. Preece is care-

Digitized by Google

ful to insist that the wire be bent around its own diameter. Any of our hard drawn coppers will break after one, two or three bends. The little instrument which Mr. Maver and myself constructed is merely a pair of plyers which can have a pin of different sizes inserted at its centre of motion, and will grasp the wire uniformly, and it is meant to be screwed to a board, so that the angle at which the wire finally breaks on the last turn is accurately shown. I think, as the mechanical properties of wire come more and more into consideration, that it is extremely important that we have a uniform system for this bending test, and I do not know of any better condition than that the wire shall be bent around its own diameter, a pin of its own size held by some such instrument as this, and that the number of degrees that it takes on its last turn shall be registered. For instance, we know that a wire will take three right angle bends and we will say fifty degrees more. You can make any arbitrary standard, as convenient, as to the number of degrees of bending that a wire should stand, and as many of our wires will break at a single bend or bend and a half, it is very important that we keep the last number of degrees which the wire bends in order to have any indication of the mechanical value of these high grades and hard drawn copper conductors. This little instrument will lie in the office of the *Electrical World*. It is very crude; it is the first one that was made. Of course the next one will be simpler and better.

In a discussion with Mr. Preece, and also in conference with the telephone people in Paris, I became a good deal interested in the silicon-bronze wire question. I take it that we can look upon all conductors of electricity as merely transparent to electricity, so to speak, and that electricity will travel through them a good deal as light will travel through glass. In our dense ignorance as to the ultimate nature of electricity, of course we can only surmise in regard to this point, but I take it that that is a good practical conception to bear in mind. Now, it has been found that very small quantities of alloy introduced into a very good conductor have very much the effect of the introduction of a small amount of iron or any discoloring substance into glass upon the transmission of light, and that has been found true particularly of some of the earthy alloys—arsenic, for instance, and phosphorous and silicon. But there is also a peculiar physical change which takes place when silicon or phosphorous is added to the bronze. What that change is I do not know, but in thinking the matter over, it has seemed to me that the addition of a small amount of silicon or phosphorus must enable the atoms of molten copper to effect a certain nearer relation to each other; that the centres of the atoms, so to speak, are allowed to come a little closer, and that the tensile strength is much increased by the addition of these small quantities of the earthy alloys. But whatever the cause may be, it is an experimental fact that the addition of small quantities of phosphorus and silicon, and perhaps some other alloys, has given us bronzes which have high tensile strength without any greatly lessened conductivity. Now I began a series of experiments on silicon and its application to these bronzes to see whether we could get conductors which should have mechanical properties of a high order and at the same time have the transparency to electricity which copper has. The first results of these experiments, after two years of work, are beginning to show themselves, and I have here a number of specimens, which I shall be very glad to give to any person interested, of some silicon-bronze conductors in which a high tensile strength has been obtained by using a core of silicon bronze and a covering of copper. You are all aware, perhaps, that some of the French engineers have made stretchings of a mile between supports in some parts of Algiers of very hard-drawn pure silicon-bronze wire. But the trouble with it is that the conductivity is no greater than the conductivity of steel, and for our purposes we want high conductivity, so I was led into a variation of the ordinary form of conductors, and returned to the idea of a cored wire. It was not possible to push the silicon-bronze conductors up to a tensile strength of 120,000 pounds to the square inch—and that rivals the tensile strength of the best steel—without reducing the conductivity to a comparatively useless point, and I therefore, was led into the experiment of coring the wire. I, think, by common consent, the disadvantages of the old style cored wire arose largely from the difference in electrical conditions between the core and its coverings. If any moisture got between the steel core and the copper covering, we had a perfect electric pile, and a certain amount of disintegration would take place between the core and its covering. Now, that difference of potential does not exist between the bronze core and the copper covering of a silicon-bronze wire, because they are so nearly alike chemically, and their electrical condition is almost identical. But there is another very great advantage. The fusing point of silicon—that being an alloy of copper—is slightly lower than the fusing point of copper itself, and it became possible to put in ingots of silicon-bronze and to cast around these ingots pure copper. There would be a perfect joint of fusion, so that when the ingots were taken from the moulds there was an ingot of silicon-bronze covered with copper, which would have a perfect mechanical homogeneity, and these little samples which have been passed around the room are specimens of wire drawn with a silicon-bronze core, with the ends polished so that you can see there is a difference in constitution of the metal, but it is almost impossible to separate the silicon bronze core from its outside covering. This is a more or less complete solution of the problem of having electric light conductors of very considerably more tensile strength than anything which copper can give and yet possessing almost the conductivity of copper. In the case of smaller wires the amount of success reached is equivalent to about the following figures: A wire 103-1,000 of an inch in diameter will break at about 650 pounds, and for torsion and bending it is much more satisfactory than the best hard drawn coppers which we have been able to get. You have, too, variable quantities of conductivity and the tensile strength, and you can save either at the expense of the other; so that it becomes possible by using the silicon-bronzes, to vary for particular conditions either of those qualities; and I think the experiments which we have made bid fair to be successful in producing permanently a conductor—not perhaps better than copper, because we purify our copper more and more—but a conductor which is very good, and which will possess mechanical properties which thus far have not been attainable.

One thing more as to the ultimate course of experimenting in this direction. The silicon-bronzes made in Europe have been expensive, because of the prohibitory prices put on by the owners of the only patents under which they could be made—the Lazar-Wyler patents; but owing to the genius of the Cowleses in the working of their smelting furnaces, by which silicon can be reduced from its quartz in a much less expensive way than any other that has yet been tried, and in consequence of the low price of silicon these silicon-bronzes will be made doubtless at a cost which will be not at all prohibitory for their use in places where wires have to be swung from supports and tensile strength becomes of great value.

Dr. Moses—The very interesting remarks of Dr. Waldo have elicited from my neighbors here a comment which I would like to bring to the attention of the convention. He suggests that perhaps the hard drawn core being more slowly acted upon by its own weight in stretching, would perhaps break after the outer covering had yielded. Experiments on the tensile strength of wires are conducted so rapidly, that there is no opportunity that I see for fatigue of metals becoming a factor.

Dr. Waldo—I think the whole question of the mechanical testings of wire is one of extreme importance. I have been very much struck in testing long series of wires with the disturbance caused by this very fatigue of the metal of which Dr. Moses speaks In using a testing machine for testing strengths, it is of the utmost importance that the strain be applied very gradually because you could all get different results in a machine where the strain is applied gradually at an interval of several minutes, we will say, for each wire and where the strain is applied rapidly. I, for one, would like to see a committee or some representative body which should take under consideration the unifying of the mechanical tests for wire for electrical purposes. I think both the bending and the torsion and the breaking tests are all now made very much as a particular whim of the company or person using the wire prescribes, and if we had a uniform method of making these tests, we should have data for preparing conductors mechanically in a way which is not now possible. I do not know but that I am ready to make a suggestion that a committee be appointed, having for its province the consideration for report at some future meeting of the convention of the best means of establishing a uniform system for the mechanical testing of wire for electrical purposes.

Dr. Moses—I think, Mr. President, that is a very excellent suggestion, and I hope that the president, in appointing that committee, will consider the extent of the investigations of Dr. Waldo by referring the matter to him as one of the members of the committee. There is, I think, a committee appointed for the purpose of considering insulations and wires in general. But this might be made a special subject of investigation, and if it is the pleasure of the convention to appoint such a committee, I hope Dr. Waldo will take charge of it.

The Chairman—Gentlemen, I should be very much in favor of appointing such a committee as that. But I was rather in hopes that the appointment would come from Mr. Morrison, as he is perhaps more familiar with the transactions of this association than I am. But as he is not here, I will appoint Dr. Waldo on that committee and Dr. Moses. Is there another committee already in existence that this could be attached to?

Dr. Moses—It strikes me that the committee on insulation and installation, of which Prof. Houston, of Philadelphia, was in charge, had a similar matter in hand.

The Secretary—That committee resigned and another committee was to be appointed. That committee was on the proper insulation of wire, and the proper installation and construction of plants.

The Chairman—We will leave that matter open then, until the president appoints the other committee and join this committee with that.

Digitized by Google

Mr. Mailloux—I would like to ask Dr. Waldo whether electrolytically produced copper has ever been used in making wires. I have had considerable experience in making copper by electrodeposition, and I find it possible in that way to make a copper which is not only very pure—sometimes 999 fine—but it is also a very ductile substance, and it can be bent a large number of times without showing an absolute rupture. It occurred to me that perhaps some attention should be given by wire makers to the use of that kind of copper.

Dr. Waldo—I confined our experiments at first to copper which was electrically deposited on the cores, and we obtained some remarkably fine specimens of wire in that way; but the cost of the process was prohibitory, and the copper which I have used frequently is merely the highest grade of Lake Superior copper.

Mr. Mailloux—Referring to electrolytically deposited copper, I did not mean that it was deposited on a core by electricity, but I referred rather to copper which has been produced in the form of slabs by means of electrical deposition. There is now a firm here in New York that has produced, I understand, some 500 tons of plates of copper per month by means of electrolysis, and I meant particularly copper which can be used in ingots just like any other form, except that it is very pure and exceedingly ductile.

Dr. Waldo—There is great danger in the melting of copper. One of the most insidious difficulties in the manufacture of high grade conductors is the introduction of a sub-oxide and a protoxyd of copper as an impurity, and I am very much afraid of any process which involves the constant melting or re-melting, and I should be afraid that electrolytically deposited copper would lose all it would gain by being electrolytically deposited in any ordinary process of melting. The protection of that copper during melting has been one of the most serious difficulties that we have had to face.

The convention then adjourned until the following day at 10 A. M.

THIRD DAY'S PROCEEDINGS.

The convention was called to order at 10.30 A. M. Thursday, August 11th.

The committee on revision of the constitution presented a form of constitution which was adopted. As reported by the committee, the constitution contained a clause providing that the same person should not hold office as president for two consecutive terms. The striking out of this provision was the only material change made in the constitution as reported by the committee.

The new constitution is as follows:

The name of this association shall be "The National Electric Light Association."

Members of this association shall be companies, firms, or persons, operating electric light and power stations for public or commercial purposes, manufacturers of electrical supplies and apparatus. Electricians, electrical engineers and persons, firms or companies whose professions or business is directly collateral thereto, may become members, upon the recommendation of the ex-committee and approved of by the association.

Each member, in a vote by ballot, shall be entitled to one vote.

A ballot may be demanded by one-fourth of members present.

Persons may become honorary members, without the right to vote, by ballot of the association.

The officers of this association shall be a president, two vice-presidents, treasurer and secretary, and an executive committee of six members, the president, vice-presidents, treasurer and secretary being members *ex-officio*.

The president and vice-presidents shall be elected by ballot to serve from the close of the annual meeting at which they are elected, until the close of the next annual meeting.

The treasurer and secretary, who may be one and the same person, shall be nominated by the president, subject to the approval of the executive committee. The executive committee shall be chosen by ballot at each meeting, either annual, semi-annual or special, to hold office from the close of the meeting at which they are elected until the end of the meeting at which their successors are chosen.

The duties of the several officers shall be those usually pertaining to their respective offices.

The treasurer, secretary and executive committee shall make a written report at each meeting to be spread upon the records of the association.

The executive committee shall be the governing body of the association, three of which shall constitute a quorum. They shall meet from time to time and shall report upon application for membership, gather and prepare information upon topics of interest and arrange for their discussion at the several meetings of the association.

The annual meeting of the association shall be held in February, and the semi-annual in August of each year at such place as the association shall determine, and such date as may be determined by the executive committee.

The membership fee of each member shall be $10—which shall accompany the application.

The annual dues shall be $10—payable in advance, and shall cover the calendar year.

All amendments to the constitution shall be presented in writing, and referred to a committee to be appointed by the chair before being acted upon by the association; a two-thirds vote of those present shall be necessary to their adoption.

A ballot on such amendment may be called for upon the request of five members of the association.

The President—The next business in order is the report on wire gauge by Mr. Garratt. The convention laid the matter over until to-day, and the question is upon the adoption of the report made by the committee on wire gauge.

Mr. Phelps—I have a resolution to present for consideration in respect to the report of the committee, in consonance with the ideas I expressed here Tuesday on the subject, namely:

Resolved, That the report of the committee on wire gauge be received, and the committee discharged with the hearty thanks of the association for the valuable work accomplished by them and presented in their table of the mathematical properties of the metric gauge; and it is further

Resolved, That in view of the large number of gauges already in existence and the confusion arising in their use, it would in the judgment of the National Electric Light Association be inexpedient to promulgate an additional gauge. The association earnestly recommends to its members and all others using copper wire the practice of designating sizes by definite diameters, such practice having already come into extensive use, as a feasible escape from the confusion of many gauges. The association further recommends the use of the meter and its fractions in designating diameters, and in furtherance of that end, publishes the tables presented by its wire gauge committee August 9th.

Mr. Mason—When I made the motion to make this the order of the day, it was in view of a resolution like the following, which I will beg leave to submit as a substitute for the other:

Resolved, That the report of the wire gauge committee be accepted; it being understood that by accepting it, we, as an association, commit ourselves to the following:

First—That in reports, communications, &c., we will designate wires by their diameters expressed in fractions of the meter.

Second—That in our personal conversation and business, we will designate wires in the same way in so far as we find possible.

Third—That this association offer to wire manufacturers such aid in the way of information, as shall enable them intelligently to list their wires on the metric system.

Now, Mr. President, my point is this: If a man wants a gauge we have a gauge there in the table which has been presented to us. I beg leave to differ a little from the chairman of the committee on that point. The left hand column of figures upon the table which is before the convention contains arbitrary numbers, although they are based upon the second column—the tenth of a millimeter—but we have there a gauge and those numbers will, undoubtedly, if such resolutions be passed, come into use by us. We can telegraph for wires under these numbers. I am very confident that the majority of the association feel that while we do not wish to go any further than is necessary in this matter, we want to do something that will commend itself to the users of wire and the makers of wire throughout the country. It seems to me that we are only following in the line of action taken by our government, and taking a very modest step if we shall adopt the resolutions just read. I understood, Mr. President, that a letter was read six months ago in our session from Messrs. Brown & Sharpe, in which they stated that they regarded the proposed metric gauge as very superior to their own, and if this convention would in some way adopt it or express its approval of it they would be very glad to adopt it for use in the measurement of their wires. That was a very strong testimonial to the value of this proposed system, and I would like some action taken which would lead them to do that which they proposed to the association that they would do. Other wire manufacturers will probably follow in the same line, and as a dealer in wires I feel that we shall all be greatly convenienced. I received an order a short time ago for a number of miles of wire from the far west. The order simply read so much No. 8, so much No. 10 and so much No. 12. I sent them the Brown & Sharpe gauge. The wire was, to a certain extent, useless to the purchaser. He had *meant* the Birmingham gauge. If it is understood that this association has, in a general sort of way even, adopted this metric system, we shall have our orders and know what they mean.

Mr. Garratt—I would vote strenuously against any adoption of any system of wire measuring which should, in a cast-iron way, commit us to it. I would not vote for the adoption of any system of measuring wire which would not leave each individual completely at liberty to do whatever he wished to do. If a man cannot find it more to his advantage to use this system of measuring than any other, we never can oblige him to do so. My idea in regard to that would be this: Take such action as would leave us at liberty with the commendation and encourage-

Digitized by Google

ment of the association, to use a better system of measuring than we heretofore have had; the best I know of being the application to the wire of its simplest principle, namely, its diameter.

Mr. Mailloux—I wish to express my appreciation of the precision and care with which the work of the committee has been done. I agree perfectly with the sentiments just expressed by Mr. Garratt. I regard the valuable work done by them as a priceless contribution to the fund of knowledge which we have regarding the methods by which we measure the various properties of wire. At the same time I am aware, as you all are aware, that in this country the inch is used very extensively. Since the discussion on Tuesday, I have taken the opportunity to speak of the matter with several gentlemen, makers of electrical machinery, who are using wire in very large quantities, and they have told me that so far as they were concerned, they could only make use of this gauge to a very limited extent—that it would not apply to their purposes—that they would adhere to the method of determining sizes by thousandths of an inch, because as they use the foot as the unit of length it would be very inconvenient to determine the area of sections of conductors in one system of measurement, and the length of it in another system of measurement; so that in making computation as to the space occupied by wire, or as to the weight of wire, they would find themselves in a worse predicament than they were before. I also noticed that in wires of certain applications the thousandth of an inch is more convenient than the other. Now, while I believe the system proposed by the committee to be very valuable, and that it has undoubtedly a great range of application, I do not think that we ought to force people to accept it, because if one system is more applicable than another, the person who finds it of greatest convenience to use that system ought to have the privilege of using it.

Mr. Eustis—I would like to speak in regard to that computation of weight which the gentleman was speaking of—changing from millimeters into feet, that is, measuring the diameter in millimeters and yet computing the weight for a given length in feet. I think if he had studied the table as much as I have, perhaps, he would have found it just as easy to make that calculation, or for anybody to make that calculation from the number which is given as the logarithm of the sectional area, and then by simply multiplying that one number by a constant, you can get the pounds per thousand feet which is given here. It is immaterial in any computation of this sort, whether you start with an inch or with a millimeter in making the final determination. The constant holds true; because your length, your weight per thousand feet is proportional to the sectional area multiplied by some given constant. Whether you take the sectional area in inches, or whether you base it on millimeters it is immaterial. I have here the constant for the calculation of pounds per thousand feet. I will just put that on the board in case anybody would like to have it (2.096472). That is the constant which is to be subtracted from the logarithm of the area given in square millimeters.

Mr. Steuart—I have only one word to say. This opposition to the motion as it now lies before the house, reminds me very much of a bugaboo—it is an imaginary evil that may come and may never come. The question of whether this gauge would be useful is altogether a question of the survival of the fittest. The question which presents itself practically is whether this thing will prove to be so much better that every one will adopt it in preference to inches, and I think that is the only question which is to be determined, and that can only be determined by practical tests in actual use, and I think that the opposition to the passage of this motion, which is merely a suggestion on the part of this association is altogether out of place.

The President—The question now is on the substitute of Mr. Mason for the resolution offered by Mr. Phelps.

Mr. Phelps—I have only a word to say, sir. Having prepared the first resolutions I naturally have a little preference for them. There is not very much difference between them. What I have undertaken to do there was to emphasize particularly the desirability of sticking to the principle of designating actual diameters and avoid the notion of promulgating a new gauge. The other resolution does not differ very much from it, but there is a slight difference in tone between them which perhaps should be considered.

Mr. Wheeler—That resolution is so strongly worded in regard to this association committing itself to certain things, that I think we want to be very sure before we do commit ourselves, that the gauge proposed is a good one. All the gauges that have grown up from the needs of wire makers have had the notches made so that the larger sizes differed by larger spaces than the smaller sizes. That is very well shown by the charts prepared by the committee on wire gauges where the numbers are placed so as to correspond with the old gauges, and the first number equals No. 38 of the ordinary gauge, and the second number equals No. 32. Therefore, the gauges we have been using for the fine wire sizes have six numbers in between the first two of the new proposed gauge, and at about the bottom of the chart, at about No. 00 of the old gauges, there are nine numbers of the new gauge which correspond to the one number 00 of the old, which shows that in the fine numbers the new gauge does not have fine enough differences, and at the bottom the new gauge has too fine spaces. That is to say, take a No. 38 wire, for instance, which differs from No. 37 by half a thousandth of an inch, and in the new gauge the difference is six times that, which is not fine enough for practical work. We are sure to need some number between No. 1 and No. 2 of the new gauge, and at the bottom we have one number of the old gauge which covers nine numbers of the new.

Mr. Garratt—I would say in that connection simply, that before two conventions I have debated and explained at length the objection raised by the gentleman. He will find it in the electrical and in a number of the ordinary newspapers. I have suggested no gauge. That is simply a table by which from the tenth or the hundredth of a millimeter you can determine the properties of any wire you wish. Again, the gentleman says let us pick out a gauge from the existing gauges. Of the present existing gauges there are 14 Birmingham gauges in use to my knowledge, and there are 30 or 40 Brown and Sharpe gauges used in America. The question of there being in the small numbers too great variation has been replied to and replied to until I am sick and tired of it. Any mathematician who knows the rule of three can construct from any one of those small numbers the properties, electrical and physical, which he requires. In ordering wire he can order by the hundredth of a millimeter, and he can determine that by the micrometer. The statement that those numbers do not correspond to the Brown and Sharpe ratio is entirely impertinent to the question. I repeat that I have advanced no gauge.

The President—This discussion has gone along far enough, and the hour for adjourning the morning session has arrived. Before adjourning, however, it is necessary to dispose of this business. The question now is, on the adoption of Mr. Mason's substitute for Mr. Phelps's resolution.

Mr. Mason's substitute was lost.

The President—The question now occurs on Mr. Phelps's resolution.

The resolution was carried.

The President—The first paper that will come up at the afternoon session will be that of Mr. Mailloux on "Storage Batteries," followed by Mr. Reckenzaun, of London, on "Electricity as a Motive Power," and a paper by Mr. Duncan on motors, and that is all that is on the programme at the present time, except to decide the place for the next meeting.

Mr. Wheeler—I want to say that Mr. Garratt is dead right about the gauge question. I was trying to answer the second resolution; that was all.

On motion of Mr. DeCamp, an appropriation of $50 was voted for the expenses of the attendance of the secretary at this convention, together with a further sum of $60 for printing.

The convention adjourned until afternoon.

THURSDAY AFTERNOON SESSION.

The convention was called to order at 2.30 P.M.

Mr. Leggett—There is a matter which should be of very great importance to many of us—probably to all of us—the undergrounding of wires, which has not been touched upon in the convention. I would like, if feasible, to have it understood that after the reading of the last paper, we take that subject up for consideration.

The President—The suggestion is a very sensible one. You have all got to come to it in the end, as I told you two years ago.

On motion of Mr. Leggett it was voted that the subject of underground wires be taken up after the reading of the papers on the programme.

Mr. Mailloux then read a paper on "The Present State of the Storage Battery." (See page 351.)

Mr. Martin—Mr. Reckenzaun's paper, which is to follow, as I understand, also includes the use of the storage battery, more particularly with regard to its application in street railway service. As he touches upon many points, I presume, that have already arisen in Mr. Mailloux's paper, I would like to offer a motion that Mr. Reckenzaun's paper be now read, and then that the two papers be discussed together.

The President—I presume there will be no objection to that.

Mr. A. Reckenzaun then read his paper (see page 349), and added the following remark:

Gentlemen, I hope you will do me the honor to discuss this subject as thoroughly as our time will permit, and raise as many difficulties and objections as you possibly can, and I shall do my best to answer them.

Dr. Moses—There is one of the maxims of this association, unwritten and not in the constitution we adopted to-day, that I think we all have in mind at all times—it is, honor to whom honor is due. Mr. Reckenzaun, with a facility that is most amazing to me, in a foreign tongue, has written a very able paper,

Digitized by Google

which no doubt will be placed on the files of the association. There is one sentence in the beginning of his paper which I would have him kindly correct, before spreading it upon the minutes, which is owing, as I say, to his not being to the manner born, and which will leave an impression that we should not have go forth. He says Mr. Plante turned to *profit* certain inventions, meaning simply, took advantage of certain natural effects, or used them—that I think to be his meaning. Mr. Plante has never turned to profit—in the ordinary sense, that is money profit—a single one of that brilliant series of inventions connected with the secondary battery which have immortalized his name, and which caused him to receive a grand medal of honor from the French government.

Mr. Reckenzaun—I meant scientific profit, doctor. Allow me to repeat that sentence. I say here: "He was the first to turn to profit the action of secondary currents."

Dr. Moses—Would you amend that and say, take advantage of, or use?

Mr. Reckenzaun—I would be very pleased to.

Dr. Moses—Now for the shaking up Mr. Reckenzaun asks for.

There is a question I would like to ask him which is important in its bearings on the running of street cars, will he give us the weight in pounds of the car that he speaks of in Philadelphia and which he wants us to go and ride upon? We do not want too many of us to go, and for that reason I am anxious to know what the strength of the car is, so that we wont break it down.

Mr. Reckenzaun—I have given the weight of the batteries in this paper. In the car which we use in Philadelphia, there are actually 80 cells, because there are considerable gradients to go over. Each cell weighs 40 pounds, and the average horse-power is six. Sometimes we only use two horse-power and sometimes, going up grades of 5 per cent., we use as much as 12 horse-power, but the average rate is six electrical horse-power. With reference to the weight of passengers on the cars, we have never carried more than 50 passengers on that car, because it is impossible to put more than 50 men in to it. There are seats for 24, and the rest have to stand on the platform along the step.

Dr. Moses—Another question, if you please. What time does it take you to change your battery?

Mr. Reckenzaun—The changing of the batteries takes three minutes with proper appliances. One set of cells is drawn out by means of a small winch, and a freshly charged set is put in. It takes the same time to charge the battery as it does to discharge it in the working of the cars, so one reserve set would be sufficient to keep the car continually moving.

Dr. Moses—What loss of energy have you found accompanies the mere change of a set of batteries?

Mr. Reckenzaun—Our loss of energy right through between the steam engine and the car wheels?

Dr. Moses—No, simply moving the batteries from the car to the depositary where it is charged.

Mr. Reckenzaun—Well, the car is pushed into the depot where the cells are being charged. Therefore, there is no moving of the cells required with the exception of just taking them out of the car and pushing a fresh lot in and one powerful man can attend to that. The loss of energy from standing about is probably nothing. If a battery were to stand charged for three months in a dry place, the loss of energy might be 10 per cent. I purposely had a set of cells standing charged for two years unused. After two years there was still a small amount of energy left. So as regards the loss of energy in a battery standing idle, it is practically nothing, because no one would think of charging a battery and letting it stand for three months or a year.

There was a small amount of energy left after two years. I have had cells stand three or four months, and I could hardly appreciate the loss going on, providing always that the cells are standing on a dry floor. If the exterior of the box be moist, if it stands on a moist floor, there will naturally be a surface leakage going on; but when there is no surface leakage, the mere local action between the oxides and metallic lead will not discharge the battery for a very considerable time.

Mr. Powers—There is one important matter, that is the amount of power used. When it requires from 4 to 12 horse-power to accomplish the work, I would like to know where the loss occurs if the energy of the street car horse is good for 2 to 6 horse-power. I think I shall have a great deal more respect for the car horse than I have had before.

Mr. Reckenzaun—I have made experiments in London with a loaded car pulled by two horses. I put a dynamometer between the attachments of the horses and the cars—a spring dynamometer—so as to ascertain the pull they exerted in pounds. Multiplying this pull in pounds by the distance traversed in a minute we could get the number of foot pounds that the horses exerted, and you will be surprised that two horses doing the easiest work exert two horse-powers to three horse-powers. On a car in Philadelphia we used between 2 and 12 horse-power. Two horse-power is the least amount of power that a pair of horses exert, and you will be surprised to know that each horse is capable of exerting eight horse-power for a few minutes, and when a car is being driven up a grade, pulling a complete load of passengers, those two horses during the whole time that they are pulling up that grade exert 12 to 16 mechanical horse-power, and that is the reason why street car horses cannot be run more than three or four hours out of the twenty-four. If they run longer they are dead in a few weeks. If they run two hours a day they last three or four years.

Mr. Phelps—Might I ask Mr. Reckenzaun if he is prepared to estimate at all as to the life of the cells, that is, to say approximately, how long it will be before the outfit will have to be entirely renewed? That is a very large item in the consideration of the question economically.

Mr. Martin—I would like to supplement that, and ask what was the cost of running per car mile including depreciation.

The President—Let us get at that question Mr. Phelps put first.

Mr. Reckenzaun—The life of the cells must be expressed upon the principle of ampere hours or the amount of energy given off by them. Street car service requires that the cells work their hardest for fifteen or sixteen hours a day. The life of the cells has to be divided; first, into the life of the box which contains the plates. This box, if appropriately constructed of the best materials, will last many years, because there is no actual wear on it. The life of the negative plates will be very considerable, because no chemical action is going on in the negative plate. The negative plate consists almost entirely of spongy lead, and the hydrogen is mechanically occluded in that spongy lead. Therefore the depreciation of the battery is almost entirely due to the oxidation of the positive plates. If we were to make a lead battery of plates ¼-inch thick, it would last many years; but for street car work that would be far too heavy. Therefore we make the positive plates a little more than one-eighth of an inch thick. I find that the plates get sufficiently brittle to almost fall to pieces after the car has run fifteen hours a day for six months. The plates then have to be renewed. But this renewal does not mean the throwing away of the plates. The weight is the same as before, because no consumption of material takes place. We take out peroxide of lead instead of red lead. That peroxide, if converted, produces 70 per cent. of metallic lead, so that there is a loss of 30 per cent in value. Then comes the question of the manufacture of these positive plates, which, I believe, at the present day are rather expensive. But I believe the time will come when battery plates will be manufactured like shoe nails, and the process of renewing the positive plates will be a very cheap one.

Mr. Martin asks the question how much is the cost per car mile. I ascertained in Europe that the motive power for a full street car costs one penny—two cents per car mile, that is, for the motive power; and I have to allow twice as much, that is, two pence per car mile, for the depreciation of the battery at the very high rate which we had to pay for a battery, and that was about twelve dollars for each cell; but I believe that as soon as the storage system has been sufficiently expanded, that the renewals of plates will not come to more than one penny per mile, and the entire cost of propelling these cars will be two pence per mile or four cents, which is about one-half of the cheapest horse traction.

Mr. Martin—I have listened to Mr. Reckenzaun's paper with a great deal of interest and attention, and was very glad to have the opportunity of gathering so much information in so short a time and presented so compactly. Mr. Reckenzaun has had a privilege which very few of us can enjoy, and that is of visiting every one of the electric railways in Europe now in operation. His very valuable observations on that subject were recently presented to the London Society of Arts, and presented in so able, masterly and exhaustive a manner as to obtain for Mr. Reckenzaun the silver medal of that society. (Applause.) I read Mr. Reckenzaun's paper brought before that society with a great deal of interest, but there was one point which impressed me very much, and that was that in Europe the merits, the claims and the advantages of the cable system did not seem to enter into the consideration of the case at all. Here we have to deal with that problem. The cable is running in this country; it is running in most of our large cities where the storage battery must find its chief scope and play, and unless with the storage battery we can make a better presentation than the cable men make with the cable and the grip, it is not likely that we shall see the storage battery assume the position and importance which we believe it is entitled to. I have seen various statistics on the subject of the amount of power required for operating a cable railway, and I have seen some of the statements go as high as a loss or waste of 80 per cent. I would like to ask Mr. Reckenzaun whether, since his arrival in this country, he has looked into that subject at all, and whether he finds that the loss in getting the current into the storage battery and then delivering it to the motor, is less in comparison than that in the use of the cable in the power finally delivered to the car.

Digitized by Google

Mr. Reckenzaun—I have made some very careful observations on the cable tramway in Philadelphia, which is quite an extensive system. I have never been able to ascertain the exact amount of waste in pulling the cable itself; but I have it on the authority of certain technical papers that there is a waste of about eighty per cent. I do not intend to depreciate cable or any other tramways, but there is a difficulty about introducing cable tramways. It is necessary to dig up the streets and interfere with the roadways. I have been told that the cable arrangements in Philadelphia cost $100,000 a mile, and that the cable road in San Francisco cost more than that. One of the directors of the cable company in Philadelphia told me that if he had seen the battery system before the introduction of the cable he would probably have made up his mind in favor of the former. The wear and tear in the case of the storage system is also considerable. There is a waste of energy in the dynamo; secondly, in the accumulator charged by that dynamo; thirdly, in the motor which is driven by the accumulator, and fourthly, in the gearing which reduces the speed of the motor to the speed required by the car axles. It would be difficult to make a motor run at the rate of eighty revolutions per minute, which is the number of revolutions of the street car axle when running at the rate of ten miles an hour. Take all these wastes and you find in practice that you do not utilize more than 40 per cent. of the energy given by the steam engine. But this is quite sufficient to make this system much cheaper than horse traction.

Mr. Mansfield—I would like to ask Mr. Reckenzaun in regard to the waste of energy necessary to carry the storage batteries or cells. Wouldn't it take so many batteries in some cases as to make the weight of the batteries many times the weight of the car? On a level street it would not take so many. Batteries of two horse-power might be sufficient, but on a grade of five per cent. it would be necessary to carry twelve horse-power storage batteries for probably ninety per cent. of the time. Although I understand that the energies of these batteries would not be used except when needed, at the same time they would weigh a great deal when carrying them through the streets. I have figured somewhat on these problems, and I am still inclined to favor the more direct system. I believe that the time arrives in the history of a city when it is necessary that considerations of beauty should be sacrificed for utility. When necessity demands it we can run wires overhead through our streets.

Then I would like to ask if he would give us any figures that he has in regard to the rate of loss that he would allow on an average load between the power necessary to carry the passengers, and that to propel the car.

Mr. Reckenzaun—In my paper I gave the exact figures of the weights of the entire material used in propulsion and the weight of the car as a whole. I think I stated that the electrical apparatus has one-fifth of the weight of the car when filled with passengers. Then Mr. Mansfield says that we have to carry 12 horse-power batteries, because occasionally that power is required. Now, it is well-known that we can discharge the storage battery *ad libitum*, at the rate of two amperes or 200 amperes. I can get out of a storage battery almost any horse-power I like for a short space of time. I have not the least objection to the direct system. But when you come to run twenty or thirty or fifty cars on one line, you will require very large conductors or dangerously high electromotive force. The overhead system is applicable to its own particular purposes. Where there are only five or ten, or even twenty cars, running on one line, and that line runs through a suburb or a part of a city where there are not many houses, that system is to be preferred. The objection to the overhead system is not so much the want of beauty, but the want of practicability. You have to put your posts very high indeed so as to let great wagon loads of hay and all sorts of things pass underneath. Most of the trouble comes in winter, and when it is snowing hard a great many difficulties arise. As regards the loss, suppose that the resistance of the overhead lines is one ohm. To draw one car it will take an average of 20 amperes, and the only loss will be 20 multiplied by 20, that is 400 watts through line resistance. But if there are ten cars, on that line you get 40,000 watts loss of energy, unless you increase the conductor in proportion to the number of cars. If you do that you get an enormous conductor, and have a sort of elevated railroad instead of a telegraph wire, as most people imagine an overhead conductor to be.

Mr. Reckenzaun said further in answer to a question put by Mr. Smith: The current required to run a street car is about 30 amperes, and an electromotive force of about 180 volts. If cars are run in connection with an incandescent light station, we can arrange our apparatus so that we can use an E. M. F., say of 110 volts, and then we can put in a smaller number of cells with a larger capacity that will give a corresponding horse-power. We can charge such larger cells with 50 or 60 amperes instead of 30.

In regard to arc lighting machinery, the arc lighting dynamo should not be used to charge the accumulators. They can be used, but they require such constant attention as to make them impracticable. We can only use shunt-wound dynamos conveniently for that purpose.

Mr. Pendleton—I understood that the loss of power in drawing the cables in Philadelphia was ascertained at 50 per cent. In San Francisco it was 68 per cent. used in drawing the cables, 28 per cent. in operating the cars, and 4 per cent. in carrying passengers. In the remarks made by Mr. Reckenzaun I understood him to say that he considered the shunt-wound dynamo essential in charging the storage battery.

I have had in continual use a dynamo for the purpose of charging storage batteries, but I found it necessary to use a current breaker in order to avoid the reversal of the dynamo, which at one time bothered me a good deal. I think, perhaps, there is no other difficulty whatever in using any ordinary series dynamo, although the shunt-wound dynamo has certain advantages for general use.

I am reminded by hearing Mr. Mansfield speak of the direct system of transmission, that about a year ago I was asked the question by the board of directors of the Brooklyn City Railway, what the difference in cost was between the direct transmission of electricity for the purpose of propelling cars and the storage battery. It was a complex question, and I felt that it could be solved by a diagram more readily than by language. Therefore, I drew two parallel lines of rails, supposed to be five miles in extent, and I pointed out that the resistance of the circuit when it reached a sum to divide the power developed at the station equally between the conductors and the motors, would make the secondary battery beyond that the most economical. On one occasion, before the New York Electrical Society, where we were debating the subject, I mentioned a method which I had of using direct transmission near the station, charging the batteries and operating the motor by means of a combination of the battery, and then utilizing the electrical energy at the extreme ends of the route. A storage battery might be able to work far more usefully than by merely exhausting a charged cell. I believe that, under the circumstances, a secondary battery can be made to operate a car for a day of fifteen hours without removal, and only require to be removed when, by extra discharges, the motor became heated or required attention in the battery hospital, which every car station must have.

Mr. Mailloux—I am largely interested in the problem of street-car traction with accumulators, being consulting electrician for the company which I believe put the first street-car propelled by accumulators in commission—a car run on the Madison and Fourth avenue lines in New York city. Some of the data which I add by way of corroboration or comparison with those of my friend Mr. Reckenzaun might, perhaps, be interesting. The grades on that line, as some of you may know, are extremely severe; not only that, but they are long, so that they tax not only the capacity of the motor, but that of the battery very severely. We have on one part of the line a grade of nearly 5½ per cent., and there are a number of grades as high as 4 per cent. Besides that, in several places the grades happen to be on curves, which add greatly to the effort required by the motor to propel the car. We have found that it was preferable to use two motors instead of one. We think it would be better to use motors rather larger than necessary in order to obtain larger effects with a comparatively high efficiency. We use 130 cells, which weigh somewhere in the neighborhood of 3,000 pounds. The whole car, with the motor and batteries, weighs as nearly as possible about six tons without passengers. This weight is altogether excessive, for the reason that the car has very strong iron beams. It was strengthened in Europe before it was sent over here, with the idea that we might want to carry enormous weights upon it.

I wished to ask Mr. Reckenzaun as to the amount of electrical energy per mile, that he finds necessary. I have found as the result of repeated observations that we must count upon an electrical supply of energy equivalent to from one to one and two-tenths electrical horse-power per car mile. This means that if we have a supply of electrical energy equal to, say, 40 electrical horse-power hours, we have enough energy to run somewhere between 35 and 40 miles. In practice we do not deem it expedient to exhaust completely the capacity of the car, and we find that a run of 30 to 35 miles is all that it is best to make in the ordinary everyday work of a car. We find, therefore, that in the average day's run of 60 or 70 miles it is necessary to change the accumulators once a day The car would start with a charge in the morning and would change somewhere about the middle of its work, irrespective of the number of hours it had been in operation, because the number of hours run includes the stops.

The question of transmitting the power from the axle of the motor shaft to the wheel shaft is one that has received a great deal of attention. I know that Mr. Reckenzaun has gone over that subject very carefully in Europe, and that he has some original plans and systems of his own. I think it would be very interesting if he would tell us of his experience.

In one system we have found it preferable to use a counter shafting in order to reduce the speed of the motor, but the reduction which we obtain is perhaps larger than it would be in regular practice. We reduce in the ratio of nearly one in ten. In other words, the motor runs nearly ten times as fast as the shafting.

Digitized by Google

In considering the expediency of a change from horses to electric motors, it is important to determine how quickly that change can be made. It is there that the secondary battery system presents, undoubtedly, great advantages. If we operate by overhead conductors or underground conductors, it is necessary at once to incur the expense of organizing the system of conductors completely from one end of a road to the other. In the upper part of the road in which we have this storage system, there is a suburban end from 86th street to Harlem. There are very severe grades there, but the travel is not very large. There they run some thirteen cars. Now, the superintendent of the road, tells me that with the electrical street system it would be possible to give the people in that neighborhood something very close to rapid transit. It would be possible to run all the cars at a much faster rate of speed—it would be permissible, under certain conditions when it is remembered that the line is almost entirely in the suburbs of the city—and in that way the time of making the trip would be very much shortened. We found that we could very easily attain a speed of twelve miles an hour. Of course, we are not at liberty to make very lengthy runs at that speed, but we have experimented with the line during the night several times, when the tracks were entirely free, and in that way we have been able to determine pretty accurately the rate of speed that might be maintained.

There is another important thing in relation to the electric railroad. It is braking the momentum by electricity. I found that railroad men, as conservative as they are, when once they conclude to adopt electricity, like to have everything on the car done by electricity; and one of the first questions which they propounded was as to the practicability of braking the momentum by electricity. One electrician proposed to use the motor in charging a battery while descending a grade, which would produce an intermittent charging. I confess that I do not see very much margin to be expected from this, judging from what has been developed up to the present time, in the way of economy or gain; but I should be interested in hearing the views of so experienced an electrician as Mr. Reckenzaun on that subject. With the car that we are running on Fourth avenue, we were enabled to run up a high grade with a load of some 30 passengers, with an additional car attached containing some few passengers more. But the superintendent was not satisfied with that. He made a stop on the grade, and after stopping, a start was accomplished without any difficulty.

Mr. Pendleton—I see that Mr. Reckenzaun is making some notes, and, if the president please, I will say a word in reply to Mr. Mailloux. Inasmuch as the accumulators are so rapidly changed, there cannot be very much difference. Instead of having two sets of accumulators to the car, you would have only a few additional accumulators, which would be a manifest gain. I desire to call Mr. Mailloux's attention to that matter in answer to his remarks.

Mr. Reckenzaun—I am very much obliged to Mr. Mailloux for his complimentary remarks concerning me personally. In regard to using two motors on a car, there are several advantages in it. I use two motors on all my cars in Europe, and always have done so from the beginning. One of the advantages is, that in case of an accident to one motor the other will bring the car home; secondly, with two motors we can vary the speed without changing the E.M.F. of the battery. If I want very much power I put two motors in parallel, getting four times the power that I do with one machine, and an intermediate power of two motors. There is another advantage of having two motors, and that is that we can use two driving axles instead of one, and we can go up grades with almost double the facility that way, because the adhesion would be double. These are the main advantages arising from the use of two or more motors. Mr. Mailloux asked if I would give my experience in regard to the mechanical transmission between the motor and the car axle. I have used almost everything that was known at the time, but in order to give you a full and detailed account of the various modes of transmission which I have used I should have to give you figures to bear out certain experiments. I should only be able to do that in a lecture of at least five hours duration, so I hope that you will kindly excuse me on that point.

With regard to the durability of plates, I have taken into consideration fifteen hours a day. In regard to the application of electrical brakes, I will say that that was one of the first ideas that entered my head when I began to use electric motors, and other people had that idea long before me. I have used an electric brake, using the motor itself as a brake—that is, as the car runs down a grade by momentum it generates a current, but this current cannot be used for recharging a battery. It is utter nonsense to talk about that unless we have a steady grade four or five miles long. The advantages are very small indeed, and the complications which would be introduced by employing automatic cut-outs, governors, and so on, would counterbalance anything that might be gained. As regards going up an incline, of course stopping and starting again has to be done often, and anybody who at any time works cars by electricity, whether they have storage batteries or not, has to allow for sufficient motive power to overcome all the difficulties that any line might present. One of the great mistakes which some of the pioneers in this direction made was that they did not put sufficient power upon the cars. You always ought to put on the cars power capable of exerting perhaps 20 to 40 per cent. more than is necessary in the ordinary street service, so that in case of the road being snowed up, or in the case of any other accident which is liable to occur, you ought to have plenty of power to get out of the scrape. Mr. Pendleton made certain suggestions in regard to a combined system of conductors and accumulators. I do not know much about those, and I could not give an opinion unless I had studied the matter thoroughly.

Mr. Kinsman—What would be the effect on an accumulator of intermittent charging, such as the gentleman spoke of, in going down grade?

Mr. Mailloux—It would not have any bad effects so far as that is concerned, but it is simply a question of the expediency of the process—whether there would be sufficient energy gained by it to make it worth while.

Mr. Kinsman—The point I wanted to make was, is intermittent charging economical and desirable?

Mr. Mailloux—I don't think it matters very much whether the current be intermittent or not. There may be a slight difference in fluctuation of the counter-electromotive force through variation of the rate of charging, and that might affect the efficiency of the storage battery as an instrument for conversion, but it would not affect its storing capacity to any appreciable extent.

Mr. Martin—We have all listened with pleasure to Mr. Reckenzaun's outlining of his experience. Mr. Reckenzaun is among us for a very short time. We have already in our ranks several distinguished European electricians as honorary members, and I would like the opportunity of offering the resolution that we receive Mr. Reckenzaun into our ranks as an honorary member.

The President—Mr. Reckenzaun is already an active member. There is more honor in that than in being an honorary member.

Mr. Reckenzaun—I can only express my feelings of gratitude for the honor conferred upon me. I am quite sure I do not deserve it.

The president then called on Mr. Duncan for his

REPORT ON ELECTRIC MOTORS.

Mr. Duncan—At the last meeting a committee was appointed to prepare statistics in regard to the number of motors in operation at central light stations, the prices paid, and so on. A circular was issued; some of the companies responded but a very large proportion did not respond. One member of the committee, however, in New York, paid particular attention to the New England states and collected a large amount of valuable information which he promised to have with him here on Monday evening, and to meet the other members of the committee. However, that information and the gentleman himself have not arrived, and the papers which I have contain some information which I do not think should be published unless through the hands of the executive committee. It gives information regarding charges, etc., of some of the local companies which it might not be judicious to spread out for general information, and, therefore, instead of preparing a written report, I ask the privilege of making a motion to refer those papers to the executive committee, so that they shall pass upon them, select such data from them as they may think best, and have them distributed for information. I make that motion and ask for the discharge of the committee.

The motion was carried.

The committee appointed to recommend a place for holding the next meeting of the association submitted the following resolution, which was adopted:

Resolved, That the next place of meeting of this association be in the city of Pittsburgh, at such date in February as the executive committee may determine.

Dr. Otto A. Moses, Mr. Stephen Holbrook and Mr. F. A. Gilbert presented their resignations as members of the executive committee, which, on motion, were accepted.

Mr. S. A. Duncan, of Pittsburgh, Mr. T. Carpenter Smith, of Allegheny City, and Mr. Wells W. Leggett, of Detroit, were nominated as members of the executive committee, to take the places of the gentlemen who had resigned, and there being no objection, the secretary cast the ballot of the association for the persons nominated.

DISCUSSION ON UNDERGROUND WIRES.

Mr. Leggett—I believe that it was agreed at the opening of the meeting that we would talk up this matter of underground wires at the close of the session. I desire to state what position we are in at Detroit. At Detroit, as most of you gentlemen are aware, having seen our city, we are lighted by the tower system. We have got some 400 miles of wires in our system there. Just at the present time our City Council, our Board of Trade and our Mayor, all of them very excellent gentlemen who have at heart the welfare of our city (and there is no question but that they have at heart also the welfare of our country) have deemed it expedient

Digitized by Google

on their part to stop immediately the operation of running the wires underground. Now, we are met with this condition of affairs, that we do not know what to adopt. We would be very glad to have the views of this convention, or the views of such members of it as have had experience in this line, and to know if there is any system which any one can recommend that is beyond the experimental stage. We have invested in the city of Detroit nearly half a million of dollars in our plant, and you can readily see that we are driven to an extremity. That, of course, to us, is a matter of very grave importance. We want to know whether we are obliged to take one of a number of things, each of which is experimental, or whether there is some system which some person, some member of this association, can say that he has found to be expedient and practicable throughout for this purpose.

I must confess that after all our investigations in this matter, we are as yet entirely undecided to know what to do. We recognize, as well as our Mayor, our Board of Public Works and our City Council, that this matter of overhead wire is becoming a very serious one; interfering with fire ladders, causing more or less danger to property and to person, but the remedy is what we are seeking. If there is anything which we can adopt, we would be very glad to adopt it; and for that reason I hope that there will be short remarks from a number of sources, stating the experience of different individuals in this line, and whether there is anything that they can now recommend; and I should also be glad to know of the difficulties that they had experienced in regard to the matter. I would like very much if Mr. DeCamp would state briefly whatever experience he may have had with the matter in Philadelphia; and if we have a representative in the room from the city of Brooklyn, I would like also to hear from him.

Mr. DeCamp—In Philadelphia, as in Detroit, we are not beyond the experimental stages. There has probably been more work done in that direction in the city of Philadelphia than in any other city in the country, and this is the condition of it: The department known as the electrical department of the city of Philadelphia, about a year and a half ago, made an appropriation of $5,000 to put down a line about one mile long. A lead-cased cable was put in, well insulated, put in a trough, the trough was filled up with residuum of petroleum. That carried 12 lights of 30 volts each, which was the extent of that particular line. At the end of a year, a further appropriation permitted the department to extend its line. It however, was not extended in a double line. The remainder of the circuit was made on one side in the conduit, and the other overhead. That has been in operation about six months. It is now carrying a load of 59 lamps of 45 volts each, and has been doing that for probably the last three months. The cable is working fairly well, but from various causes has had more or less grounds on it—very many more than the overhead circuit. Additional experience was recently had at South street, where there was a circuit of one mile put in. The first circuit put in was taken up for some reason, it being a failure. The cable, which is there to-day, is a good one, but the superintendent tells me that the grounds are so numerous that he hardly knows where to commence to pick them out, and there they are to-day in that condition. Whether it is the fault of the cable, or of the conduit, or of the work done, I do not know. That, however, has brought us to this conclusion, that we have got to replace all of that before we shall be justified in running more lines over such a circuit.

The sectional underground wire operated by the Electric Light and Power Company, of which company I am the manager, is the latest experiment in the way of underground electric lighting which we have in Philadelphia. The gentleman in charge of that work is a clever man, and a man of more practical experience in the operation of underground wires I think, than almost any other man in the country. He is a man of exceptional intelligence, and is an enthusiast in his work. He has left no stone unturned to look into the difficulties which we have experienced, and to try to foresee them. The conduit itself I believe to be one of the best structures in existence. I am speaking now merely for its convenience. It is an iron conduit. Previous to my taking charge of it, I do not know how many cables they had in; I do not know how they were selected, but they were selected certainly, with the best judgment that the company then possessed. The condition of the streets of the city of Philadelphia, particularly the old section, where the gas mains are laid is such, that I find it to be utterly impossible to keep street conduits free from gas. In the city of Chicago, I am told, they are troubled with gas in their conduits, and I hear that the city of Brooklyn has had two or three explosions in connection with its telephone service. Therefore, I am forced to the conclusion that conduits in the city of Philadelphia at least will have to be abandoned—open conduits. The cost would make them prohibitory. I am not sure that they would be successful, but it looks reasonable that they would be, if that amount of money could be spent on them. As a matter of information, backed by what little experience we have in that line, I want to say that our use of any metallic covered table has not been encouraging. We have had a great deal of trouble with it. There seems to be a disposition of the current—reactionary current or something on account of the lead casing, which makes it very difficult to handle at the terminals, and that accounts for a great many of the grounds that we have on that line.

Mr. Brown (Chicago)—I have had about eighteen months experience with underground work in Chicago, and would agree with Mr. DeCamp in a great many things that he has mentioned but hardly in all. We have the Dorsett conduit there, and we are troubled greatly with gas, and have had one or two explosions, although they have not caused much damage. We find that the principal trouble with the conduit is at the joints. We think that if a perfectly tight joint could be made between the sections that we would not have so much trouble with gas and even water that leaks in. The newest conduits to-day of which we know is the Hurlburt conduit which has a flexible joint. I do not know that any of it has been laid. It has been on the market but a short time, but it seems to me that it would surely carry out their expectations from the fact that the joint is flexible. We have man-holes at an average distance of 400 feet apart, and between the man-holes we find that the conduit sags after it has been laid any length of time from the pressure from above—the street traffic. I have seen on exhibition this new conduit and the joint is very flexible indeed. It would allow the bending of at least 6 inches in 400 feet, and I have seen a joint in water which has been in that condition six months now without any leak at all. We have some sixty or seventy miles of wire underground, and in that sixty or seventy miles of wire, all classes nearly of cable underground wires are represented. We tried lead covered cable at first, and finally thought it was best to give that up, but lately have gone back to it. We find that in places lead covered cable fills the bill. We think it is best to make our main circuits running from the stations before we reach any lights, of lead with wiped joints, and after we leave the conduits and run through the laterals under the sidewalk, we find it would be best to have something besides lead cables, because as you know on all arc light circuits we have to cut them everywhere and anywhere at all times to put in and take out lights. Lead covered cables I do not think suitable under the sidewalk. You see there is a dead ground, less than a quarter of an inch away from the main circuit, and as we run through the areas, the cable is subjected to injury. We find it necessary to have wiped joints on the lead cable, and when we leave the conduit to leave lead cable for good and put some other. We also have great annoyance from the rats. They eat the lead of the cable, and we average a dead rat a week. You can see where their feet and their tails burn on the cables, and we find them on the ground with their noses burnt off.

Mr. Powers—I have been in the past year somewhat interested in this underground system. The principal cities of the state of New York, outside of New York and Brooklyn, have been greatly exercised during the past year on account of the interference of the wires at the Buffalo hotel fire with the ladders of the firemen, and on account of that a number of bills were introduced and two or three were passed by the legislature and signed by the governor, allowing wires to be introduced underground with the consent of the local council. We told the contract board of the city of Troy that we would break our contract and would make no contract with them under any condition that did not contain a clause eliminating the underground business. In other words, that our contract should be binding as long as our wires were overhead. Unless we are to have a great deal of trouble, in the smaller cities especially, it is necessary for the electric light men to take an uncompromising attitude. People say because we want the wires underground that is good reason why they must go. That is all they know about it. A prominent paper of the state of New York actually urged as an argument that because an Edison company in the city of Albany put their wires underground, we in the city of Troy should put our wires underground. Now, in that state of ignorance it is the business of this convention to enlighten people on that subject as much as possible, and also to take the most uncompromising attitude toward forcing the wires underground. Let them understand it is not possible in the present state of the art, especially where lights are spread over a large area. The point I am insisting on is that the people do not understand it. They regard the matter of putting wires underground as an everyday occurrence, like putting the gas mains underground. If this association can speak with authority on that subject I am sure it will help people when they need help in the matter.

Mr. Leggatt—I would like very much to hear from the president on this subject, and to learn what experience he has had in Baltimore.

The President—We have not had any. I have declined for a good many years, going before legislative or municipal committees for the simple reason that it is only a question of costs as to the feasibility of placing wires underground. It is a question I do not care to debate, because we do not want to put our wires underground. It costs too much.

Mr. Leggatt—That is just the information I wanted to arrive at.

The President—Very expensive, sir, but entirely feasible.

Dr. Moses—There is a little matter, but one of great importance—as trifles sometimes have a most important influence—

Digitized by Google

there is a little thing that might be reported upon at some future meeting, and that is the influence of electric currents, both continuous and alternating, on small masses of magnetic matter, and on the demagnetization of the same. That is intended to cover the question of the rapid magnetization and demagnetization of small masses of iron used in measuring instruments; and also, what is the effect of currents, large and small, upon watches, which are in everybody's pocket; and whether it is possible for them to be demagnetized, when once they are really magnetized, by any appliances we have. It is a question of great importance, when you consider that the first chronometer that went accurately was the means of bringing the inventor a reward of £20,000 from the British government. You can see it is a matter of importance to have time-pieces absolutely accurate for certain purposes. All of the chronometers used on board ship contain masses of iron in them, and it would not be pleasant to have somebody come down on an electric light company for causing the magnetization of the chronometer and thereby bringing about the loss of a ship.

The president appointed Mr. E. Lange, of Pittsburgh, a committee of one on the subject.

The President—I will appoint on the committee on insulation, &c., to take the place of those who have resigned, Prof. Thomson, of Boston; Dr. Otto Moses, of New York; Dr. L. Waldo, of New Haven; Dr. Duncan, of Baltimore; E. Lockwood, of New York; George Hamilton, of New York, and O. N. Shallenburger, of Pittsburgh.

Prof. Thomson—I thank the president for the honor of being appointed on that committee. I will endeavor to collect all the information I can in regard to those subjects, with the assistance of the other members of the committee.

Mr. Duncan—If there is no other business before we adjourn, I would just like to call the attention of the convention to one point. I was not present yesterday morning when the report of the carbon committee was presented, and it seems to me that there is one point which interests local lighting companies which has been passed over without very much consideration, and in that connection it seems to me it would be well to take some action, preparatory to the next meeting, to look into this question of carbons very thoroughly, either through the executive committee or some special committee; because, if we have got to break down a pool every two months, we ought to be in shape to do it, and it seems to me that, from the information which has been going around—not in the convention itself, but from mouth to mouth—in regard to the formation of an organization and the prices desired to be obtained by the old pool, that the time has arrived for the companies interested here through the committees of this association and through its proper officers to look after that subject very carefully. It seems that we have been able in the past to get along very comfortably with the pools, but I can conceive of circumstances where it might take considerable time to break up a combination. If that is the case it seems to me it would be well to have either a special committee appointed or the matter referred to the executive committee to keep it in hand. As I understand, the committee that reported yesterday morning was discharged. If they were discharged I should make a motion that a committee of three or five be appointed to take this matter in hand, and that all papers pertaining to carbon be referred to that committee for report at the next meeting, and that they have power at any time to call the attention of the executive committee to any proposed action, such as has taken place within the last few months. I think it is high time that we protect ourselves as well as that the parent companies protect themselves in the manufacture of carbon.

At the request of the president, Mr. Duncan put his motion in writing as follows:

Resolved, That a committee of three be appointed by the chair to inquire into and report on all matters pertaining to the carbon supply.

The resolution was adopted.

The president then declared the convention adjourned to meet in Pittsburgh on a date in February to be hereafter determined by the executive committee.

EXHIBITS.

The following companies and firms made exhibits in parlors and other rooms of the Parker House:

American Tool and Machine Co., Boston.—Dynamo starter and stopper.

The Baxter Electric Manufacturing and Motor Co., Baltimore.—Baxter motors from ¼ to 10 h. p. in operation, driving a variety of machinery. The largest motor, a 10 h. p., running an incandescent machine supplying current to a number of Sawyer-Man lamps used to light the range of parlors. A very complete exhibition, and by far the most comprehensive show of electric motors yet seen at a convention.

Blodgett Bros. & Co., Boston.—Annunciators, alarm bells, etc.

Boston Rubber Shoe Co.—Rubber tape for splices.

The Bernstein Electric Light Manufacturing Co.—Incandescent lamps on arc lamp circuits.

Billings & Spencer Co., Hartford, Conn.—Drop forgings in copper, iron, and steel, for use in dynamo construction.

The Callender Insulating and Waterproofing Co., New York.—Insulated wires and cables.

The C. & C. Electric Motor Co., New York.—Small motors with fan attachments.

A. G. Day, New York.—C. B. Hotchkiss, Agent—Kerite wire and cables.

Edgerton Electric Motor Co., Philadelphia.—Electric motors driving pump, ventilator, and coffee mill.

The Electrical Accumulator Co., New York.—Several types of storage batteries.

The Emerson Power Scale Co., Florence, Mass.—Scale for measuring power.

The Fiberite Mfg. Co., Portland, Me.—Fiberite battery jars, made from wood pulp.

The Geneva Non-Magnetic Watch Co. (limited), New York.—Non-magnetic watches.

The E. P. Gleason Mfg. Co., New York.—Glassware, fixtures, fittings and appliances for incandescent lights.

P. C. Holmes, Gardiner, Me.—New turbine wheel specially designed to run electric light machinery by water power.

Kennedy Mfg. Co., Providence, R. I.—Waterproof insulation of fibrous material.

Kimball & Davis, Boston.—New dynamo for incandescent lighting.

C. L. Ireson.—Leather link-belting.

Leatheroid Novelty Co., Boston.—A variety of its products in leatheroid.

C. J. McIntire & Co., Newark, N. J.—Connecter for joining wires.

New England Wiring and Construction Co., Boston.—Multiple switch system for incandescent lighting.

New England Glass Works.—Shades and globes for electric lights.

New York Insulated Wire Co., New York—Grimshaw white core wires, cables, and Grimshaw tape.

The Okonite Company, New York.—Insulated wires, cables, and flexible cords.

The Para Rubber Co., South Framingham, Mass.—Rubber insulated wires.

A. L. Russell, Boston.—Electrical testing instruments.

The Standard Underground Cable Co.—Underground, submarine, and aerial cables.

The Scovill Manufacturing Company, Waterbury, Conn.—Silicon-bronze, German silver and other wires.

The Simplex Electrical Co., Boston.—Campbell insulated wires.

The Shaeffer Electric Mfg. Co.—Electric lamps, switches, fixtures, etc.

The Standard Electric Time Co., New Haven, Conn.—Electric gauges.

The Sawyer-Man Electric Co.—Incandescent machine and lamps, run by 10 h. p.; Baxter electric motor.

The Sun Electric Co., Woburn, Mass.—Incandescent lamps running by alternate currents and connecters.

The Thomson-Houston Electric Company.—Motors, station fittings, and incandescent lamps; new voltmeters and ammeters. They exhibited incandescent lamps running by converters receiving a 1000-volt current from an alternate-current machine at the Thomson-Houston station in Congress st.

Rhode Island Telephone and Electric Light Co.—Wright cable clips and "Little Giant" batteries.

The Vitrite and Luminoid Company, New York.—"Luminoid" incandescent lamps.

The Washburn & Moen Mfg. Co., Worcester, Mass.—Wires for electrical purposes.

The Wainwright Mfg. Co., Boston.—Feed-water heaters, corrugated tubing, etc.

The names of those in attendance during the three days are given below:

New York—P. C. Ackerman, C. H. Barney, W. H. Blake, A. W. Butterworth, C. S. Bradley, E. Bynner, W. L. Candee, F. G. Cartwright, Wm. F. Cullen, W. M. Callender, Addison Conkling, H. N. Curtis, Isaac H. Davis, Henry C. Davis, F. C. Dowd, P. A. Dowd, C. L. Edgar, J. B. Edson, E. F. Gennert, M. W. Gleason, M. W. Goodyear, John H. Hapgood, J. M. Hill, C. B. Hotchkiss, H. McL. Harding, F. E. Kinsman, W. C. Kerr, A. A. Knudson, H. F. Lufkin, E. T. Lynch, Jr., Z. Latshaw, C. O. Mailloux, Geo. T. Manson, T. C. Martin, Romaine Mace, Dr. Otto A. Moses, Norman McCarty, Frank A. Magee, Jno. M. Pendleton, Charles W. Price, Ralph W. Pope, George M. Phelps, Jr., R. W. Ryan, L. Searing, C. E. Stump, A. C. Smith, G. H. Stockbridge, W. I. Wark, Joseph Wetzler, H. Wellington, G. L. Wiley, S. S. Wheeler, A. P. Wright.

Boston.—P. H. Alexander, Geo. W. Adams, Wm. T. Andrews, H. W. Burgett, W. I. Barker, N. H. Barker, G. H. Blodgett, Aaron D. Blodgett, G. W. Blodgett, Edward Blake, L. W. Burnham, Oscar S. Bussmann, E. S. Batcheler, Wm. Brophy, Chas. E. Bibber, F. J. Boynton, J. M. Betton, H. B. Cram, C. A. Coffin, Albert H. Chapman, H. A. Clark, F. E. Cabot, Frank E. Clark, T. W. Clark, J. H. Churchill, G. W. Davenport, G. W. Daniels, A. T. C. Daniels, T. B. Doolittle, — Davis, Jas. H. Dodge, Samuel Elder, H. H. Eustis, Charles Fuller, Frank Fuller, H. M. French, W. D. Finley, T. C. Frenyear, — Francis, B. S. Flanders, Robt. G. Fitch, E. I. Garfield, J. N. Godfrey, F. A. Gilbert, A. V. Garratt, C. N. Goward, Alex. S. Hayes, W. B. Hosmer, W. S. Hill, W. A. Hall, O. N. Howland, J. B. Hatch, Jr., G. H. Hartwell, William O. Howland, — Hutchings, Charles L. Ireson, J. Jacobs, E. W. Kellogg, W. R. Keifer, F. H. Kimball, J. L. Kimball, D. Killecutt, D. W. Lee, Thos. D. Lockwood, Thos. Leavitt, W. C. Livermore, A. F. Mason, C. J. Messer, S. P. Messer, W. H. Mendell, Irving S. Meredith, A. G. McCluir, J. B. Martin, Edmund Noble, Hon. Hugh O'Brien, Walter J. Paine, S. B. Paine, Albert C. Pond, W. E. Park, H. B. Prindle, H. G. Pratt, A. L. Russell, G. L. Richards, C. M. Ransom, R. F. Ross, E. J. Richards, M. F. Rogers, G. Richardson, G. S. Ross, Chas. W. Rand, Fred. Schlegelmilch, E. P. Sparrow, Leopold Schlegelmilch, Fred. J. Sawyer, — Sherburne, J. S. Sawtry, F. W. Sanderson, P. Sullinger, A. T. Starkey, W. M. Turner, G. F. Talcott, F. H. Thompson, H. J. Toland, H. S. Thornberry, A. F. Upton, S. P. Wardell, L. B. Wright, E. H. Williams, Geo. W. Waite, C. J. H. Woodbury, Henry J. Weil, J. J. Williamson, C. D. Wainwright, H. C. Wirt.

Providence, R. I.—Geo. H. Adams, F. H. Bradford, C. E. Bailey, E. M. Carhart, W. A. Huse, Henry B. Lytle, Marsden J. Perry, E. F. Phillips, R. T. Robertson, W. H. Sawyer, C. Sims, R. H. Whittier.

Cleveland.—W. H. Boulton, C. A. Brayton, J. B. Crouse, D. A. Dangler, E. B. Gethin, Webb C. Hayes, Wm. Henderson, W. H. Lawrence, J. J. Miller, Geo. W. Mansfield, F. E. Pettingill, E. F. Peck, Geo. W. Short, Wm. F. Swift, C. D. Smith, C. L. Wright.

Chicago.—G. W. Atkinson, S. A. Barton, Geo. S. Butte, Henry Bowen, W. J. Buckley, A. H. Brown, D. Gilbert Dexter, H. S. Glasier, F. W. Harrington, W. A. Kreidler, J. H. Shay, F. H. Soden, J. N. Thomas.

Philadelphia.—W. B. Buchanan, A. J. DeCamp, N. H. Edgerton, S. B. Hillman, Harry Hall, Stephen F. Holbrook, M. D. Law, Edwin C. Mullin, James A. Pentz, Anthony Reckenzaun, W. E. Sharpe, — St. Clair.

New Haven, Conn.—J. H. English, Will Hooper, Frank N. Hooper, C. D. Warner, Dr. Leonard Waldo.

Baltimore, Md.—Wm. Baxter, Jr., J. W. Darley, D. E. Evans, B. M. Greene, W. H. Harding, P. O. Keilholtz, J. Frank Morrison, Thomas McCoubray, Jr., M. N. Packard, Arthur Steuart.

GAS LIGHTING BY ELECTRICITY.

The Electric Gas Lighting Co. of Boston, and A. L. Bogart, of New York, have become the owners of U. S. letters patent: to Wm. A. Pitt, No. 139,811; A. T. Smith, re-issue No. 7,249; A. L. Bogart, 180,832; A. L. Bogart, No. 180,833; A. L. Bogart, No. 202,694; J P. Tirrell, No. 232,661; H. A. Packard, No. 225,071; F. V. Sanford, No. 232,304; and an undivided interest in Heyl and Diehl, No. 116,044; and the sole interest in E. E. Bean, No. 108,434; relating to hand-lighting apparatus. They announce that said letters patent control and cover all varieties of electric hand-lighting burners in which the gas is both turned on, and ignited by a primary spark, at a single movement by hand; by operating both gas-cock and electrode, directly or indirectly, by the key of the gas-cock, whatever its form, or by an angle lever and bar, or by a ratchet wheel whose revolution brings the electrodes in contact, and alternately opens and closes the gas-cock; and also all forms of simple lighters in which, by means of a bar, chain, or thumb-cock, a moveable electrode is brought into contact with a fixed electrode; and those in which the moveable electrode is withdrawn from contact by means of a spring or its equivalent.

They give notice that no corporation, firm or person is authorized to manufacture any of these varieties of apparatus, except themselves, and the Boston Electric Co., of Boston, as sole licensee.

They state that their purchase of the above letters patent has been compelled by the hardihood of infringers who have profited by litigation between owners of letters patent of undoubted validity, but undetermined relative scope, to infringe the rights of both parties.

TELEGRAPHING FROM A POLE.

Last summer we had occasion to inform our readers that notwithstanding the exclusive contract between the Western Union and the Monmouth race track, the Baltimore & Ohio was enabled to furnish its customers with the race news by means of establishing an office on top of a high tree, from which a view of the track was had. This year the Western Union leased the tree ahead of the Baltimore & Ohio, paying $40 for it, which covered the racing season, and was supposed to have shut out the rival. The Western Union was enjoying a good laugh at the expense of the Baltimore & Ohio, but to the knowing ones it was thought strange that the latter enterprise would allow itself to be outdone without making any efforts whatever. Just previous to the first day's races a piece of ground was leased by the Baltimore & Ohio, upon which was planted a pole. Mr. W. A. Northrup, a well-known old-time telegrapher, can be seen any race day perched on top of that pole, reporting the Monmouth races with more ease and with better results and quicker time than ever before. Besides being an expert operator, Mr. Northrup is a first-class lineman, which makes him at all times a valuable man to any company. The Baltimore & Ohio is enterprising to an unusual degree.—*The Electric Age.*

THE "OLD TIMERS" ASSOCIATION.

The annual convention of the Old Time Telegrapher's Association, including the United States Military Corps of Telegraphers, was held in Philadelphia, August 17 and 18. Some fifty members were present, among whom were to be found many who had risen to prominence in the telegraphic world during the past twenty years.

Among the new members elected were: Chief Walker, of the city electrical department, Mr. W. H. C. Hargrave, of the associated press, and Mr. Thomas A. Edison.

Mr. David Brooks, made an address advocating government control of the telegraph system of the country.

Mr. Brooks was unanimously elected president of the "Old Timers" for the ensuing year.

A message of greeting was sent to Charles E. Taylor, of Frankfort, Ky., the originator of the Old Timers' organization, and a committee of three was appointed to arrange for the next place of meeting. Irwin Dugan, of Louisville, was elected vice-president, and William J. Dealy, manager of the Western Union office, New York, secretary and treasurer. The report of the secretary and treasurer showed a balance of nearly $600 on hand.

The military corps convened in the afternoon. The effort is still being made by them to obtain some recognition as a separate division of the army from the government.

On Thursday all the delegates made a visit to the city's electrical department and other points of interest, and in the evening a banquet was given at the Union League Club House. The toast "The Old Timers" was responded to by J. D. Reid, of New York; "Military Telegraph Operators," by William D. Wilson, of Philadelphia; "Telegraph Operators of To-Day," by H. C. Robinson, of Philadelphia; "The City of Philadelphia," by common councilman John Bardsley; "The Ladies," by C. C. Hine, of New York; "God Bless Us All," by A. H. Bliss, of Chicago, and "The Press" by J. B. Taltavall, of New York.

THE NEW YORK ELECTRIC CLUB.

The last sea-shore meeting of the Electric Club, was held at the Hotel Brighton, Coney Island, Thursday evening, August 18th. Dinner was served at 7 o'clock, and heartily enjoyed by the members and friends in attendance. Among the guests present were Lieut. Zalinski, U. S. Army; Capt. Severo Gomez Nunez, of the Spanish army and Lieut. Remigio Goininez y Zapatero, of the Spanish navy, both the latter now stationed at Havana.

A paper on Secondary Batteries, of much interest, was read by Dr. Louis Duncan, of Johns Hopkins University, and discussed by Dr. Otto Moses, Messrs. J. M. Pendleton, C. O. Mailloux and A. J. De Camp.

FIFTH MEETING OF THE EDISON ASSOCIATION.

The fifth semi-annual convention of the Association of Edison Illuminating Companies was held at Altoona, Pa., on Aug. 10.

The President, Mr. John I Beggs, congratulated the association on the large increase of its growth. The following officers for the ensuing year were elected: president, John I. Beggs, New York city; vice-president, F. A. Copeland, LaCrosse, Wis.; secretary, J H. Vail, New York city; treasurer, Wilson S. Howell, New Brunswick, N J.; executive committee, P. B. Shaw, Williamsport; Wm. J. Hammer, Boston, Mass.; C. H. Lindenberg, Columbus, O.; J. R. McLaughlin, Detroit, Mich.; A. L. Smith, Appleton, Wis.

Important topics relating to incandescent lighting were fully and freely considered. Among the papers read and discussed were the following:

"The Edison Municipal System of Long-Distance Lighting," by W. J. Jenks, manager of the municipal department Edison Electric Light Co.

"The Commercial Value of Electric Motive Power, as supplied from Edison Central Stations," by Wm. J. Hammer, manager Edison Electric Illuminating Co., Boston, Mass.

"The Regulation of Electrical Pressures and Reduction of Lamp Breakage," by John W. Howell, electrician Edison Lamp Co.

Digitized by Google

"The Value of the Storage Battery as an Adjunct to Central Stations," by J. H. Vail, gen'l sup't Edison Electric Light Co.

"The Convenience, Economy, Luxury and Pleasure derived from the Edison Light, and the best Practice in its Application," by William S. Howell, supt. Edison Electric Illuminating Co., New Brunswick, N. J,

Careful consideration was given to the subject of the best practice of wiring buildings for the incandescent light, and the following resolution was unanimously adopted:

Resolved, That in consequence of the fact that "Underwriters'" wire, so-called, has been shown by experience to be unreliable and treacherous in its action, and we regard it as introducing injurious possibilities in all interior wiring; we discountenance its use and urge upon the attention of the companies composing this association the desirability of abolishing it entirely in the work of wiring buildings over which they severally exercise a control."

The progress of the Edison patent suits and their general condition was fully described by president Johnson, and the following resolution was unanimously adopted by the convention:

Whereas, The present status of the suits prosecuted by the Edison Electric Light Co. against the infringers of their patents (which suits have in some cases been several years in the courts) has been fully stated before this convention: and

Whereas, We, having been licensed to hold exclusive rights in our respective territories, have thereby acquired a partnership interest in the general prosperity of the Edison Electric Light Co., as depending upon the validity of the patents for our protection against the destructive effects of unscrupulous competition:

Resolved, That we, the Association of Edison Illuminating Companies, in convention assembled, desire to express our hearty commendation of the energetic efforts and policy of the parent company and the progress which has resulted, as shown by an exhaustive report made to us by president Johnson.

Resolved, That we extend to the Edison Electric Light Co. our cordial and moral support, and an assurance of our conviction that the present unprincipled rivalry now affecting some of the local companies here represented will be speedily terminated by decisions in favor of the Edison patents, thus bringing to justice all who have ignored the rights granted by the patent laws of the United States to the Edison company, as the heirs of Mr. Edison's electric light invention.

Other interesting subjects were discussed, viz: distribution of currents, overhead and underground systems; regulation of currents and pressures, economy of fuel and labor; comparative merits and commercial value of the three-wire and converter systems. Every member present expressed himself more than pleased with the prosperity of the Edison business and the growth of the association. The convention adjourned at 7 P. M. on Aug 11. The next meeting will be held at Chicago, Ill., Feb. 8, 1888.

OBITUARY.

JOSIAH P. FITCH, the well-known patent lawyer, of this city, died on August 21. He was born in Vermont in 1817, and educated at Hamilton College, Clinton, N. Y. He settled in Rome, N. Y., from 1845 to 1851, and while there owned and edited the Rome *Citizen*. Mr. Fitch was admitted to the bar from the office of O. B. Matteson, of Utica. He came to New York in 1856, and turned his attention to patent cases. He has been counsel for the Gamewell Fire Alarm Company, for the Western Union Telegraph Company, and for Charles Grafton Page, the associate of Prof. Morse, the inventor of the telegraph. Mr. Fitch had in his possession at the time of his death Page's original set of instruments. He was prominent in several electric light litigations, and up to the time of his death was conducting some very important cases

THE ELECTRICAL CLAM-BAKE.

The meeting of the National Electric Light Association at Boston suggested to president Eugene F. Phillips, of the American Electrical Works, the propriety of fixing the date of the ninth annual clam-bake about a month earlier than usual. One hundred and fifty guests were present, who showed their warm appreciation of Mr. Phillips' hospitality by their happy countenances as they gathered on board the 11 o'clock boat at Providence, on the morning of August 12th, bound for the beautiful grounds of the Vue de l'Eau Club, at Silver Spring, on the eastern shore of Narragansett Bay. Upon arriving at their destination, the usual ample preparations were found to have been made for enabling all to forget the cares of business; and rusty base-ball players made their customary attempt to demonstrate how little they knew about the national game, while alleged marksmen, with arrows and bullets, added a spice of danger to the pleasures of the day.

The accommodations of the dining-room were exactly equal to the emergency, and at half-past three the event of the day was ushered in by the welcoming words of the host, who introduced Dr. Otto A. Moses as the toast-master, who most successfully combined the intellectual and gastronomic courses in his happiest style. In response to his invitation, the gentlemen called upon for remarks promptly aided in making the occasion a pleasant one by briefly and pithily giving their personal impressions of the effects of clam-eating. Among those who were not too full for utterance were Messrs. A. Reckenzaun, Thomas D. Lockwood, Henry C. Davis, Frank Ridlon, P. H. Alexander, Ralph W. Pope, W. P. O'Donoghue, and Col. Ransom. John I. Sabin, of San Francisco, was present in spirit through a telegraphic order for two baskets of champagne.

The menu card was an artistic combination of pictorial representations of the various ingredients which enter into the composition of a Rhode Island clam-bake. Each was enclosed in the shell of a cannon fire-cracker, and went off quietly in the pockets of the guests as they left the festive scene about 6 o'clock. The general verdict was that the last clam-bake was equal in every respect to its predecessors, and all were willing to repeat the experience whenever the opportunity offers.

ELECTRIC RAILWAYS IN AMERICA.

Now in Operation.

APPLETON, WIS.—Appleton Electric Street Railway; overhead conductor, 4½ miles. 5 motor cars. Van Depoele system.
BALTIMORE, MD.—Union Passenger Railway Co.; overhead conductor. Daft system.
DENVER, COL.—Denver Tramway Co.; conduit, 4 miles. Short-Nesmith series system.
BINGHAMTON, N. Y.—Washington Street and State Asylum Electric R. R.; overhead conductor, 5½ miles. Van Depoele system.
DETROIT, MICH.—Detroit Electric Railway Co.; overhead conductor, 2 miles, 4 motor cars. Van Depoele system. Highland Park Railway Co.; overhead conductors, 3 miles, 2 motor cars.
GRATIOT, MICH.—Gratiot Electric Railway Co.: overhead conductor, 1 motor car. Van Depoele system.
KANSAS CITY, MO.—Kansas City Electric Railway Co. Henry system.
LIMA, O.—Lima Street Railway Motor and Power Co.; overhead conductor, 6¼ miles, 7 motor cars. Van Depoele system.
LOS ANGELES, CAL.—Los Angeles Electric Railway Co.; overhead conductor, 5 miles, 4 motor cars. Daft system.
MONTGOMERY, ALA.—Capital City Electric Street Railway Co.; overhead conductor, 11 miles, 20 motor cars. Van Depoele system.
PORT HURON, MICH.—Port Huron Electric Railway Co.; overhead conductors, 2¾ miles, 3 motor cars. Van Depoele system.
SCRANTON, PA.—Scranton Suburban Railway Co.; overhead conductor, 2¼ miles, 3 motor cars. Van Depoele system.
WINDSOR, CAN.—Windsor and Walkerville Electric Railway Co.; overhead conductor, 1½ miles, 1 motor car. Van Depoele system.

THE VAN DEPOELE system has been adopted at Ansonia, Conn., where the Derby Horse Railway Co. expect to have the electric motor cars running September 1. Four passenger and eight freight cars will be the output this season.

THE WEST END STREET RAILWAY CO. of Boston, will very shortly receive the car constructed for them in New York, by the Stephenson company, and equipped with Sprague motors and Julien storage batteries.

BROOKLYN CITY R. R. CO. The recent break-down of the cable line in Park avenue, has set some leading directors of the company to thinking of the advantages of electric motors.

PHILADELPHIA. Successful experimental trips are kept up with the car built for Messrs. Wharton, using Sprague motors and storage batteries of the Electrical Accumulator Co. Mr. A. Reckenzaun, whose extensive experience in electric locomotion, on both land and water, is familiar to readers of electrical journals, has directed the recent experiments of Messrs. Wharton.

THE BENTLEY-KNIGHT system will be used at Allegheny, Pa., by the Observatory Hill Pass. Railway Co. The line of 4 miles is well underway. They expect to run the road, October 1st.

MANUFACTURING AND TRADE NOTES.

THE C. & C. ELECTRIC MOTOR Co. have got up a complete motor and fan outfit for use on electric light circuits. The motor is inverted, thus making a base of the neutral portion or yoke of the field magnets. The armature shaft is thus elevated sufficiently to give the 12-inch propellor fan clearance, so avoiding belting. A key-socket is placed on the top, in which can be inserted either a short circuit plug or a lamp of proper resistance. Automatic fans are an agreeable subject nowadays.

THE SIMPLEX ELECTRICAL Co., 145 Broadway, New York, and 328 Washington street, Boston, is successfully introducing its "Campbell" insulated wires among electric light people, and earning a place in the numerous list of competitors in this field.

THE BABCOCK & WILCOX boilers will be used in the three new stations of the Edison Electric Illuminating Co., of New York, a contract having been made July 27th. The stations are planned for an aggregate of 8,700 h. p. The Babcock & Wilcox boilers have been in use at the Pearl street station of the Edison company since 1881, and have proved highly satisfactory to the managers of the lighting company. A circular recently issued by the manufacturers of these boilers gives a table exhibiting the results of some thirty tests of efficiency made at many places and extending over a period of nine years. The table indicates a very high efficiency of evaporation.

THE following is a list of central station plants which have been installed by the Westinghouse Electric Company, of Pittsburgh, Pa., up to September 1, 1887, with the number of lamps in each:

New Hampshire, Littleton, 650; Massachusetts, Pittsfield, 1,300; Connecticut, Hartford, 1,950; Torrington, 650; New York, Kingston, 1,950; Buffalo, 1,300; Staten Island, 2,600; New Jersey, Plainfield, 2,600; Trenton, 5,200; Pennsylvania, Greensburgh, 600; Tyrone, 300; Carbondale, 1,000; Pittsburgh, 7,800; South Side (Pittsburgh), 3,000; Allegheny, 2,600 (being increased to 10,000); West Virginia, Wheeling, 1,300; Parkersburgh, 1,300; Charleston, 650; Maryland, Easton, 650; Ohio, Steubenville, 650; Texas, Galveston, 1,300; Louisiana, New Orleans, 3,900; Georgia, Savannah, 1,300; Florida, Tampa, 650; Wisconsin, Beaver Dam, 650; Colorado, Ouray, 300; Ontario, Cornwall, 650.

THE following central station plants are now under construction by the same Company:

Portland, Me., 650; Springfield, Mass., 1,950; Schenectady, N. Y., 5,200; New York, N. Y., 10,000; Morristown, N. J., 650; East Liberty, Pa., 5,200; Richmond, Va., 650; St. Louis, Mo., 5,200; Minneapolis, Minn., 6,500; Denver, Col., 6,500; Colorado Springs, Col., 1,300; Lincoln, Neb., 1,950; Chattanooga, Tenn., 650; Nashville, Tenn., 650; Sheffield, Ala., 650; Austin, Tex., 2,600; making a total completed and under construction of 44 central stations, aggregating 109,200 lamps.

THE Westinghouse company are putting in quite a number of large isolated plants on the alternating system, among which are the following: Manning, Maxwell & Moore, Plainfield, N. J., 650; Baldwin Locomotive Works, Philadelphia, 2,600; Strawbridge & Clothier, Philadelphia, 1,300; Westinghouse Electric Co., Pittsburgh, 2,000.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions, 11 Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From July 19th to August 16th, 1887 (inclusive).

Alarms and Signals:—*Burglar-Alarm*, B. F. Hough, 367,523, August 2, same, 368,336, August 16. *Electrical Annunciator*, W. C. Poole and J. Schnepf, 367,925, August 9.

Clocks:—*Electric Programme-Clock*, A. J. Reams, 367,663, August 2. *Magnetic Clock*, D. Drawbaugh, 367,898. *Electric Clock System*, C. L. Clarke, 367,960, August 9.

Conductors, Insulators, Supports and Systems:—*Insulating Compound*, J. Tatham, 366,898, July 19. *Insulator*, H. K. Ruger, 367,164, July 26. *Electric Conductor*, T. S. Reed, 367,548. *Terminal for Electric Cables*, R. H. Widdicombe, 367,734. *Conduit for Electric Wires and Cables*, G. D. Sutton, 367,763, August 2. *Cable-Hanger*, F. E. Degenhardt, 368,136, August 9. *Electric Wire Clamp Insulator*, J. R. Fletcher, 368,284, August 16.

Distribution:—*System of Electric Distribution*, E. Thomson, 367,469. *Coupling Compound Dynamo-Electric Machines*, same, 367,471, August 2. *Coupling Dynamo-Electric Machines*, same, 367,866, August 9. *Electric Distribution by Secondary Batteries*, W. Hochhausen, 367,630, August 2.

Dynamos and Motors:—*Dynamo-Electric Machine*, J. W. Easton, 366,941, July 19. *Armature for Dynamo-Electric Machines*, M. J. Wightman and O. Urban, 367,080. *Means for Connecting Engines and Dynamos*, A. W. Schleicher, 367,241, July 26. *Regulator for Dynamo-Electric Machines and Motors*, E. Thomson, 367,470. *Electric Motor*, A. W. Meston, 367,651, August 2. *Commutator for Electric Generators*, O. B. Shallenberger, 367,934, August 9.

Galvanic Batteries:—*Inclosing Cell for Electric Batteries*, C. A. Faure, 366,717, July 19. *Galvanic Battery*, H. I. Harris, 367,294, July 26, H. J. Brewer, 367,359, J. Serson, 367,451, P. R. de F. D'Humy, 367,705, August 2. *Binding-Clamp for Battery Electrodes*, H. J. Brewer, 367,956. *Primary Battery*, S. W. Maquay, 368,093, August 9. *Galvanic Cell*, W. E. Case, 368,-191. *Battery Connection for Electric Conductors*, P. Bowe, 368,321, August 16.

Ignition:—*Electric Gas-Lighting System*, G. F. Perkins and J. P. Hurley, 367,-841, August 9.

Lamps and Appurtenances:—*Electric-Arc Light*, S. Doubrava, 366,938. *Electric Lamp*, C. A. Homans, 367,002, July 19. *Electric Arc Lamp*, M. J. Wightman and H. Lemp, 367,598, August 2. *Device for Holding Incandescent Lamp Filaments while the Same are being Flashed*, H. Lemp and M. J. Wightman, 366,673, July 19. *Dash-Pot for Arc Lamps*, same, 367,081. *Switch and Automatic Cut-Out*, same, 367,082, July 26. *Electric Light Switch-Board*, C. E. Scribner, 367,670, August 2.

Measurement:—*Apparatus for Measuring Electricity*, G. Forbes, 366,824, July 19.

Medical and Surgical:—*Voltaic Belt*, C. B. Judd, 366,777, July 19. *Electric Bell*, A. Owen, 368,546, August 16.

Metallurgy:—*Deposition of Platinum by Electricity*, W. A. Thoms, 367,731, August 2.

Miscellaneous:—*Electric Boot-Blacking Apparatus*, H. R. Gardner, 366,660, July 19. *Electric Test System*, J. W. Frost, 367,205. *Electrically-Actuated Vibrator*, F. B. Colman, 367,270. *Fire-Extinguisher*, C. H. Shaffer, 367,323. *Means for Individually Controlling a Number of Devices by Electricity*, C. Baxter, 367,332. *Electric Smelling-Bottle*, L. B. Fuller, 367,341. *Lightning-Rod Brace*, L. L. Mast, 367,348. *Apparatus for Extinguishing Fires on Railroad Trains*, J. F. McLaughlin, 367,350, July 26. *Electric Pyrotechnics*, J. H. Irwin, 367,402. *Electrical Ore-Detector*, L. Mellett, 367,-422. *Electric Ore Indicator*, L. Mellett and J. Prince, 367,541. *Lightning Arrester for Protecting Oil-Tanks*, D. O'Brien, 367,435. *Tubular Axle and Method of Manufacturing the Same*, A. Paterson, 367,438. *Electrical Type-Writer*, J. F. McLaughlin, 367,650. *Cable-Rack for Switch-Boards*, J. A. Seely, 367,730, August 2. *Arrester for Electric Currents*, J. P. Freeman, 367,901. *Electric Coupling*, C. Runels, 367,931. *Inclosing-Case for Electric Machines*, C. H. Hinds, 368,088. *Binding-Post*, P. J. Higgins, 368,149, August 9. *Art of Converting Chemical Energy into Electrical Energy*, W. E. Case, 368,190. *Electrical Piano*, G. F. Dieckmann, 368,195. *Electric Lock*, T. B. Hornaday, 368,212. *Circuit-Changer*, C. W. McDaniel, 368,221. *Means for Dissipating Electricity for Printing-Machines*, L. E. Bathrick, 368,315. *Electric Rock-Drill*, H. N. Marvin, 368,405 and 368,-406. *Synchronal Motor for Electrical Type-Writers*, J. F. McLaughlin, 368,411, August 16.

Railways and Appliances:—*Electric Bell-Coupler for Steam Railroads*, J. M. Duby and J. L. Edmester, 366,654. *Combined Street Railway Rail and Conduit*, G. C. Bolgiano, 366,811, July 19. *Electric Locomotive*, E. S. Shaw-367,069, July 26. *Roof for Suspended Electric Conductors*, C. J. Van De-poele, 367,475. *Electric Railway-Signal*, E. M. Chase, 367,598. *Electric Magnetic Car-Brake*, J. Herrington, 367,627. *Electro-Magnetic Railway-Brake*, C. J. Van Depoele, 367,685, August 2. *Railway-Signal*, I. H. Brown, 368,066, August 9; G. D. Burton and C. H. Magoon, 368,512, August 16. *Electro-Mechanical Brake*, G. T. Woods, 368,265, August 16.

Telegraphs:—*Quadruplex Telegraphy*, G. Smith, 366,695. *Telegraph Instrument*, W. A. Melbourne, 366,970, July 19. *Acoustic Telegraph*, J. H. Irwin, 367,042, July 26. *Printing Telegraph Receiver*, H. Mahnken, 367,720, August 2. *Printing Telegraph*, J. H. Linville, 368,217. *Submarine Signal*, J. M. Batchelder, 368,272. *Telegraph Key*, D. Kunhardt, 368,312. *Telegraphic Transmitter*, W. H. Bloom, 368,450. *Printing Telegraph*, H. Mahnken, 368,-541, August 16.

Telephones, Systems and Apparatus:—*Attachment for Telephones*, T. C. Bradford, 366,994. *Ear-Piece for Telephones*, G. A. Huewe, 367,003 and 367,004, July 19. *System of Telephonic Intercommunication*, J. A. McCoy, 367,219, July 26. *Telephone Exchange Apparatus*, W. W. Goodridge, 367,-754, August 2.

The India-Rubber and Gutta-Percha Insulating Co.

MANUFACTURERS OF

ALL KINDS OF INSULATED WIRES AND CABLES.

Guaranteed to give satisfactory service under ground and over head. Specially adapted for CHEMICAL WORKS, PAPER MILLS, DYE WORKS, COAL MINES, Etc., Etc. Prices and Samples on application.

W. M. HABIRSHAW, General Manager.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, OCTOBER, 1887.

PAN-ELECTRIC NONSUITED.

THE decision rendered in the United States Circuit Court at Boston, September 26th, in the Pan-Electric government suit to annul the Bell telephone patents, sustains the demurrer of the American Bell Telephone Co., and dismisses the case.

The opinion was written by Judge Colt. The nature of the allegations of the complaint, defect of priority in the invention, fraud in obtaining the patents, are well known to our readers. The prayer of the bill was that the court decree that said patents are and have been since the date of sealing and delivery null and void; that they were wrongfully procured to be issued by means of fraud on the part of Bell, and that the American Bell Telephone Co. be perpetually enjoined from setting up any right of claim under said letters of patent.

The Court said :—

The first and principal question raised by this demurrer is whether in the absence of any specific statute the United States, by the direction of the attorney-general can maintain a bill in equity to cancel a patent for an invention. The question is by no means free from difficulties and the decision of the courts in the few cases where the point has been raised are conflicting. Upon consideration we are of the opinion that the carefully considered decision of Judge Shipley of this circuit in the Attorney-General *vs.* Stamford Chemical Works, Bannard & Adolphus, 298, to the effect that the government in the absence of any express statute has no power to bring a bill in equity to cancel a patent, is sound, and should be followed by this court in this case. Our whole patent system rests upon a constitutional provision and the statutes passed by Congress.

After a careful examination of the Constitution and acts of Congress, and the decision of cases bearing upon such acts and articles of the Constitution, the judge arrives at the conclusion that "Congress could have provided that the Government should have the right to bring suit to cancel a patent for an invention on the ground of fraud, but Congress has not seen fit to incorporate such a provision into the patent laws, and that is sufficient answer to this bill. We think, therefore, that the history of patent legislation under the Constitution tends to show that Congress never intended this power to be exercised under the present law."

He further says that if there be any power in the Government to cancel a patent for an invention, it must exist by implication and must spring from the general principles of equity jurisprudence; and he here discusses the history and character of this power, and the procedure under it in England. The power to cancel a patent in England, he states, was in the nature of a royal prerogative, and the proceeding was by writ of *scire facias*. After an elaborate discussion of the authorities cited by counsel, he concludes as follows :

The main grounds on which the validity of the Bell patents are attacked in this bill can be raised in an infringement suit brought under section 4,920 of the Revised Statutes of the United States.

The necessity which might possibly arise in some cases for the exercise of this power by the Government seems to be wanting in this case. The question of power raised in the bill is an important one and in view of the conflict of authority, it can only be definitely settled by the Supreme Court. It is our duty in the present case, unless clearly satisfied that Judge Shipley was wrong, to follow the law as established in this circuit, in the most learned and exhaustive opinions to be found on the subject. The demurrer to the bill is sustained, and the bill is dismissed.

This dismissal of the suit to annul the Bell patents, affords the administration a very convenient opportunity to withdraw from the unpleasant predicament into which it has been betrayed by the superserviceableness or obtuseness—whichever it may be—of the Attorney-General. It is possible that an appeal to the Supreme Court may be made, but we do not look for such action. In the condition of affairs consequent upon this decision the administration may well take the ground, expressly or by implication, that having gone so far as to test in court its legal right to sue a patentee for fraud, and this having been decided adversely, its duty in behalf of the interests of the public has been discharged, and the issues in question may be left, as we have always maintained they should be, to be determined by the action of the ordinary judicial machinery.

SUBWAYS IN NEW YORK.

IT is sometimes more important to get a thing done at once than to get it done in the most perfect way. The burying of all electric wires in New York is not such a thing. The desirability, even the necessity, of providing some better system than the existing pole lines is very generally admitted. The objections to pole lines in the streets are so many, and have been so often recited in the public press that everybody is familiar with them. Yet all of them together do not constitute a public inconvenience so pressing as to justify hasty work, on immature plans, such as that undertaken by direction of the Board of Electrical Control.

Since the public agitation for the removal of the pole lines, followed by the establishment of the Subway Com-

Digitized by Google

mission, we have several times expressed our opinion that the significance and scope of the proposal to put all the electric wires in the city underground was very imperfectly apprehended by the public and by the authorities undertaking to effect it. The success of electric motors during the past two years, establishing the certainty that they will be largely employed for power throughout the city, and the development during the same period of successful means for a wide distribution of the incandescent electric light from central stations, have very largely added to the magnitude and difficulty of the problem. It has become very clear that a system of underground electric conductors will be required sufficiently comprehensive to provide facilities far in excess of the relatively simple requirements of the telegraph and telephone service. Such system must include provision for conductors of heavy currents for the supply of power and light for general distribution throughout the city. The problem seems scarcely less in magnitude and difficulty, and in its bearing upon the welfare and beauty of the city, than that of rapid passenger traffic. The inadequacy of our means of transit is apparent to every one who travels to and fro within the city; the capacities of the elevated roads are far overtaken by the requirements of the public.

We are very confident that if the work of providing the city with a system of underground electric conductors be left to the present methods of the Board of Electrical Control (substantially the old Subway Commission) and to their direction, our last state will be worse than our first. There is yet no evidence of the adoption of a comprehensive and thoroughly worked out plan, such as should be perfected before any extensive work is undertaken. Some elements of the problem seem to have been scarcely considered—for instance the distribution of wires from the conduits to blocks of buildings. It cannot be said that any conduit system has been shown to be capable of meeting permanently the difficulties of a system of general distribution. Of the several conduit systems approved by the board, some may prove serviceable for a long time, but all the work must still be considered tentative.

It is our conviction that no system of "drawing in" conduits will avail as a permanent solution of the complex and difficult problem. It seems to us more than probable that for principal routes, where many conductors, of various kinds and sizes, and for many different purposes, must be provided for, resort must be had to some form of tunnel, large enough to contain wires and cables hung in such a way that they shall be accessible at all points, and also large enough to permit the passage through it of linemen and small trucks for conveyance of conductors. That a way to accomplish the desired end of ridding the streets of pole lines, and to place all, or nearly all, electric conductors underground with safety and convenience, and to the satisfaction of the public, as well as of the electric companies, we make no doubt; but the undertaking should have the careful attention of electrical and engineering talent of the highest order, and should be carried out under the control of those who take a long look ahead and are more anxious to achieve a great public work carefully and thoroughly, than to satisfy an unreasonable public clamor for burying all wires at once.

The correspondence between the United States Electric Lighting Co. and the Westinghouse Electric Co. printed in another column, will strike most people as a somewhat novel preliminary to a patent suit.

We sometimes hear it said that electric lighting in England is at a standstill. This, we are convinced from personal observation, is an error. A year ago, last winter, while temporarily sojourning at the Midland Grand Hotel, in London, our morning slumbers after 9 A. M. were disturbed by electric light wiremen engaged in drilling a hole through a brick partition near by, for the passage of the conductors. Last winter, after the lapse of thirteen months we were there again, and were gratified to observe that the dining-room and reading-room were wired and the lamp fixtures being put up, and now it gives us pleasure to announce, on the authority of a late issue of an "esteemed transatlantic contemporary," that the greater portion of the entire plant of 250 incandescent lamps is now in successful operation. The hasty and inconsiderate manner in which plants of this size are often installed in this country needs no comment, and we therefore refrain from making any.

We were, it seems, in error last month, in saying that an electric railway conductor fell at Montgomery, Ala., occasioning the death of a horse. It was another wire which got into contact with the railway wire. But, as our old professor was wont to remark, "the principle nevertheless remains the same." A due regard to the safety of the public, requires that uninsulated conductors should not be suspended above the streets of a town, having a potential several hundred volts above that of the earth. A single fatal accident will work serious harm to electric railway interests, while the difficulty and expense of avoiding such a possibility are not enough to justify any limitation in taking precautionary measures.

The electrical exhibition of the New York Electrical Society, in connection with the annual fair of the American Institute, will, when fully under way, constitute an extremely interesting display, and will offer a better opportunity than has ever before been provided in New York for the public to become acquainted with the numerous modern applications of electricity to useful purposes. The electrical exhibit occupies about half of the floor of the main building of the institute. The list of exhibitors includes more than 60 establishments, and represents well nigh the whole field of electrical work. One of the most interesting features will be found in the historical collection of apparatus, which will embrace original apparatus of Franklin, Henry, Morse, and other distinguished investigators and inventors.

It is announced that an agreement has been consummated between the Westinghouse Electric Co. of Pittsburg and the Thomson-Houston Electric Co. of Boston, by which these two corporations are hereafter to work in harmony. Some particulars of the terms of the agreement are given in another column. It is an auspicious sign for the future of electric lighting interests, when we find two of the foremost organizations of the country, engaged in this business, instead of persisting in a long course of tedious and necessarily expensive litigation, the ultimate outcome of which can hardly be other than some form of co-operation or consolidation, have agreed to bury the hatchet in the beginning, and hereafter to devote their attention to supply the immediate and pressing demand for universal domestic lighting by electricity, and to make money for their stockholders. The latter result will undoubtedly be regarded as a most refreshing novelty in the incandescent lighting business; but there appears no reason, under the new dispensation, why it should not speedily be brought about.

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Continued from page 354.)

CHAPTER VIII.—FIELD MAGNET COILS.—(CONCLUDED.)

SHUNT MACHINES.

A SHUNT machine may, as far as the calculation of the winding of the coils is concerned, be considered as a separately excited machine whose exciter has a fixed potential, and the current from which may be made as great as is required for the coils. Most of what was said above, regarding separately excited machines in general, and this class in particular, applies, therefore, also to shunt machines.

In making the test for ampere-turns, with temporary coils, the magnets should be excited until the armature generates the required potential when the current is equal to that which is required in the external circuit and, in addition, that which is to be used in the coils. What was said regarding the potential absorbed in the coils of a series machine applies, therefore, equally well to the current required in the coils of a shunt machine.

The number of turns on the magnets is not always definite as in a series machine, but like the diameter of the wire, is generally limited to a certain range of values, from which that which best meets the conditions for cheapness or for efficiency, may be chosen, as described before. There is a definite limit to decreasing the size of the wire and therefore to increasing the number of turns, for it is evident that when the wire is smaller than a certain fixed size, which can readily be determined for each case, the total resistance will be so high that the coils will not take the current required to generate the necessary ampere-turns. It is necessary, therefore, in shunt machines, to use a comparatively large factor of safety in order to guard carefully against passing this minimum value for the diameter or maximum value for the number of turns. The only way to correct such an error in the finished machine is to increase the speed. The maximum limit to the diameter of the wire is not so sharply defined, being dependent on the heating of the coils. Should the coils be required to generate a comparatively large number of ampere-turns in a small coil space, it may always be accomplished at the expense of the efficiency, by increasing the diameter of the wire, thereby increasing the current and diminishing the number of turns, provided only that the heating limit is not exceeded.

The factor of safety used in calculating the diameter from the formula is, as in series machines, dependent on a number of factors. In ordinary cases 20 to 25% will probably be sufficient, depending on the number of errors which must be allowed for.

Should any slight differences be found to exist between the actual and the desired output of the finished machine, they may be corrected by a slight alteration in the speed. An increase of the speed will evidently increase the induction in the armature, that is, the potential at the brushes and at the magnet coils; this will increase the current in these coils, and, therefore, the magnetism, which will again increase the potential. A slight increase in speed will therefore increase the potential in a much greater proportion. For small differences it may be assumed to vary approximately as the square of the speed. To make this correction, run the finished machine until it has attained its highest temperature, and adjust the external resistance until the current has the proper strength, independently of the potential. Measure its speed, S, and the potential V at the binding posts when thus running, then if the required potential is V^1 the speed at which it should be run to correct for this potential is

$$S\sqrt{\frac{V^1}{V}}.$$

COMPOUND MACHINES.

As the magnets for compound machines generally consist of both shunt and series coils, their winding is governed by the same general principles as those given above. There remains only to determine how much of the required magnetism is to be generated by shunt coils and how much by series coils, which can readily be determined from the functions of these coils. For instance, in a simple shunt machine the difference of potential at the terminals will fall with an increase of the current, because there will be more of the potential absorbed in the machine itself in sending the inoreased current through the armature, thus making the useful or available difference of potential so much less. This will in turn diminish the current in the shunt coils, which will, by decreasing the magnetism, diminish the potential still more. If, therefore, constant potential is desired in a simple shunt machine, it will be necessary to make the armature resistance exceedingly small in order that the potential which is absorbed in it will be inappreciably small as compared with the total electromotive force of the machine. Although this can be done it is probable that the shunt machine will thereby become very large and heavy as compared to the output. If, however, series coils of a certain number of turns be added to the shunt coils, an increased current in the armature by passing through these series coils will increase the magnetism just enough to regenerate the increased potential absorbed in the armature by the greater current, and therefore the available or useful potential will be kept constant. The function of the shunt coils in a compound machine is, therefore, to generate the required potential for a small current, while that of the series coils is to generate the potential absorbed in the machine itself. For an armature with a relatively small resistance there will be required only a few turns in the series coils, while if its resistance is relatively great the number of series turns will have to be proportionally greater.

If the series coils have a relatively high resistance, due either to a comparatively large number of turns or to a limited coil space, the potential absorbed by them will become appreciable and will again cause the potential of the machine to fall with an increase of current. This can readily be corrected by adding a few more turns of the series coils to regenerate this lost potential. When constant potential machines are used for incandescent lights there is a certain amount of potential lost in the leads which increases with the current; the lamps will consequently grow less bright as more of them are turned on. In order to correct this, the writer suggested some years ago, to wind such compound machines, not for a constant potential as was usual, but for a potential which increases with the current, in order that the available potential at the lamps and not at the machine remains constant for all currents. This is done by simply increasing the series windings still more, in order to correct for the loss of potential in the leads in addition to that lost in the series coils and in the armature. Such machines are now largely used in place of the older constant potential machines. The chief advantage obtained, apart from the constant brightness of the lamps, is that the loss in the leads may then be made comparatively great, 15 to 20%, or for great distances even 30%, by which a great saving of copper will be gained, the cost of the additional lost power in the leads being small as compared with the interest on the cost of the copper of the leads if this loss were made small.

Digitized by Google

There are two methods of making the connections of compound machines, shown diagrammatically in figures 32 and 33. In the first of these, known as the ordinary compound machine, the shunt coils marked *Sh* are connected to the brushes, while the whole external current flows through the series coils *Sr*, the binding post of the machine being + and — *P*. In the second method, figure 33, known as the "long shunt" compound machine, the shunt coils are connected to the poles of the machine instead of to the armature brushes, and, therefore, the whole armature current passes through the series coils. The differences in the two methods will become more apparent when considering the calculations of the winding. In large, well proportioned machines with few series windings, the differences are very slight if at all appreciable.

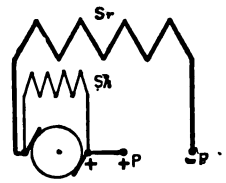

Fig. 32

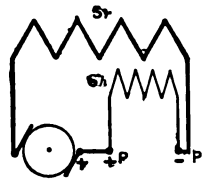

Fig. 33

The test with temporary coils for ascertaining the required ampere-turns should be made in the same way as before, but instead of testing the machine for full load only, the test should be continued for a large number of different loads, say 15 to 20, varying from full load down to open circuit, measuring in each case the ampere-turns which are required to excite the machine to the desired potential at the armature. Before making this test the machine should be examined for magnetic saturation, as will be described in a subsequent chapter, in order to ascertain whether the iron of the frame is properly proportioned for compound machines and to find what the maximum limit to the ampere-turns is. It is very necessary in compound machines not to have them oversaturated and to have the useful magnetism increase as nearly proportional to the magnetizing current as possible, which is most nearly accomplished by having much iron of good quality, evenly distributed and not too near saturation, otherwise there will be only a rough approximation to self-regulation.

The proper position of the brushes should be ascertained and fixed once for all; it should not be required to be altered for different loads, for it is evident that the machine is not self-regulating if the brushes require to be adjusted for different loads. A well proportioned compound machine should not spark perceptibly for the same position of the brushes, even when the full load is thrown off and on suddenly.

Having made all these tests and adjustments the compounding of the coils may be calculated according to the following method, which will be limited to machines compounded for constant potential at the machine or at the lamps, as these are the only kinds that have been found practicable. On a piece of cross sectional paper lay off along the vertical line, *O Y*, figure 34, on any convenient

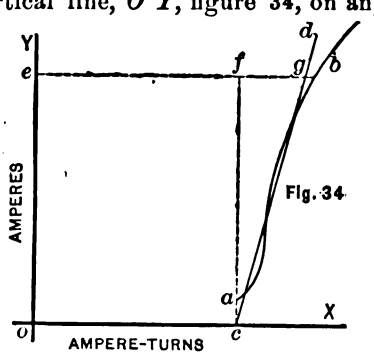

Fig. 34

scale, the currents which the machine generated in the above described test, and along horizontal lines through these points lay off the ampere-turns required in each case to excite the machine for constant potential, and draw a line, *a b*, through the points thus located. This line will, even in the best machines, be somewhat curved, particularly at the ends. The magnetization of the machine should not be continued beyond the point marked *b*, where the line begins to have a decided curvature, as the compounding is possible only for the tolerably straight portion of the curve. Draw a straight line, *c d*, through the most important points of the line, *a b*, that is through such points at which the machine is to be used most frequently; this line will then represent the nearest approach to constant potential for that machine; the greater the variation of the straight from the curved line the greater will be the variation of the potential from a constant. The deviation from this straight line will therefore show at once whether the machine is suitably proportioned for being wound for constant potential.

This line *a b* represents a certain proportion of the series and shunt coils. The horizontal distances between it and the line *O Y* represent ampere-turns required for the respective currents in the external circuit. These distances are made up of a constant portion, *e f*, and a gradually increasing portion, *f g*, which is greater in proportion to the external current. As the shunt coils are to be connected to the poles of the machine or to the armature where the potential is to be constant, the current in them and, therefore, the number of ampere-turns is constant for all loads. The constant portion *e f* or *o c* of the whole number of ampere-turns should therefore be allotted to the shunt coils, and as the ampere-turns of the series coils increases in proportion to the current in the external circuit, that portion of the whole number of ampere-turns which lies between *f c* and *d c* should be generated by the series coils. The shunt coils are therefore calculated as for an ordinary shunt machine requiring the ampere-turns represented by the distance *e f* or *o c*, while the series coils are calculated as for an ordinary series machine requiring the ampere-turns represented by *f g* when the current is that represented by *o e*.

The total energy allotted to the magnets, should be divided between the series and the shunt coils in proportion to the ampere-turns generated by them respectively, at full load, the series coils absorbing potential, and the shunt coils current. In determining the coil space for the shunt coils, care should be taken to correct for that occupied by the series coils which are usually wound first, as the real resistance might otherwise be considerably higher than the calculated, owing to the increased length. In determining the heating limit to the diameter, the total maximum number of watts which may be dissipated in the coils may be calculated from one of the formulæ given above, the cooling surface being that of the outside coil only; this total may then be divided between the coils in proportion to their number of ampere-turns, or in any other proportion provided only that the sum of the watts lost in both does not exceed this total.

The general method just described, applies only to large, well proportioned machines, or to others when only a rough approximation is desired; for smaller machines, or when the machine is to correct for loss of potential in the leads for incandescent lamps, or in cases where accuracy is desired, certain corrections are required in the calculation of the compounding of the coils. These corrections will be different, according to which of the two connections shown in figures 32 and 33 are used; they may be briefly described by the following diagrams, their importance in different cases being rendered apparent by their actual values. Referring first to figure 32, it is evident that if the shunt current is appreciably great, it should be subtracted from the armature current to give the real external and series winding current. In figure 35, therefore, in which *c d* represents the same as *c d* in figure 34, this shunt cur-

Digitized by Google

rent should be laid off at $o\,h$; the external or series winding current should, therefore, be measured from h, instead of from o, and the shunt winding calculated for $h\,i$ ampere-turns instead of $o\,c$. Furthermore, if the potential is constant at + and — P, figure 32, it will have to increase slightly at the terminals of the shunt coil for full load, owing to that consumed in the series coils, which will be appreciably great when the armature resistance is relatively great; the magnetization of the shunt coils will, therefore, increase slightly with an increased load, instead of being constant. This increased potential for the greatest load can readily be calculated by Ohm's law from the resistance and current in the series coils; let this be v, and let V be the potential at the poles + and — P, then that at the shunt coils, for full load will be $V + v$; if $h\,e$ is the maximum external current lay off $e\,k$, so that it bears the same proportion to $h\,i$, as $V + v$ does to V; in other words, make $e\,k = \frac{V+v}{V}\,(h\,i)$, then $e\,k$ will represent the magnetism of the shunt coils at full load, and will be slightly greater than $e\,f$, figure 34. The potential v, lost in the series coils must be generated again by a few additional windings of the series coils; if it takes $e\,d$ ampere-turns to generate V volts, it will require $e\,l$ ampere-turns to generate $V + v$ volts, in which by simple proportion, $e\,l = \frac{V+v}{V}\,(e\,d)$. The line $l\,i$, therefore, represents the correction of the line $d\,i$, and the series coils should be calculated from the ampere-turns represented by $k\,l$, and the external current, $h\,e$, instead of from $f\,g$ and $o\,e$, respectively, in figure 34.

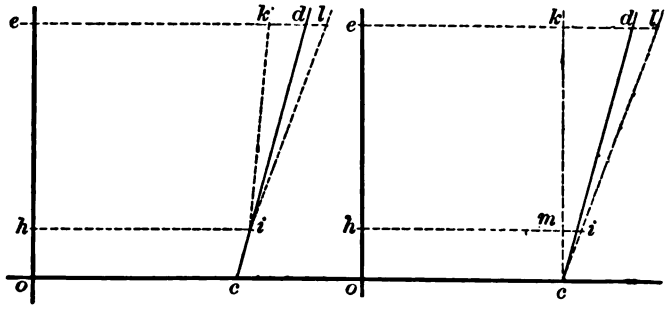

Fig. 35

Fig. 36

If the connections are as in figure 33, these corrections will be slightly different. If the potential is constant at + and — P, the current and magnetization of the shunt coils is constant, and no correction is necessary for them. In figure 36, therefore, lay off as before, $o\,h$, equal to the shunt current, then $h\,m = o\,c$, will be the shunt ampere-turns. To correct the series coils for the potential lost in them, lay off $e\,l$, determined as in figure 35, then $l\,c$, will be the correction of the line, $d\,c$, and the series coils should, as before, be calculated from the ampere-turns, $k\,l$, and the current $e\,h$. In both figures 35 and 36, these corrections are greatly exaggerated for the sake of clearness. As the shunt current in figure 33 must also pass through the series coils, they act to a certain extent as shunt coils also, though they should not be included in the calculation of the latter. In figure 36, $m\,i$ represents the ampere-turns which are generated in these series coils by the shunt coil current.

If the machine is furthermore to correct for the fall of potential in the leads, the simplest way to determine the winding, is to make the test for ampere-turns by passing the main current through a resistance equal to that which the leads are to have, and thence through the lamps or other resistance, and to excite the machine so that the potential at the end of this lead resistance remains the same for different loads. The calculations are then made as before, except that the potential at the shunt coils is not that measured at the ends of these leads, but that at the machine, which is, of course, higher, and may be either measured during the test or calculated from the resistance of the leads and the current. If this test cannot conveniently be made with a resistance equal to that of the leads, the correction of the ampere-turns may be calculated in the same way as described above, for correcting for the loss in the series coils, except that the shunt coils are not determined from the potential at the ends of these leads, but only from that at the machine.

The relative values of the two methods of connecting, shown in figures 32 and 33, may be seen by comparing figures 35 and 36. When the corrections, shown exaggerated here, are small, the two methods are practically the same, which will be the case for large, well proportioned machines. In small machines these corrections become more important, in which case there will probably be a slight advantage in favor of the second, as the shunt coils, which are the more expensive, are somewhat smaller, as seen from the distance $h\,m$, figure 36, compared to $h\,i$, figure 35, besides being subjected to a lower potential; the series coils are consequently somewhat larger, but the whole coils will be less bulky than in the first method.

Figure 34, as well as the corrections shown in 35 and 36, indicate what the most desirable general proportions are for compound machines. The curved line, $a\,b$, should be as straight as possible, which may be accomplished by using a good quality of soft iron in the field, by making the cross-section large enough to be well below the point of saturation, and by distributing it so that all parts are magnetized to about the same degree, instead of having some parts over-saturated while others are far below saturation, as is often the case. Furthermore, the inclination of the line $c\,d$, to the vertical should be as small as possible, as the variations of the potential which the series coils have to correct will then be less. This is accomplished by making the armature resistance as small as practicable. To avoid shifting of the brushes, the number of armature windings, and particularly the number of windings per armature coil, should be as small as possible. In general, all that was said in previous chapters regarding the most desirable proportions of armature and field, applies particularly to compound machines, as it is of the greatest importance to have these well proportioned. The magnets should respond quickly and readily to changes of magnetization, in order that regulation may be easily effected by the ampere-turns, over-saturation or even too close approximation to saturation should, therefore, be carefully guarded against.

From the principles of constant potential compound machines, it is evident that they will be self-regulating only for variations in the current, but not for variations in the speed or in the resistance of the coils due to heating, neither of these can be compensated for by compound winding, and it is, therefore, necessary to maintain both the speed and the heating as nearly constant as possible. Furthermore, it is necessary to run the finished machine at the same speed as that in the test, as the proportions of the series and shunt coils will be quite different for different speeds. The calculations should be made as carefully as possible, as it is not possible to correct any mistake by changing the speed as in simple shunt or series machines. If, however, a final correction is found necessary, the speed may be increased and an adjustable resistance placed in series with the shunt coils, and one as shunt to the series coils; these can be adjusted by trial to compensate for the error, and should then remain unaltered for varying loads; from the functions of the shunt and the series coils, it can readily be seen which of these two should be adjusted.[1]

1. For further information regarding the winding of field magnet coils, the reader is referred to the author's "Practical Directions for Winding Magnets for Dynamos."

PRACTICAL NOTES CONCERNING THE CONSTRUCTION, USE AND MANAGEMENT OF STORAGE BATTERIES.[1]

BY A. RECKENZAUN.

(Continued from page 304.)

DURABILITY OF STORAGE BATTERIES.

When speaking of the durability of batteries, we have to consider separately the age of positive plates, the age of negative plates and the age of the boxes or receptacles. As regards the latter, we have to take into consideration the kind and quality of the material of which the boxes are made; if these are of toughened glass which is never exposed to extremes of temperature, and if the same are not roughly handled or knocked, then we may assume that such receptacles are everlasting. For stationary purposes glass cells are generally used. In other cases, however, where the batteries have to be moved frequently, or when the same are utilized for locomotive purposes, then glass is not a reliable material and wood or hard rubber is substituted. Wooden boxes are easily attacked and destroyed by the acid, therefore it is customary to line them internally with pure sheet lead carefully burned at the joints. Such boxes are generally made of teak, or other hard wood, which is not liable to warping; when boiled in paraffine wax and pitched inside before the lead lining is fixed, wooden cells will last a long time—several years—if kept dry and clean externally. Sometimes hard rubber or ebonite boxes are used, but these are more expensive and less strong than wooden ones. Boxes have also been made of an alloy of lead of tolerable stiffness, and many other materials have been tried with more or less success. In any case, the durability of such receptacles will be found of minor consequence if compared with the durability of the electrodes. The age of plates is *the* point of vital interest; when we are asked what the life of a storage battery may be, we at once think of the plates and almost ignore everything else; and we feel mostly concerned about the positive plates. We have already explained some of the causes which destroy the positive plates, and we have shown that the *treatment* of secondary batteries has as much to do with their durability as methods of construction or quality of materials. Thick plates, for instance, are found to last longer than thin ones; this is only natural when it is remembered that corrosion takes place upon the metallic support, which wears out in time. This corrosion proceeds mainly from the surface inwards, and the internal parts of a thick plate are protected to a great extent by the mass of superincumbent material. Thick plates offer an advantage if, firstly, the cost of material is much less than the cost of manufacture, and secondly, if weight and space are of little consequence. The cost of material may, however, exceed the cost of labor, and the value of the worn-out material may have a market value not much less than the original metal; under these circumstances it might happen that it is cheaper to renew the plates frequently rather than increase their volume. Weight and space are of the utmost importance in secondary batteries used for electric cars and boats, and in such cases we make the plates as light as compatible with strength of structure, almost irrespective of the cost of labor and the price of lead. Here we have to take into account the energy continually wasted in propelling the battery along with the vehicle it propels, and the point of economy is reached when the depreciation of the battery equals the cost of the motive power which is spent in this auto-propulsion. By decreasing the weight of material we reduce the activity of the plates, or the *rate* at which the current is consumed, and the life of the plates is to a great extent proportional to the amount of work done. In every instance we reach a certain limit which has to be considered with reference to any particular application. If the frequency with which plates have to be renewed is such as to cause little inconvenience, then one stage of the durability difficulty has been overcome. Frequent renewals do not cause a deal of inconvenience when systematically carried out, as would be the case with tramways, but in electric light installations much annoyance is likely to result through such a process, therefore it is advisable on several grounds to produce durable and strong plates for stationary purposes.

From the *Telegraphic Journal and Electrical Review* (London).

DURABILITY *vs.* WASTE OF ENERGY.

Let us make a rough calculation to show the relative losses which occur in the case of tram cars propelled by means of storage batteries, leaving out the question of small volume, which is merely a matter of convenience. We assume that the tractive force on a level tram line is 26 pounds per ton when the car is in motion, and that it takes 100 pounds per ton to set it in motion; furthermore, that there are some easy gradients and curves which demand a tractive force of, say, 60 pounds per ton; we may get an average of about 52 pounds per ton throughout an ordinary track when running at the rate of seven miles an hour. The saving of one ton weight in the shape of secondary batteries would, under the above conditions, represent a saving of $\frac{5280 \times 7 \times 52}{60 \times 33000} = .97$ h. p. applied at the driving wheels. If we allow efficiencies of 80 per cent. in the gearing, 80 per cent. in the motor, 75 per cent. in the accumulator and 90 per cent. in the generating dynamo, then we have a total efficiency of about 33 per cent. between the driving wheels and the steam engine; therefore, in order to produce the above tractive force upon the tram rails we require $\frac{.97}{.33} = 2.94$, or say 3 h. p. from the prime mover.

The value of a horse-power hour varies considerably according to the price of coal, of labor, and especially with the size of the engine; but we may take the cost of a steam horse-power at £12 per annum in large engines, inclusive of all charges, consequently 3 h. p. for, say 15 hours a day, will be worth £36 sterling a year. For this amount of money we can purchase three tons of new lead at the present prices, or we may employ this sum in paying wages for labor. Four pence per plate, for instance, paid for casting, pasting and fixing may be a fair remuneration, and the amount stated above (£36) would at this rate suffice for the conversion of 2,160 old positive plates into new ones. By saving weight we save power, and the point of economy is reached, as we have hinted before, when the energy wasted in propelling the accumulator of a car equals the cost of replacing worn-out plates. We cannot recover the entire quantity of lead originally put into a plate, although the weight of a worn-out plate is practically the same as that of a new one; there is necessarily some loss in the reconversion of peroxide and sulphate into metallic lead which may be valued at between 30 and 40 per cent. in money, inclusive of labor and fuel used in the furnaces.

All the above figures are approximate only; the exact values can only be ascertained when all the factors are known, and among the principal factors are firstly, the size and total weight of a car; secondly, the nature of the road and the speed to be applied; thirdly, the number of cars supplied by one charging station, and lastly, the cost of fuel, labor, and all necessary materials.

EXPERIMENTAL RESEARCHES ON THE ELECTRO-DEPOSITION OF ALLOYS.[1]

BY ALEXANDER WATT.

Believing that this subject has not been so thoroughly investigated as its importance would merit, I resolved to pursue a series of experiments to determine which metals,

1. From the *Telegraphic Journal and Electrical Review* London).

Digitized by Google

and under what conditions, would deposit, in the form of alloys, upon other metals from various solutions, setting aside all those electrolytes (cyanide solutions) from which brass, german silver and colored golds are deposited in the ordinary operations of the practical plater. I may state that my experiments were conceived more with a view to ascertain facts than to discover new processes which might be applicable to the arts. Although these experiments had no practical significance in their inception, it is possible, however, that some of the results obtained may prove useful, not only to persons engaged in electro-deposition, but also to those occupied in that important branch of the subject now recognized as "electro-metallurgy."

In preparing a series of solutions of mixed metals for electrolytic treatment, I was not unmindful of the law of Berzelius, that "out of a solution of mixed metals, the least electro-positive metal is deposited first," but as I had met with results in practice which tended somewhat to weaken my confidence in the accuracy of this law, I resolved to disregard it for the time and try, by actual experiment, whether it was reliable or otherwise. I was also aware that Prof. Silvanus Thompson had somewhat recently read a paper before the Royal Society on the "Electro-deposition of Alloys, and on the Electromotive forces of metals in cyanide solutions," in which he held, in reference to the electro-deposition of brass, bronze and german silver from cyanide solutions, that this was "apparently departing from the law of Berzelius, that out of a solution of mixed metals, the least electro-positive metal was deposited first." In the same paper Prof. Thompson states "it is well known that the electro-deposition of such alloys as brass, bronze and german silver is not practicable from mixed solutions of the sulphates or chlorides of the constituent metals." Again, Gore says: "With a solution of mixed sulphates of zinc and copper, copper anode and cathode, and a single small battery, copper alone was deposited; zinc was strongly positive to copper in this liquid by the galvanometer, and coated itself immediately with copper in it by simple immersion;" and he further adds—though why he should claim credit for the discovery it is difficult to imagine—"From these and many other experiments which I have made with similar results, we deduce the following rule:—If a liquid contains several metals or electro-positive substances, and a *weak* electric current is passed through it, only that substance which is least electro-positive will be deposited."

Having quoted the above authorities to explain what is recognized as the governing principle in connection with the electro-deposition of alloys, I may now state that, so far as my own experiments have shown, the law of Berzelius is not sustained. Indeed, the results which I have so far obtained, appear to me to render the "departures" from this law rather the rule than the exception. In order to render my experiments as uniform as possible, I employed the same number of battery cells in each case, and as the battery was very constant, and, I should add, very weak, there was practically no difference in the conditions under which each result was obtained. In following up the subject, I determined—1. To ascertain if an alloy could be obtained from acid solutions by means of a direct current. 2. Whether an alloy could be obtained upon a piece of metal by contact with another metal in the same solution. 3. Whether the same solution would yield an alloy *by simple immersion*, Under the two latter conditions of working I may say that I obtained results which, so far as my rather extensive practical experience is concerned, I was quite unprepared for. I may here remark that in the electro-deposition of alloys—brass for example—great care is necessary to prevent one or other of the constituent metals (zinc and copper) from depositing alone. I have known an instance, when working a cyanide brassing bath, in which an iron rod, suspended horizontally in the bath, received a coating of copper at one end, zinc at the opposite end, and brass of various shades of color on the intermediate surface. Again, in the same solution, with a large anode surface immersed, zinc alone would deposit; with very small anode surface, copper alone, and when the electrodes were properly balanced (not necessarily of equal surface, however) the requisite alloy—brass—was deposited of a fine golden color, provided that the cathode remained stationary in the liquid; if, on the contrary, the article was moved briskly about in the bath, copper alone would be deposited. Bearing these facts in mind, great care was taken, in carrying out the experiments under consideration, to secure the best possible conditions of working, by making such modifications as were necessary in each individual case. Moreover, since too strong or too weak a current would have produced the same results as those above indicated, care was observed to avoid error from this source.

Experiment I.—*Citrates of Copper and Zinc.*—A mixed solution of these salts was prepared, the latter salt being in excess. The solution was moderately strong, and was used cold. Five small battery cells (zinc and copper elements) in series were used. This battery, having been in use for several weeks, gave a very feeble current, but amply sufficient for the purpose. With small anode surface copper alone was deposited; with large anode surface zinc alone. When these differences were adjusted, and the suitable anode surface arrived at, the cathode—a plate of steel—received a coating of *brass*. Finding that the deposition of an alloy, *from an acid solution*, presented little or no difficulty, and verified my belief that electro-negative and electro-positive metals would deposit together in the form of an alloy, if the proper conditions of working were established, I resolved to pursue the subject on the same lines, through a series of experiments with acid solutions, and with various metals, the results of which I now desire to make known.

By Contact with Another Metal.—A plate of steel, placed in contact with a strip of zinc in the citrate of copper and zinc solution, received a coating of brass of good color on the *contact* side and copper only on the opposite side.

By Simple Immersion.—A clean strip of zinc received a yellow coating of brass immediately, and continued to do so after several immersions.

II. *Acetates of Copper and Zinc.*—A mixed solution of these salts was prepared, with the latter in excess, and worked at various degrees of concentration until the desired object was attained, namely, the deposit of an unmistakable alloy. When the solution was too strong, a powdery deposit of copper alone appeared upon the cathode; gradual dilution, with water, however, soon improved the character of the deposit, and eventually put the liquid in a proper condition to yield a deposit of brass. To obtain a coating of brass of good color from this solution, it was found necessary to immerse what may be considered a remarkably small surface of anode, that is to say, less than one-fourth of an inch of anode surface only was required to secure a coating of alloy upon a cathode surface (a steel plate) equal to at least five square inches. When the anode was allowed merely to touch the surface of the solution the steel plate instantly became coated on both sides, with brass of a good yellow color, except at the extreme end, farthest from the anode, which was tipped with zinc only. To regulate this, and place the anode opposite the entire length of the steel plate, a piece of thin brass wire was employed as an anode, and answered the desired purpose in every respect, for a freshly prepared steel plate, soon after immersion in the bath, became uniformly coated on both surfaces with brass of a very good color. Under these conditions the deposition of a genuine alloy was far more prompt than with an ordinary cyanide brassing solution.

Digitized by Google

By Contact.—A steel plate, in contact with a strip of zinc, immediately received a coating of brass on the contact side, but copper alone was deposited on the opposite side.

By Simple Immersion.—A clean strip of zinc became coated with brass immediately after immersion in the above solution.

III. *Sulphates of Copper and Zinc.*—A solution was made with these salts, the zinc salt being in excess, and, as before, the liquid was tried at various degrees of concentration, water being repeatedly added until the twin metals deposited in the form of an alloy. While adjusting the strength of the solution care was observed to regulate the anode surface until the requisite color of the deposit—yellow brass—was obtained. This point was not reached until the solution, by continued additions of water, had become exceedingly attenuated. In this state, however, a deposit of brass, of good color, was received upon a steel plate, with the weak current from the five cells before referred to.

By Contact.—A steel plate, in contact with a strip of zinc, received a coating of yellow alloy in the above solution.

By Simple Immersion.—A clean strip of sheet zinc became coated with brass in the same solution by keeping the piece of metal gently in motion while in the liquid.

IV. *Chlorides of Copper and Zinc.*—In this case a very weak solution of the mixed metals was required to obtain a deposit of brass. When, however, the proper degree of dilution had been arrived at, an alloy of zinc and copper was received upon a steel plate, exhibiting the characteristic yellow color of brass. The deposits from this solution, however, were not quite so readily obtained as with the former solutions.

By Contact.—Steel in contact with zinc received a coating of brass of an indifferent color.

By Simple Immersion.—A yellow film, but not of good color, was obtained upon a strip of zinc.

V. *Nitrates of Copper and Zinc.*—As in the last instance, an exceedingly weak solution of the mixed metals was necessary, otherwise, a black, powdery deposit only was obtained. Even with a very dilute solution much difficulty was experienced in obtaining even a trace of yellow metal, the deposit being chiefly copper of a palish tint. Patches of a yellow color were, however, visible on parts of the steel cathode, indicating the presence of an alloy.

By Contact.—A plate of steel in contact with zinc became highly iridescent in the above solution, the colored film being very adherent. No alloy obtained by this method.

By Simple Immersion.—A strip of zinc immersed in the above solution received a black deposit only.

In the preceding paper I gave the results of some experiments in which I had successfully deposited alloys from solutions of mixed metals, the salts employed being either neutral or faintly acid, but in no case alkaline. Finding that it was the general belief amongst physicists and others that alloys could not be deposited from what I will term *acid solutions*, in contradistinction to the cyanide baths from which alloys have hitherto been obtained, all my experiments were made with mixtures of metallic salts, more or less neutral, the exact condition apparently being of little consequence, since in some cases liquids which were positively acid gave similar results to those in a more neutral condition.

In depositing alloys (brass, for example), from cyanide solutions, it has always been found necessary to employ a current of high E. M. F. to throw down the zinc in due proportion with the copper to form brass of good color, and where batteries were employed for this purpose, Bunsen's zinc-carbon battery has always been applied by preference. Now it is a somewhat remarkable fact in connection with the experiments which I am now pursuing, that although I preferred to employ my little battery of five cells arranged in series, I successfully obtained deposits of brass when the cells were arranged in multiple arc, apparently showing that a high E. M. F. is by no means necessary to cause the electro-negative and electro-positive metals to deposit simultaneously from acid solutions. In further proof of this I have but to call attention to the fact that the alloys were also obtained without the aid of a direct current at all, that is to say, by the simple contact of a strip of zinc and a strip of steel in either of the mixed metallic solutions, and even by the simple immersion of a strip of zinc, *per se*, in the solution. The late Alfred Smee, in his admirable work, "Elements of Electro-Metallurgy," in reference to the possibility of depositing alloys electrolytically, says: "We have now to discuss the important question whether two or more metals can be reduced at the same time, and whether the metals can be thrown down conjointly with other bodies. This, considering the amazing number of solutions, is a very complex question, and only a general outline of the principles regulating these phenomena can in the present state of our knowledge [1851] be attempted. In entering upon this subject I began by selecting metals far apart in the facility of their reduction by hydrogen; the solutions of the salts of zinc and copper being mixed, only copper was reduced at the negative pole. Without detailing a mass of similar experiments, I shall at once state, as a fundamental principle, an absolute law, derived from a most extensive examination of the voltaic force, that the *voltaic circuit is invariably completed in that mode which offers least resistance to the passage of the force.* That is to say, that if a great variety of roads are offered by which that object may be effected, that the *force*, provided the road be large enough, would pass exclusively through the one offering the least resistance. * * * As a general principle, to obtain a deposit of two or more bodies on any negative pole, we must use a quantity of the voltaic force, more than sufficient to reduce the elementary substance from the compound most readily decomposed. By the first law regulating the quality of metal reduced by the voltaic current, the metal is always reduced as a sponge when hydrogen is evolved from the negative plate; therefore it would be impossible to obtain a reguline alloy in a solution of any two metals, one of which is above, the other below the evolution of hydrogen, from the particular negative pole we employ in these solutions. * * * Such is a rough sketch of the principles to be pursued for the reduction of alloys, but at present, practically, I have not reduced a perfect reguline alloy of any metal, though I feel no doubt, by following out the above principles, a person might succeed in attaining his object with some metals by a careful examination of the various salts."

The above words were written by the gifted author at a time when electro-deposition was in its infancy, and no one, up to that period, had done so much as he to popularize the art and render its pursuit comparatively easy to the non-scientific student. The results of my recent experiments, however, appear somewhat antagonistic to the principles above enunciated, concerning the deposition of alloys, for I not only obtained deposits of brass upon steel, which was perfectly reguline, adherent, and readily burnished without stripping, while hydrogen was evolved from the cathode, but also deposits of brass on steel by simple contact of a piece of zinc in many mixed metallic solutions, and also by simple immersion. It is possible that if I had read the foregoing passages in Smee's work before commencing my experiments, I might have been disposed to pursue his line of reasoning, and have endeavored to follow his precepts—in which case it is doubtful whether I should have succeeded so readily as I did in my first trial, which was really prompted, as before stated, by some observations in Prof. Silvanus Thompson's paper on this subject, recalling to my mind certain facts which I had noticed when experimenting upon the electro-deposition of alloys some years ago.

VI. *Acetates of Copper and Zinc.*—In this experi-

Digitized by Google

ment it was determined to ascertain whether an *acid brassing solution* could be obtained by the *battery process* as it is termed, and if so, whether the cathode would receive a reguline deposit of brass, as in the former cases. For this purpose about equal parts of commercial acetic acid and water were taken as the solvent solution. A strip of sheet brass was employed as an anode, and a rod of carbon for a cathode. The current was then allowed to pass, when, soon after, the liquid acquired a greenish tint near the anode; the solution was frequently stirred while the electrolysis was proceeding, and at the end of about twenty minutes the carbon cathode was replaced by a steel plate, which became partially coated with a yellow film in less than half a minute. The steel plate was now withdrawn, and the carbon cathode again immersed to allow the solution to acquire a sufficient quantity of the mixed metals to form a practical working bath. In about three-quarters of an hour from the commencement of the operation, the bath was found to have become sufficiently charged with zinc and copper to yield a ready deposit of good color, for on again immersing a prepared steel plate it became instantly coated with a film of brass of a good yellow color. After a few minutes' immersion the plate was withdrawn and well scoured with silver sand, soap and water. Finding that the coated metal withstood this treatment without stripping, it was next scoured with the sand and water only, with as much force as possible, to ascertain to what extent the deposit was adherent, and it is not saying too much to state that it required the most severe friction of moist sand, applied without soap, to remove the film, which became dislodged in this brutal fashion after a minute or two, and in a remarkably uniform manner, showing that the alloyed metals had adhered with unusual tenacity. I may here state that so far as I remember I never met with a brass deposit upon any metal so thoroughly adherent. The plate was afterwards reimmersed in the acetate bath, and allowed to receive a fairly good coating. When this had been attained, the plate was withdrawn and scoured with sand and soap as before, and after well rinsing a steel burnisher was applied, when it was noticed that the deposit felt exceedingly soft under the pressure of the tool, and had not the slightest disposition to blister, or in any way separate from the steel surface beneath. The coating of brass was, therefore, reguline in the highest degree. After coating several other pieces of metal in the same solution, by means of the direct current, the contact method was applied with the result given below.

By Contact.—A strip of steel, in contact with a strip of zinc of the same superficial surface, was immersed in the above bath, and it promptly received a coating of brass on the contact side. The reverse side, with the exception of the edges, was coated with copper only.

By Simple Immersion.—A strip of zinc became coated with a yellow film immediately after immersion; this was promoted by gently moving the piece of metal about while in the liquid.

VII.—The previous results having been obtained with five small cells arranged in series, it was determined to ascertain whether similar results could be obtained with a current of lower tension; with this view the same number of cells were arranged in multiple arc, and some of the experiments with the same solutions repeated. In this case there was a decided tendency for the copper alone to deposit, but when a larger anode surface was exposed, both metals deposited in the form of a yellow alloy.

VIII. *Sulphates of Nickel and Copper.*—I may here remark that in all my first experiments I determined to ascertain which of the metals would alloy with *copper* by electrolysis—the red color of this metal rendering it specially advantageous for the purpose. In the present experiment solutions of the respective salts were first prepared; a small quantity of the copper solution was then poured into the depositing vessel, and to this was added a somewhat larger proportion of the nickel solution. A piece of sheet copper was used as an anode, and a steel plate for the cathode. On immersing the latter a deposit of copper only was obtained. A further addition of the nickel solution was then made, and a fresh cathode immersed, with the same result, namely, copper alone appeared on its surface. A much larger addition of the nickel salt was then given, when, instead of copper alone, a darkish wavy film was obtained, which, when wiped with the finger, exhibited a film approaching the color of german silver. A still further but moderate addition of the nickel solution was then given, and the next plate, as before, received a wavy dark colored film, but it was found that when this was scoured with sand and soap, the coating exhibited positive evidence of an alloy of nickel and copper—not of so good a color as ordinary german silver however (which contains zinc also), but still an unmistakable alloy.

By Contact.—A strip of steel, in contact with a strip of zinc, was immersed in the above mixed solution, and received a coating of alloy of the same tint of color as that obtained with the battery current.

By Simple Immersion.—A film of the same character was obtained upon a strip of zinc, by briskly moving it about while in the liquid.

IX. *Tartrates of Copper and Zinc.*—A weak solution of the mixed salts was found necessary to obtain a yellow deposit from this combination. With five cells arranged in series as before, a coating of brass was deposited upon a plate of steel very readily. The deposit was of good color.

By Contact.—A steel plate, in contact with a strip of zinc, received a yellow coating of brass on the contact side in the above compound solution, copper alone on the reverse side.

By Simple Immersion.—A yellow film, but not of good color was obtained on a strip of zinc.

X. *Chlorides of Copper and Tin.*—A weak solution of the mixed salts was employed, because it was found that with stronger solutions a black powdery deposit only could be obtained upon the negative plate. When the liquid had been reduced, by gradual additions of water to a fair depositing condition, there was a slight tendency for the two metals, tin and copper, to go down together, when a large anode surface was immersed. No results of a really satisfactory character, however, were obtained with these mixed salts, either by direct current or by the contact method, while by simple immersion only a dirty yellowish film was obtained upon a strip of clean zinc.

(*To be continued.*)

RECKENZAUN'S SECONDARY BATTERY.[1]

In the *Review* for April 22d, we briefly described a form of secondary battery devised and patented by Dr. Frankland, F. R. S., and it will not escape notice that the invention of Mr. Reckenzaun is to all intents and purposes identical with the foregoing, the latter patentee, however, having the good fortune to antedate Dr. Frankland by a very short period of time only. Before entering into the details of Mr. Reckenzaun's battery it may not be amiss to dilate, although somewhat briefly, upon storage cells generally.

Among the numerous systems of secondary batteries those of the Electrical Power Storage Co., have been regarded as the most successful in the commercial sense, as well as in their constructive arrangements.

This company owns the patents of Faure, Sellon, Volckmar, Swan, and others, the first being acquired for the purpose of obtaining the use of his invention for the application of red lead or other oxides, which he pasted upon or into metallic lead supports. All the other patents held by the company control the use of perforated, indented, cor-

1. From the *Electrical Review*, London Sept. 2, 1887.

Digitized by Google

rugated, or reticulated metal supports or plates, the hollow parts of which are filled with the paste devised by M. Faure.

The Electrical Power Storage Co. and their host of imitators, amongst whom may be reckoned Julien, Epstein, Farbaky, and others, make or cast grids with square holes, somewhat conical internally, for the better retention of the oxide which is subsequently pasted into them. It is well-known that this paste expands, when converted into peroxide, through the electrolytic action in the cells when charging. This expansion takes place in each square, and consequently all over the plate, but, unfortunately, as the natural result of the varying mechanical resistance offered by the support, not *evenly*. Thus the paste in the centre of a square plate will have a considerable resistance to overcome by virtue of all the surrounding substance, whereas those parts nearer the edges encounter less opposition and expand more freely; hence the plate must become distorted, a state generally termed "buckling." Two neighboring plates, if they do not buckle in the same direction will thus come into actual contact, and in the endeavor to avoid this the manufacturers place india-rubber plugs into the plates at short distances apart, so as to render the free unsupported surfaces as small as possible. These precautions, however, do not remove the *tendency* to unequal expansion; they merely offer a rude remedy which cannot remove the *cause*. Moreover, it occurs very frequently that the lead frames burst after prolonged use, this being another result of unequal expansion.

But a worse evil than this is found in the fact that the paste detaches itself from the conical support and drops out in halves or in smaller fractions.

This invariably occurs after a time even in the stationary cells, and such a fault renders perforated plates practically useless for purposes of locomotion. When shaken in a tram-car, for instance, the detachment of the paste is promoted to a large extent, so that the plates become unserviceable in the course of a few months, or even weeks.

The life or depreciation of secondary batteries of the systems indicated depends, first, upon the time necessary to cause the bursting of the grids through buckling, or the tendency to buckle, and, secondly, upon the period of retention of the paste in the holes. Under the best conditions, we do not think we shall be in error if we say that the life of such plates does not usually exceed two years if worked to their full capacity, and this means an expense which but few electric light installations can bear, and, so far as tram-cars worked by accumulators of this description are concerned, there is little hope for success from a commercial point of view.

It may be mentioned that the india-rubber plugs form a very expensive item in the cost of secondary battery manufacture, both on account of the price of the material and the labor involved in fitting the plugs into the plates. Furthermore, the use of red lead as generally adopted renders the "forming" process at once troublesome, complicated and costly.

We will now proceed to describe the improvements effected by Mr. Reckenzaun with the view of overcoming the disadvantages which we have enumerated, the sketch shown being taken from an actual plate in our possession. The inventor prepares small cylinders of spongy or finely divided lead or other suitable porous material, and places them at short distances from each other and in regular lines upon the lower half of an indented metal die. The two halves being fitted together, molten metal, preferably lead or a suitable alloy thereof, is poured in, thus forming a resultant conglomerate plate of great strength structurally, and from which the paste cannot by any chance become disengaged. The advantages claimed for this method of construction over other types of cells are as follows:—

1. Freedom from buckling, since any possible expansion can only take place in the direction of length.

2. No possibility of the active material becoming detached.

3. No india-rubber plugs or other costly separators; sticks or rings of any insulating substance suffice to keep the plates the requisite distance apart.

4. No double process of formation is required, the positive plates being exactly similar and of the same material as the negatives. When the plates are connected up the cells are ready for immediate use.

5. No pasting in the ordinary sense is necessary; the porous cylinders are made by machinery and are consequently cheap.

6. The durability and certainty of action is vastly increased.

7. Whilst the cost of manufacture is considerably less, the depreciation is correspondingly smaller.

8. Large working capacity with small amount of material and little space—a 200 ampere hour cell measures 7½ inches × 7 inches × 10 inches high.

9. Can be discharged at any rate without materially affecting the plates.

The following comparison showing the saving of material and labor, taking the E. P. S. cells as a basis, is given as an example:—The doing away with india-rubber plugs, and substituting sticks or rings, will give a saving of six per cent. in the prime cost. The plates of the E. P. S. Co. have to be "formed" separately in forming boxes. The negatives are placed with "blind" positives and soldered up; these negatives are then subjected to the "reducing" process for a period of about three to four days. The positives again are packed into similar forming boxes with "formed" or "partially formed" negatives and then sol-

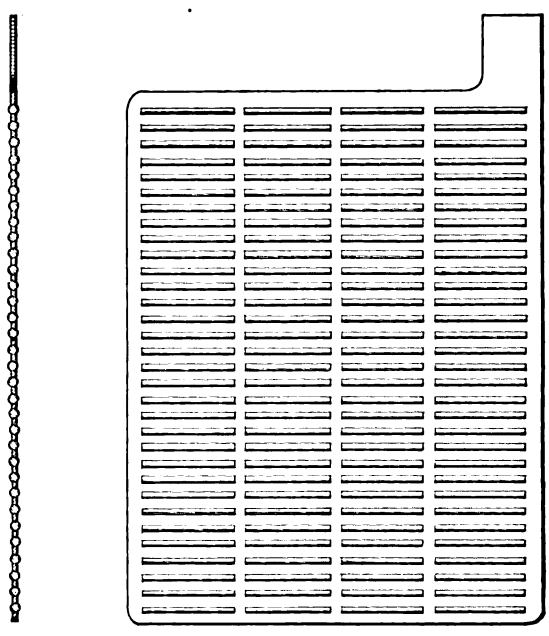

FIGURE 1.

dered up; the red lead paste is converted into peroxide and this process lasts two days. The connections of the positives and negatives have to be unsoldered again, the plates must be unpacked, and this with the double method of "forming" causes much expenditure of time, labor and material. The value of this labor is estimated at 10 per cent. on the prime cost of the battery. We regret that owing to Mr. Reckenzaun's presence in America we cannot offer our readers any data compiled from actual tests of the cells, but from casual figures obtained with a battery which has been in operation for a period of something like 18 months, and from personal inspection at intervals, we have every reason to believe that a distinct and important advance in secondary battery construction is here shown.

It is most essential that a cheap, reliable, and durable

Digitized by Google

accumulator should be forthcoming for the purposes of electric locomotion, and this we think Mr. Reckenzaun has produced.

It stands to reason that if the electrical propulsion of tram-cars is to become more general, and who can doubt that this will eventually be the case, there must be a point where the conductor system, be it overhead or in conduits, is no longer admissible, and here it is that the accumulator *must* step in.

To make our meaning still plainer the loss on a conductor increases with the length of the line, whereas the loss in the transformation of electrical energy from dynamo to battery and from battery to motor remains a constant, no matter how long the tramway. It would be very interesting if some of our electrical engineers would enter into this question, and show for what distances properly proportioned conductor systems are less costly than the self-contained car with secondary batteries, and at what point the latter bears off the palm.

THE WATERHOUSE STANDARD AMMETER.

In response to the demand created by the electric light and power industries for convenient means of measuring heavy currents, a very considerable number of ammeters have been devised and produced, of varying degrees of usefulness and reliability. In most of them permanent magnets or metal springs have been employed as a directive force against the action of the current to be measured. As neither of these forces is absolutely constant an accurate permanent calibration is unattainable with their use.

In the Waterhouse ammeter both permanent magnets and springs are discarded, the indicator being maintained at o by gravity, and actuated in its movement by the repulsive force of like poles of electro magnets.

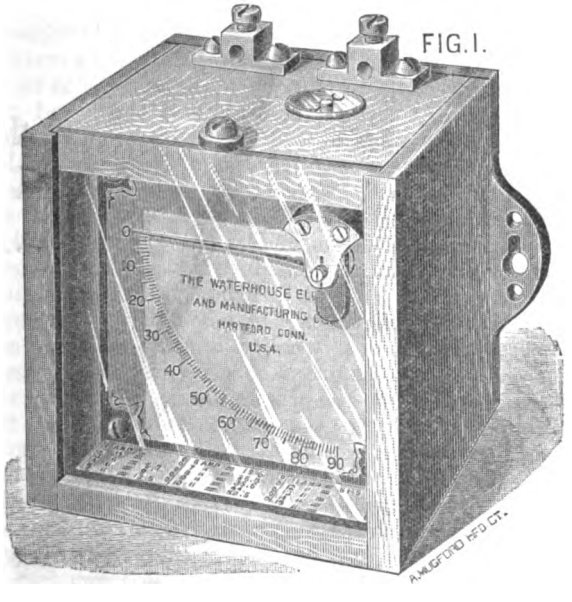

Figure 1, shows the ammeter complete.

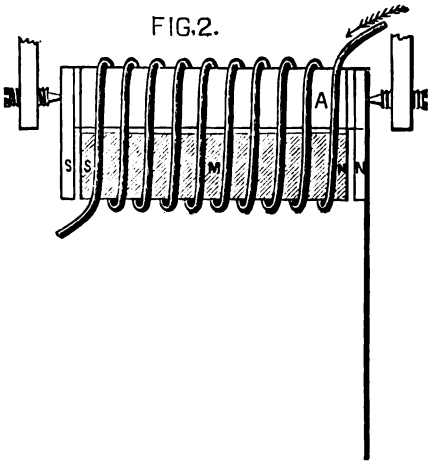
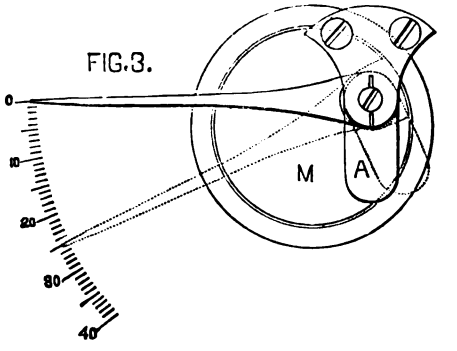
On the top are the binding posts for circuit wires, and also a small compass for denoting the direction of the current. The front presents a dial with silver indicator, and on the base is a table on which the calibration of the instrument is recorded. These are enclosed by a glass that is secured in position by a screw and washer on top.

The principle involved is shown in figure 2 and figure 3.

Figure 2, shows a coiled conductor wound around a stationary soft iron core, M, this core having a longitudinal slot, situated to one side of the median line of the upper edge of the periphery of the core. In this slot is placed a soft iron armature, A, which is provided with iron pendant pole pieces and a silver pointer. The armature A and its pole pieces and pointer are finely pivoted at each end and free to swing or vibrate, while the core M is stationary.



The current in the coiled conductor polarizes M and A alike, so that the poles attached to A are of the same sign as the same ends of M. The repulsion of like poles causes the pendant parts of A to swing away from the centre of the core M, as shown in figure 3, carrying the pointer as shown in dotted lines to an angle corresponding to the



strength of the current passing through the coil. When the current is cut off gravitation carries the pointer back to o.

The Waterhouse Electric and Manufacturing Co. make voltmeters also on the same principle.

ON ELECTRIC STREET CARS, WITH SPECIAL REFERENCE TO METHODS OF GEARING.[1]

BY A. RECKENZAUN, C. E.

Scarcely nine months have passed since your esteemed president, Mr. T. C. Martin, presented a paper on "Electric Street Cars" to the American Institute of Electrical Engineers. I have read this excellent paper with interest, and I have learned a great deal from it, as also from the discussion which followed. Mr. Martin compiled some very important statistics regarding the number of horse cars in actual use in the United States, and he computed them to number 25,000, for the propulsion of which no less than 120,000 horses are requisite.

1. Read before the American Institute of Electrical Engineers, New York, Sept. 20, 1887.

Digitized by Google

These figures filled me with wonderment and surprise, and when I read further on, that over 20,000 of these noble animals are rendered useless every year with overwork in street railway service, I felt it to be the duty of every engineer, electrical or mechanical, to assist with every means in his power in the emancipation of the horse from such cruel service. The percentage of loss given in the paper referred to agrees closely with our European experience. We know that the natural life of a street car horse is reduced to about four years, although it never works more than four hours a day. It seems barbarous, therefore, to employ animals for such purposes; yet, until recently no economical substitute could be found. Steam, compressed air, gas and spring motors have been tried and found inefficient. Improvements may be made in one or more of these, but at the present moment the field of enterprise is entirely open to the cable and to electricity. There are over 80 miles of cable roads in operation in the United States, more than half of which have been laid down within the last five years, and there are indications that further and rapid progress will be made with this mode of traction, particularly in hilly districts, where it is impossible to apply self-propelled cars, owing to the want of cohesion between the wheels and rails when the angle of repose is approached.

On ordinary streets with gradients of not more than five per cent., electric traction will doubtless be more economical and far more convenient than cables, for well-known reasons. Not only is the first cost of construction far cheaper than the cable and its conduit, but the efficiency of the electric system is much greater.

It is admitted that on cable tramways some 70 or 80 per cent. of the total available power is consumed in dragging the cable itself leaving a maximum of 30 per cent. for moving the cars, whereas with electric transmission over 50 per cent. can be utilized, as will be seen by the following figures, which I have obtained from experiments on the electrical railway at Frankfort, in Germany. This line is worked by the overhead conductor system. Its total length is four and one-tenth miles, double track and grooved rails. The entire circuit of the conductor is eight and one-fourth miles long, and its electrical resistance was calculated to be 1.6 ohms.

EFFICIENCY AND WORKING COSTS.

During the experiments referred to, two cars were propelled at a speed of seven and a half miles an hour; one of these cars had an electric motor, and the other was an ordinary car attached to the first, and the entire weight was ascertained to be 8.35 tons, including passengers. Electrical measurements were taken from the dynamo at the power station simultaneously with those on the car. The rails were in their usual dirty condition. When running on the level road the energy used on the cars was 3.87 horse-power, and on the generating dynamo 6.47, giving an efficiency of 59.82 per cent.; when traveling up a grade of 1 in 45, the motor gave eight horse-power and the dynamo 13.5, which again corresponds to 59 per cent. of the available electric energy. These measurements do not include the losses in the dynamo and motor, but it must be remembered that only two cars were on the road, whilst the capacity of the plant at the central station was sufficient for 14 cars. With 12 cars running under the ordinary circumstances of traffic, the steam engines were indicated, and this showed a maximum of 164 horse-power, consuming two and three-fourth tons of coal per day of 15 hours, or two and one-half pounds per indicated horse-power per hour. Reduced to car miles, the weight of coal came to 7.5 pounds, which, at three dollars a ton, would cost one cent per mile run.

The Frankfort electric railway has carried over 3,000,000 passengers since its opening in April, 1884. The working expenses in the year 1886 amounted to $24,904, including the following items:

Salaries of directors, superintendent, engineers, electricians, conductors, drivers, firemen and laborers	$13,615
Repairs of roadway, rails, cars, machinery, and buildings	5,088
Fuel (coals and kindling wood)	3,955
Oil and waste	831
Lighting and heating of buildings, lighting of cars and streets	1,415
	$24,904

The rolling stock consisted of 14 cars, all of which were used on Sundays and holidays, but only eight cars were usually running on week days. If we take an average of 10 cars, then the entire expenses would amount to $6.82 per car per day, but not more than one-third of this, or $2.27, can be reckoned for the item of traction, which should only include wages of engineers, electricians, firemen, cost of coals, oil, and repairs to machinery.

There are about a dozen electric railways in successful operation in Europe, some more extensive than the one I have just described, some smaller; but this one in Frankfort is worked at a greater expense than any of the others I know of; it has been in continuous use for nearly three and a half years, and I thought that by giving you detailed and exact figures of *one* line, I would serve your purpose better than by attempting to crowd a few generalities of all our electric tramways into the small compass of a short paper. You can take this as a safe standard of comparison with other systems of street car traction.

It will be observed, with justice, that the dynamos and motors of the Frankfort line, which was projected more than four years ago, do not yield as high an efficiency as more recent machines. This would leave us another margin. It is well to have a margin in all our estimates, for there is nothing that retards the progress of a novel enterprise more than exaggeration of facts, or statements which cannot be fully borne out in practice.

Some people are apt to base their calculations and estimates upon theoretical conditions. We should never assume perfection in the case of street railway tracks, but on the contrary we ought to adapt ourselves to the roughest of the rough in order to succeed.

TRACTIVE FORCE AND MECHANICAL RESISTANCES.

We know from experience that street rails which are exposed to dirt, grit, stones and the like, offer a resistance of at least 20 pounds per ton with the wheels in motion. Taking the loaded car at six tons, and the speed at six miles an hour, we have to exert 1.92 horse-power at the driving wheels, neglecting friction of gearing and losses in the electric motors. On narrow grooved rails, as used in England, we allow a tractive force of from 25 to 30 pounds per ton. These high resistances are readily accounted for when it is considered that the flanges of wheels frequently take a bearing on the dirt in the grooves; at the same time the wheel tires may roll on the surface of the rails, when a regular grinding action is produced. Furthermore, it occurs frequently that one wheel is running on its proper bearing surface, whilst the other, belonging to the same axle, has its flange touching the bottom of the groove, when by virtue of different circumferential velocities, additional friction is introduced. Sometimes the rails are a little out of gauge. All these points increase the tractive force requisite with grooved rails. Here in America you have few if any such rails, consequently the facilities are superior; but your rails are not so strong as those used in England and on the continent of Europe, and the foundations are less substantial. The joints are also somewhat irregular, and these faults render the motion of a car very unsteady. A ride on some of the roads in Philadelphia reminds one of a voyage on the ocean when the sea is a little rough. Then you crowd very often 70 passengers into a car which is supposed to hold about 30. All these circumstances compel us to provide plenty of power in order that every obstacle can be overcome.

Digitized by Google

The force necessary for starting a car is of course much greater than the force required for maintaining a uniform speed, and experiments show that this initial effort amounts to three times and even four times the tractive force of the car in motion. In dry weather, on curves of 50 feet radius, the resistance to traction is doubled, and on those of 35 feet radius trebled; but when the rails are wet this resistance, due to curvature, is considerably reduced. With a short wheel base, or, better still, with small trucks or radiating axles, the motion on curved rails is very much easier.

GRADIENTS.

The effect of gradients is a matter of simple calculation, and it must be provided for in designing and constructing a motor. We have calculated above, that the minimum effective power for a six ton car running at six miles an hour on the level is nearly two horse-power, exclusive of gear friction or any other waste. If we have to overcome a gradient of one per cent., for instance, the resistance due to gravity will be 22.4 pounds for each ton, or 134.4 pounds for the loaded car. Therefore, we shall require about 4 horse-power to pull this car up a grade of 1 in 100. With a 2 per cent grade we must have about three times the power used on level roads, and roughly speaking each per cent. of grade involves as much energy as the propulsion of a given weight over a horizontal road, if the speed is to be kept constant. On steep grades, however, it is customary to run a little slower, whereby some of the energy is saved, but for a car of the above weight, if it has to overcome grades of 4 per cent., it will not be safe to have less than eight horse-power available upon the driving axles. In addition to this the motor has to supply the power which is unavoidably wasted in the gearing used for transmitting motion from the armature shaft to the car axle. An ordinary street car wheel of 30 inch diameter has to revolve at least 77 times in the minute, in order to traverse a distance of seven miles an hour. Up to the present time no one has succeeded in constructing an electric motor of reasonable dimensions, weight and efficiency to work at such a low speed. Most of the existing motors revolve at from six to twelve times the above velocity ratio, therefore it became necessary to introduce speed-reducing appliances between the motor and the driving axles.

GEARING.

The problem of devising suitable gearing for street cars carrying their own motor has been and is still one of the greatest importance, and I propose now to offer a few remarks with reference to this subject, by citing some examples which came under my own observations. The conditions to be satisfied are by no means simple, and it is somewhat difficult to arrange them in their order of merit. Most engineers endeavor to retain the recognized dimensions of street cars, because great deviations therefrom involve many inconveniences, and it is wise to adhere as much as possible to the rules which have been established by custom, convenience and general utility. The fact that most of the street cars in all parts of the world are similar in shape, indicates forcibly that a particular pattern satisfies the demand. When taking that popular pattern of car and adapting it to our electrical and mechanical apparatus, we find that the space at our disposal underneath the floor and between the axles is meager and extremely limited. Within this small compass we have to fix the gearing which has to give the highest possible return of a given power; it has to be strong, durable, yet light in weight; noise and vibration have to be carefully avoided; the mechanism must be simple, certain in its action, protected from wet and dirt, and, finally, of reasonable cost. How to combine all these virtues has been the study of every engineer who has made electrical traction his serious study.

STEEL SPIRAL CORDS.

In regard to my own observations, one of the prettiest kinds of gearing in actual use is that on one of the cars of the Berlin Lichterfeld electric tramway which was constructed six and a half years ago by Messrs. Siemens and Halske. This car has a capacity for 24 passengers; it weighs when empty 3.2 tons, and makes a speed of 12 miles an hour. The electric motor is fastened under the floor in the centre of the car, having its shaft parallel to the axles. On the motor shaft is a small cast-iron pulley, which has 27 V-grooves on its rim, and within these grooves work an equal number of spiral wire cords, which transmit the motion to both axles of the four-wheeled car. The axles carry the large pulleys, one of which has 13 V-grooves on its circumference, and the other 14 grooves corresponding with those on the pulley on the motor shaft. The wheel base is five feet nine inches, consequently there is only a distance of two feet ten and a half inches between the centres of the connected pulleys.

The cords are made of a pair of steel wires wound closely upon a mandrel of about one-eighth of an inch in diameter, and when this mandrel is withdrawn there remains a stiff, yet flexible spiral, whose external diameter is scarcely $\frac{7}{64}$ of an inch. When cut to the proper length these cords are stretched over the grooves and connected at the ends by means of steel eyes and a steel link. Experiments made with this gear showed that eight spiral cords suffice for transmitting the power to the axles when the car was full of passengers, and as there are actually 27 cords the margin of safety was deemed more than sufficient. It is a pleasure to ride on this car; there is no noise or vibration, and I was told that the spirals last a long time if carefully adjusted; but this method of transmission is not sufficiently positive to warrant its application on steep grades. On this line there is no grade of over one per cent. rise.

CHAIN GEARING.

The second car on the Lichterfeld tramway, which, by the way, must be regarded as the oldest line in the world as far as continuous successful operation is concerned, has chain gearing. The motor shaft is provided with a small toothed wheel, and one of the axles carries a large wheel with teeth to correspond to the gaps in the pitch chain links. This mode of transmission causes some noise and vibration, and this car runs slower than the other with same amount of energy. This is accounted for by the greater friction on the surface of the teeth, as well as by the bending and unbending of the link joints; there is, besides, a constant probability of the comparatively heavy chain being thrown off tangentially by centrifugal force. But this kind of gearing furnishes an absolute or positive motion, which cannot be relied on by methods depending upon frictional adhesion alone.

Some four years ago I applied two pitch chains, four toothed wheels and countershaft for propelling a heavy storage battery car in London. The chains were of steel and substantially made; the wheels of phosphor-bronze correctly shaped. I found that the chain on the fast-running, first-motion shaft, rattled considerably. This chain stretched a little, when the links began to ride upon the points of the teeth, and eventually broke the teeth of the small wheel on the armature shaft. Previous to that I employed some other gear, which will be mentioned shortly.

Mr. Trail, the manager of the Portrush electric railway in Ireland, has been more fortunate than I with chain gear, but he is not perfectly satisfied, and he is now experimenting with something else. Pitch chains are also used on the Bessbrook-Newry electric railway and on the Ryde Pier cars. Mr. Holroyd Smith adopted this mode of transmission on the first cars at Blackpool, in England, but he

Digitized by Google

has since changed it to worm gearing, with which he is better satisfied.

CONICAL DISCS AND CHAINS.

About five years ago I had the idea that it might be advantageous to vary the speed of a car mechanically without interfering with the motor or even the supply circuit. I took out a patent for this in 1882, and applied it to the propulsion of a large street car. The motor was carried by a frame supported upon the axles by bearings and springs, to counteract the effects of vibration. By this arrangement the whole apparatus was rendered independent of the car body, and it could be easily detached. The speed pulleys consisted of conical discs, which, when placed face to face on a shaft, each pair formed between them a grooved pulley, and by shifting these discs on the shaft towards or from each other, the said groove could be made wider or narrower, as desired. Two pairs of discs on different shafts were connected by means of a chain, the links of which were surrounded by wedge-shaped pieces of leather. The cross-section of this chain band was thus shaped in order to fit into the V-grooves offered by the cones. When the said discs were pressed closely together, then the band assumed a position near the circumference of the discs, but when the latter were separated, then the groove widened, the band changed its position and ran on some portion of the conical surfaces nearer the centre of the pulley. Thus the effective or acting diameter of the first motion pulley was varied at will by pressure, and the cones on the second motion shaft followed suit automatically, because the length of the band was constant, and the second pair of cones was pressed together by a strong spring. This arrangement looked very nice, but its efficiency was low; there was a great waste of power through friction, and we finally abandoned it. It worked silently; it was strong and took up little room. The band slipped often when the car was starting or mounting an incline.

STRAPS AND PULLEYS.

Mr. Volk, of Brighton, England, employs leather link belts with great success, for transmitting the power of the motor to the car axle. This railway has been in operation since August, 1883. Mr. Volk tried first, single leather belts, but they broke every day or two; then he used double belts with little better results, and some three years ago he adopted the leather link belt, which has given entire satisfaction. I have seen one of the latter which has driven a car over 50,000 miles and it was not worn out yet. These belts stretch when first put on, the bearings of the countershaft are therefore made adjustable by means of a slide whereby the slack may readily be taken up. When starting the car the belts slip a little, but this is not considered a disadvantage. There are no curves on the Brighton line, and I often wondered whether this method of gearing would satisfy the terrible pull on the very sharp curves which occur on some street railways.

Mr. Van Depoele has given a high testimony in favor of link belts of a special construction after using them for a considerable time, and running them at a great velocity. Like Mr. Volk, he attaches the motor to the car body in order to give it the benefit of the existing flexibility of the car springs. Mr. Van Depoele's link belts, I understand, are made of steel, with special bearing surfaces; they have been used on a line of his construction at Windsor, in Canada; at Scranton, Pa., he employs spur gearing.

SPUR GEARING.

There exists a variety of opinions on the subject of toothed wheels in connection with electric motors, and each opinion seems based upon actual experience. I have seen spur gearing used on electric cars in Europe and in this country, and I give you freely all I know about it. The first I saw was on the Moedling line, near Vienna in Austria. The noise created there was not very great, but there was occasionally some trouble due to the untimely deterioration of the teeth. This was especially remarked by the manager of the Frankfort electric railway in Germany, which is constructed on precisely the same principles, with the difference that the former runs through a country district where there is much less traffic, and the rails are laid on the tops of transverse sleepers like a steam railroad; there is less dust and mud to contend with. Between Frankfort and Offenbach, on the other hand, the rails are laid through populated streets, whereby all the disadvantages of city traffic are brought into play. The gearing of the cars on this line is very noisy and it wears out quickly. The train of wheels consists of a pinion on the motor shaft having 17 teeth, which gears into a spur wheel of 56 teeth keyed upon a countershaft. On this countershaft is a pinion of 26 teeth and this drives a spur wheel of 52 teeth, fastened to the car axle. The velocity ratio, therefore, is as 1 to 6.6, between the motor spindle and the driven axle. The armature makes about 550 revolutions when the car travels at the rate of seven and a half miles an hour. The pinions are made of hard gun metal, and they wear out in about a month. I have seen a number of rejected pinions the teeth of which were ground into the shape of a fine wedge. The spur wheels are of cast steel, and they last about ten months when in continuous service. I was surprised to see these; and what with the noise, the excessive weight and other drawbacks, it made me more than ever prejudiced against such a mode of mechanical transmission on street cars. My views on this point have, however, been somewhat modified since I have been in this country. I had the privilege of being invited to assist Mr. W. Wharton, Jr., of Philadelphia, in fitting up an electric street car. There we used a set of spur gearing which was supplied by the Sprague company. In this case the motor shaft, which runs at from 500 to 600 revolutions a minute, carries two steel pinions, one at each end of the shaft, and these pinions gear direct into two cast-iron spur wheels upon the driving axle, without any intermediate wheels. The motor is partly suspended on the axle and partly on the body of the car. We have run several hundred miles with this car under all conditions of loads, gradients and weather, on some of the roughest tracks in Philadelphia, but up to this moment not a single hitch has occurred. The gearing is practically noiseless, it is efficient and strong, and I see comparatively little indication of wear. The teeth are beautifully shaped, therefore somewhat expensive, but if they last long enough, and if they do not rattle when partially worn, this expense can be ignored. This car contains, besides its usual weight, about 3,200 pounds of storage batteries; it has to mount grades of 5 per cent., and run on curves of 35 and even 25 feet radius, which means very hard work.

FRICTION GEAR.

There is something quite fascinating in friction gear; it offers the advantages of simplicity, noiselessness, and theoretically a high efficiency; but as regards certainty of action and durability, it occupies a low position in the scale of appliances for the transmission of power. The late Prof. Fleeming Jenkin devised an apparatus a few years ago which he called "nest gearing," and of which great things were expected, and indeed it was regarded as the most perfect frictional gear ever invented.

Prof. Jenkin arranged several rollers within a ring; these rollers were in contact with a central friction wheel which was attached to the motor, and the outer ring was connected to the driven object. It is well known that in a pair of friction wheels when running together, the contact surfaces are exceedingly small, the pressure must be great, and consequently there is a rapid destruction of the said contact surfaces. Now by placing a number of rollers within a ring, not only are the contacts multiplied, but there is a perfectly balanced pressure upon all the working

Digitized by Google

parts. This kind of gearing, made of the best materials and of the finest workmanship, has been applied to the telpher line at Glynde. Its efficiency was tested and found to be somewhere near 95 per cent. In the case of telpher lines the motor and its attachments are well out of reach, suspended on tall posts, therefore dust and dirt can be absolutely excluded. The energy transmitted between the electric motor and the driving wheels averaged only 1.5 horse-power, and yet with all these advantages and the great care exercised in its construction and use, this gearing refused to act after a comparatively short space of time. The experiments were watched with intense interest by all who made mechanical science their profession, and especially by those who were seeking effective means of transmitting motion from electric motors. After a number of exhaustive tests, apparent improvements and modifications, the inventors of this nest gearing pronounced it a failure, and finally resorted to chains and cog-wheels. This fact, established after prolonged and most persistent efforts on the part of a number of the smartest mechanicians, should be a warning to all the advocates of friction gear for street car propulsion.

WORM GEARING.

Dissatisfied with the results of my early experiments I resolved to give worm gearing a trial. I collected all the data I could find in text books and from other people's experience. All the different authorities agreed on one point, and that was the efficiency, or rather the want of efficiency in worm gearing. According to various statements the *loss* with this mode of transmission was put down at from 33 to 75 per cent. This seemed to me a terrible waste of power; I was then, as now, engaged in the problem of utilizing storage batteries for street car propulsion. Storage batteries were at that time in disrepute generally, and as for putting these cumbersome things upon a car, the very idea of it was ridiculed by conservative-minded men. Certain would-be experts published their views on this subject, and they endeavored to prove mathematically that the battery could scarcely hold sufficient energy to propel its own weight, and that more than 50 per cent. of the power given by the charging dynamos was lost in the process of transformation. If they had known at the time that I proposed to introduce another energy consuming apparatus in the form of worm gearing they would have declared me a lunatic. There were, however, quite a number of extenuating circumstances which encouraged me to pursue this question. I knew, from experience, that the storage battery, if properly constructed and used, could return more than 70 per cent. of the energy expended upon it; I knew also that a certain type of cell could propel several times its own weight at a speed greater than that of a horse car.

With regard to worm gearing I found that this method of transmission was used for hoists and for actuating machine tools, and that in some cases it has been working for twenty years without requiring any expensive repairs. During all my researches I failed to discover any reliable data on the construction and use of a worm which had such a steep thread that the worm-wheel could cause it to revolve. I did not come across any publication with figures to show the efficiency of gearing where the worm-shaft revolved at a very high velocity whilst transmitting considerable power. Just at that time the valuable researches of Professors Thurston and Kimball and Mr. Beauchamp Tower, on the subject of friction and lubrication, were published, and these revealed the fact that all the long-established laws on friction were entirely wrong. The experiments of these scientists prove conclusively that the coefficient of friction varied with the velocity, and that it decreased up to certain limits, with an increase of speed between lubricated surfaces.

Furthermore, it has been demonstrated that the coefficient of friction between lubricated bearings is not .1 or .2, as so frequently stated in text books, but .003 and less, and that even with moderately bad lubrication it amounted to only .01. All these, and other considerations encouraged me in the belief that there is a fruitful field for further investigation, and I designed a set of worm gear of the following dimensions: Steel worm, turned and polished, 6 inches in diameter, 6 inches long, treble thread of 2 inches pitch; worm wheel of phosphor bronze, trimmed teeth, $15\frac{9}{32}$ inches diameter, $3\frac{1}{2}$ inch face, 24 teeth. Ratio of gear, 8 to 1. The worm was fitted to the spindle of an electric motor, and the worm wheel attached to the axle of a street car, which was supported on a frame with bearings to keep the wheels off the ground. When running empty, with the worm out of gear, the motor took 6 amperes of current, and when put in gear, but without any other load, 7.75 amperes were used to drive the apparatus at the same speed. Prony brakes were then applied to both the motor shaft and the car axle, and the power was measured on each at a given E. M. F. current and speed. The efficiency of the gearing was calculated by dividing the horse-power given off on the axle by that measured on the worm shaft, and we found that the useful effect increased with the speed, viz.: at 300 revolutions of the worm it gave 80 per cent.; at 520 revolutions, 81.1 per cent.; at 676 revolutions, 85.1 per cent., and finally at 770 revolutions, 87 per cent. These results were then compared with the electrical energy supplied to the motor in each experiment and they were found to correspond very closely, after the usual electrical losses in the motor itself were deducted. The mechanical horse-power was thus checked by the electrical horse-power, and at last I applied the well-known formulæ for the efficiency of worm gear, which is given in every book on mechanical engineering.

$$E = \frac{\cot\theta}{\cot(\theta - \Phi)} = \frac{1 - \mu\frac{p}{2\pi r}}{1 + \mu\frac{2\pi r}{p}}$$

Where θ is the angle of the worm thread,
μ the coefficient of friction,
r the radius of the worm, and
Φ the angle of repose between metal and metal
E gives the efficiency of the pair.

If the coefficient of friction is taken at .015, then the efficiency must be 87.5 per cent.

By means of the above tests and the formula we can find the coefficient of friction for the various speeds.

When this apparatus was attached to the car, I found that it required less current to propel it than it did previously with the chain gear, therefore I have always since used the worm gear. Mr. Holroyd Smith tried it recently on his cars, as already stated, and he told the meeting of the Society of Arts, in April last, that he "found it the most effective mode of transmitting the power from the motor spindle to the axle, taking all points into consideration."

With these remarks closes a short and incomplete chapter on gearing. There are other kinds of gearing which I have not touched upon. I cannot do better than to leave the subject in the able hands of members present, who, I hope, will supplement, criticize and amend the observations herein set forth, and thereby add to the general knowledge of one of the most important topics of the day. We are continually advancing; every hour marks a step forward in the direction of success. The grand general principles of the electrical transmission of energy are now well understood, but there are yet many other ways of adding to the sum of human knowledge, as for example in following up the details of construction, every one of which will add in some measure to the final triumph.

Digitized by Google

Even by relating our mistakes and failures we serve a good purpose. "There are," said Prof. Silvanus Thompson, "half-forgotten observations, unconnected, unexplained, and often exceptional in character, every one of which has a significance of its own—residual phenomena, every one of which is, to the scientific man, of a value beyond price. He who investigates them patiently may find a clue to their meaning and reap a rich reward from them. They are the finger-posts in the high road of discovery."

THE RIES "COMBINATION" CONDUIT FOR ELECTRIC STREET RAILWAYS.

None of the many new applications of electricity is at present watched with greater interest, or absorbs a larger share of the public attention, than its employment as a motive power for street railways, nor is there any field in which electricity can be more profitably employed, or on which it promises to effect a more rapid and noteworthy change for the better.

While electricity has been successfully applied on short suburban lines of railway, and is constantly growing in favor and popularity wherever introduced, its adoption for use in large cities, where the demand for cheaper and more rapid transit than that afforded by horse or cable traction is far more urgent, has up to this time been very backward. This lack of progress seems to be largely due to the difficulty and expense of providing practical and economical underground conduits for carrying the railway supply conductors; conduits that would not only serve properly to insulate and protect the conductors, securing safety and economy in the transmission of the current to the motor cars, but one that should combine with these essential qualities the requisite structural strength to withstand the severe strain and concussion of heavy street traffic.

An electric railway conduit which forms the subject of a patent granted September 20, to Mr. Elias E. Ries, of Baltimore, Md., appears to embrace features well adapted to the requirements of electric street railways in large cities. This conduit embodies a number of novel features, and bears evidence of having received very careful treatment in its design. One of its peculiarities is the provision made for carrying and distributing electric conductors, wires or cables for other purposes, the space at both sides of the conduit proper being utilized to this end. This, it is needless to say, is a very important advantage in many cases. It adds but slightly to the first cost of the conduit, and economizes space in the streets.

In the accompanying illustrations, figure 1 is a perspective view of the conduit, partially exposed to show the construction and arrangement. Figure 2 is a form of bracket for a double track railway, cast in a single piece, and having flanged openings for the reception of wire ducts, pneumatic tubes, etc. This view also shows the conduit channel with its contained supply conductors, and the arrangement of the track and slot rails. Figure 3 shows an ordinary cable railway conduit provided with electric railway conductors, arranged in such a manner (with respect to the cables and grips) that the conduit may be utilized simultaneously by both systems. This construction is of importance where an electric railway is required to turn into a street already occupied by a cable conduit.

Referring to figure 1, it will be seen that the supporting brackets are placed in a shallow trench, at intervals of four feet apart, and rest upon cross ties of concrete in order to insure a solid foundation. These brackets, have a flanged central spring, 6, forming the conduit channel, and on their upper surface are recessed for the reception of the track and slot rails, respectively, as shown. The track rails are

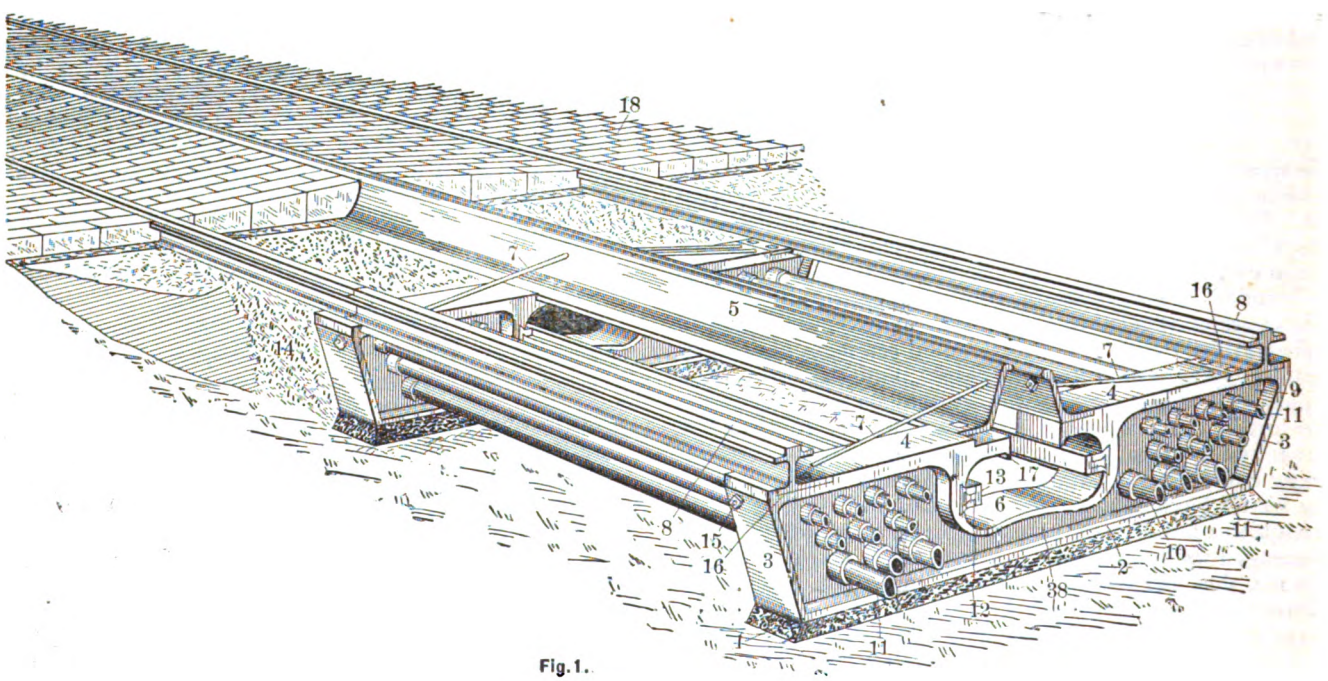


Fig. 1.

preferably of the girder type, and are self-supporting between the brackets, and they are secured in place by a locking plate, 16, so as to permit of removal without disturbing the conduit structure. The width of the conduit slot, which in this system is one-half of an inch, is regulable by means of the adjustable tie bolts 7, in the usual manner. The construction is such however, that no perceptible variation in the width of the slot, or in its distance from the rails, is possible, the entire conduit being as firmly and solidly united as if it were one single piece.

The walls of the conduit opening are provided with undercut recesses, that serve to hold insulators, 12, which are secured in place as the construction of the conduit progresses. Within these insulators the supply conductors 13 are afterwards inserted, these conductors being perfectly free to expand and contract by reason of the "slip joint" support thus formed, while at the same time sufficiently rigid to bear the pressure of the current collecting wheels that travel in a horizontal position between the two conductors. The conduit channel is provided with drainage outlets at proper

Digitized by Google

intervals, and the brackets have depending ribs, 17, that serve to deflect any water that may enter the conduit slot and to drop it clear of the conductors 13.

It will be noticed that the conduit brackets are formed with a series of flanged openings, 10, at each side of the conduit channel. These openings serve as a support for paper tubes or ducts, that are prepared in a special manner and impregnated with asphaltum to render them moisture and gas proof. These tubes extend from the centre of one bracket to the centre of the next, so as to form practically continuous tubes, and are hermetically sealed with liquid asphalt poured around a joint of special construction formed upon their ends. When the tubes between two or more brackets are in place the space between the brackets and around the conduit channel is filled with a suitable cement or concrete, which securely embeds and protects the tubes and serves as a support for the paving blocks, thus making not only a very economical and permanent conduit structure, but forming an extremely smooth, solid and durable roadbed and street surface. At intervals of one or two blocks man-holes are provided for gaining access to the ducts or tubes, and for making connection between the conductors or wires carried in the main conduit and those of branch or distributing conduits at street intersections. The interior of the paper ducts may be perfectly smooth. As the expense of providing and laying them should be comparatively small, Mr. Reis's conduit system would seem to deserve careful consideration in localities where the burying of overhead wires is receiving attention. The rental of conduits for general electrical purposes might prove a very substantial source of revenue to a street railway company.

Owing to the novel form of current collectors employed in the Ries electric railway system, which it is hoped will be described more fully in a later issue of THE ELECTRICIAN AND ELECTRICAL ENGINEER, the depth of conduit channel necessary is but six inches, and the entire depth of conduit shown in figures 1 and 2, measured from the street surface, does not exceed 18 inches, thus saving the expense and obviating the various underground obstructions common to deeper excavations.

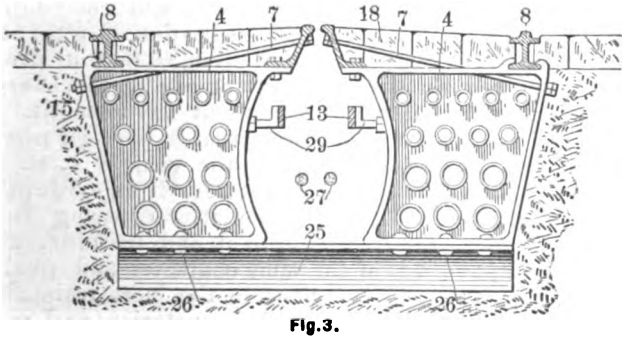

Fig.3.

It will be apparent that the wire ducts are not essential to the conduit, but may be omitted in localities where they are not required without interfering with the general construction shown.

Mr. Ries, it is understood, has devised a number of conduits differing in many respects from those forming the subject of the present article, which are specially adapted to the requirements of different localities and systems of operating. The form of conduit illustrated in figure 1, is known as "The Ries Combination Conduit, No. 3," and a special feature of all these conduits is that they are interchangeable; that is to say, the distance between the supply conductors and their depth below the street surface is the same in all cases, thus permitting motors of one railway to run with equal facility upon another line provided with a different class of conduit.

MAXIMUM WORK OF AN ALTERNATING E.M.F.[1]

BY GISBERT KAPP.

THE following investigation applies to all cases where the whole of the work is done in the circuit which receives current from some source of supply having an impressed alternating E. M. F., but it does not apply to those cases where the E. M. F. is impressed on a primary and the work is done in a secondary circuit. As an example, take the case of glow or arc lamps fed in parallel connection direct from two mains between which is maintained an E. M. F. alternating according to a simple sine function. We assume the mean value of this E. M. F. as measured by a Cardew voltmeter or a Thomson electrometer to be maintained constant whatever may be the quantity of current taken by the different lamp circuits, and the periodic time of the wave of impressed E. M. F. to be also constant.

We also assume that each parallel contains a portion having a sensible self-induction, and the problem is to find what resistance should be given to the lamp in order to

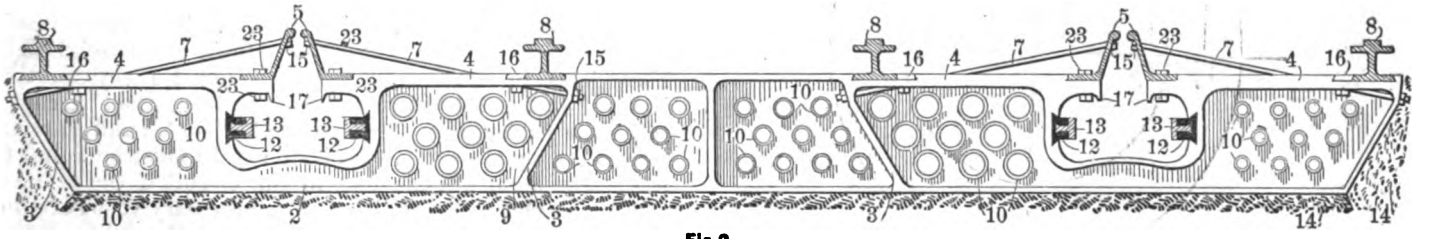

Fig.2.

use up or rather transform in it a maximum of energy with the given impressed E. M. F. With a unidirected and constant E. M. F. the lower the resistance the greater would be the energy used up in the lamp; but this is evidently not so in the case of an alternating E. M. F., since upon short circuiting the lamp completely the current does not exceed a certain maximum—which is determined by the self-induction of the circuit—and during a gradual reduction of resistance of the lamp, the current, being one of the factors determining the work, remains therefore finite, whilst the other factor (the E. M. F. over the lamp terminals) approaches zero. A maximum of work can therefore not be obtained by the simple expedient of reducing the resistance of the lamp to its lowest possible value. That an excessive increase of resistance will not accomplish the desired effect is self-evident, and we are thus led to the conclusion that between these extreme values of resistance there must be at least one special value for which the work done in the lamp becomes a maximum. The value of this particular resistance must naturally depend upon the E. M. F. of supply, the periodic time, and the self-induction of the circuit.

Before proceeding further it will be convenient to point out that the same consideration applies to a circuit fed from the secondary coil of a transformer, the primary coil of which is connected in parallel across the mains from an alternate current machine. In this case the E. M. F. appearing on the terminals of the secondary is very nearly constant if the E. M. F. between the mains is kept constant, a condition which must necessarily be fulfilled in a network of mains for public supply of electricity on the parallel system. We may therefore consider the E. M. F. induced in the secondary coil as an E. M. F. impressed upon the ter-

1. Read before the section of Mechanical Science of the British Association for the Advancement of Science, *Manchester*, September, 1887.

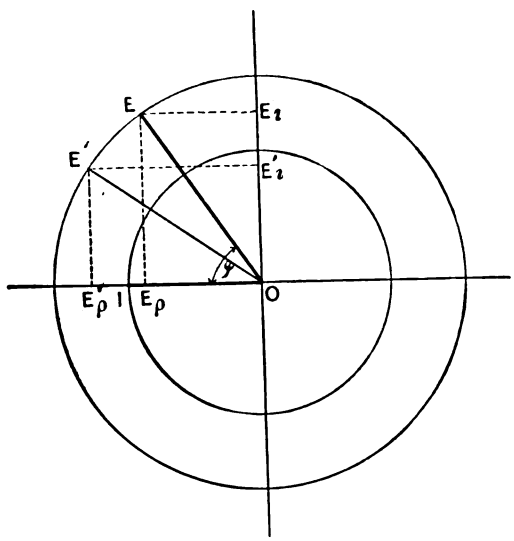
Digitized by Google

minals of the circuit in which the work is to be done, and thus our problem becomes applicable both to the direct supply and to the supply by means of transformers.

Let in the diagram $OE = E$ represent the impressed E. M. F., and $OI = I$ the resultant current, both being maxima, that is the crest of their waves, and let φ be the angle of lag. The maximum value of the E. M. F. due to self-induction is then obviously given by the line $\overline{OE_s} = E_s$, and the maximum of E. M. F. necessary to overcome the inert resistance of the circuit is given by the line $\overline{OE}\rho = E\rho$. If r denotes the resistance and L the self-induction, we have $E\rho = rI$, and $E_s = LI2\pi n$. The angle of lag, as is well known, is determined by the relation

$$ty\varphi = \frac{2\pi nL}{r}.$$

We may now represent the impressed E. M. F. and the resultant current at any moment as the projections of the two lines OE and OI on the vertical, these lines being sup-



posed to revolve round O at a fixed speed, and to always maintain their angular distance φ. Let α be their angular advance at the time t, then $e = E \sin(\alpha + \varphi)$ and $i = I \sin \alpha$ represent E. M. F. and current at that particular moment, and

$$dW = EI \sin(\alpha + \varphi) \sin \alpha \, dt$$

represents the work done during a further angular advance during time dt. If $T = \frac{1}{n}$ be the periodic time, $\alpha = 2\pi nt$ and the above equation can also be written as follows:—

$$dW = \frac{EI}{2\pi n} \sin(\alpha + \varphi) \sin \alpha \, dt$$

By integrating between the limits $\alpha = 0$ and $\alpha = 2\pi$, we obtain the work done during the time T (that of a complete period), and by dividing the result by T we obtain the work done in unit time, or the rate of doing work as generally expressed in watts. The operation gives

$$W = \frac{EI}{2} \cos \varphi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Since the mean value of E. M. F. and current measured by instruments is $\frac{1}{\sqrt{2}}$ of their maxima, we have also

$$w = ei \cos \varphi,$$

e and i being these mean values. This expression enables us to determine the work done from readings taken with a voltmeter and a current dynamometer, provided we know the resistance of the circuit. From the diagram it will be seen the angle of lag is found by the formula $\cos \varphi = \frac{ir}{e}$, and substituting we obtain $w = i^2r$, which is self evident. This result might have been obtained without introducing the E. M. F. at all; but, as will be shown presently, the investigation applies also to cases where, besides an inert resistance, there is a counter E. M. F. in the circuit, and then the term i^2r is not a correct measure for the work done, and the more general expression given in equation 1 must be used.

From a commercial point of view, it is important that the lag should be small, because the size of the dynamo and mains is governed by the product EI, whilst the work done by the dynamo is governed by the product $\frac{EI}{2} \cos \varphi$, and it is evident that if φ be very nearly 90° we would require an enormously large plant to do comparatively little work. Generally speaking, the size of the plant for a given amount of work will be inversely proportional to $\cos \varphi$. In a continuous current system there is no lag, and the whole volt-ampere capacity of the plant is actually available for useful work; in an alternate current system this capacity becomes reduced in the ratio of $1 : \cos \varphi$, and $\cos \varphi$ might therefore be considered to represent the plant efficiency of the system.

Returning now to the original problem, we have to find the condition under which the work EI $\cos \varphi$, and therefore I $\cos \varphi$, becomes a maximum. From the diagram we see that E_s or $2\pi nLI = E \sin \varphi$, and therefore $I \cos \varphi = \frac{E}{2\pi nL} \sin \varphi \cos \varphi$. To make this a maximum the angle of lag must evidently be 45°. The same result has been found analytically by Mr. Snell, and published in his articles on "Alternating and Induced Electromotive Forces," in *The Electrician* of August 13th, 1886. Graphically, the projections of OE on the horizontal and vertical must have equal length, that is to say E_s must be equal to $E\rho$. Maximum work is done in the circuit if the E. M. F. of self-induction equals the E. M. F. necessary to overcome the inert resistance. In this case the following relation must evidently obtain $r = 2\pi nL$, and by choosing the resistance so as to satisfy this equation we obtain a maximum of work from the given mean E. M. F. e, and in a circuit of given self-induction L. The E. M. F. which is used to drive the current through this resistance is .709 of the impressed E. M. F., and this figure represents also the plant efficiency of the system.

The above law of maximum work is capable of application to the case of a series wound electromotor worked by an alternating current. An ordinary series wound continuous current motor can be worked by an alternating current if the field is sufficiently laminated to prevent the formation of eddy currents. There are certain reasons which render it inexpedient and uneconomical to work any apparatus for the utilization of alternating currents at high degrees of saturation, so that in practice the strength of field of such a motor can be considered as strictly proportional to the current at any moment. In a motor of this kind the flow of current is opposed not only by its inert resistance, but also by the counter E. M. F. developed in the coils of the armature. It is evident that at constant speed of rotation the latter opposing force is proportional to the strength of field, and therefore also to the current, and it is of the same character and period as the E. M. F. necessary to overcome the inert resistance of the circuit. Retaining the above notation, and writing ki for the counter E. M. F. of the armature, where k is a co-efficient depending on the constructive data of the machine and on its speed, but not on the periodic time and self-induction, we have at any moment $e\rho = (r + k)i$, and the condition of maximum work is $r + k = 2\pi nL$. In order that the motor may absorb maximum work, it should be so constructed that the sum of the counter E. M. F. of the armature and the E. M. F. necessary to overcome its inert resistance equals the E. M. F. of self-induction. In order to obtain a high efficiency, r must be small

Digitized by Google

as compared with k, and in this case we may as a rough approximation neglect r, and say that the motor will give out maximum work if its counter E. M. F. equals the E. M. F. of self-induction. This law has a striking resemblance to Jacobi's law of maximum work obtainable from a continuous current motor. There the condition is that the counter E. M. F. should equal the E. M. F. necessary to overcome the inert resistance of the circuit; but whilst in this case the commercial efficiency must be less than 50 per cent. in the alternate current system it may be much more. In so far the alternate current motor would seem to have an advantage over the continuous current motor, but this advantage could scarcely be realized in practice. On the one hand, we never work continuous current motors with maximum output, whilst on the other hand it will be found extremely difficult, not to say impossible, to work a series wound motor by an alternating current of reasonably short period in such way as to satisfy the above conditions for maximum work. It will generally be found that in a motor of this type, owing to the great magnetic inertia of the field, the E. M. F. of self-induction is considerably greater than the counter E. M. F. of the armature, and that to increase the latter without at the same time increasing the former, we should require to run the armature at too high a speed. But even if we cannot completely fulfill the condition of maximum work we can at least attempt to approach it, and the above investigation may serve to show in what direction improvements should be made if we wish to solve the practical problem of obtaining motive power from alternating currents. In experimenting with machines of this class it is, of course, necessary to have some easy means for the determination of the co-efficient of self-induction, angle of lag, and plant efficiency. These points can be easily determined by means of the diagram. Two experiments only are required. First, note the mean current and mean terminal pressure when the armature is prevented from revolving; and secondly, note the mean current when the armature is revolving aud doing work, the terminal pressure being adjusted to have the same value as formerly. Let, in the diagram, the line $OE\rho$ represent the E. M. F. required to overcome the inert resistance of the motor. This can be calculated from the known resistance and the measured current. By erecting a perpendicular in point $E\rho$, and prolonging to the point of intersection with the circle representing the impressed E. M. F., we find the point E, the angle of lag φ, and the horizontal projection of OE gives OE_1 the E. M. F. necessary to overcome self-induction. Since the latter is proportional to the current which has been measured, the co-efficient of self-induction can now be determined. When the armature revolves the current becomes reduced, and therefore the E. M. F. of self-induction assumes a proportionately reduced value, which in the diagram is represented by the length of the line OE'_1. To this corresponds the point E′ on the circle of impressed E. M. F., and projecting this point vertically we find $E'\rho$ as the E. M. F. necessary to overcome the counter E. M. F. of the armature and the inert resistance of the motor circuit. The latter can be calculated from the current and resistance, and thus the counter E. M. F. of the armature and the electric energy actually available for conversion can be determined.

ABSTRACTS AND EXTRACTS.

ELECTRIC TRACTION ON THE BRIGHTON DISTRICT TRAMWAY.

New ideas, even if supported by experimental evidence, are slow to make headway, and electric propulsion of street cars is no exception to this rule. Whatever may have been the causes which have delayed the development of electric tramways, a certain skepticism on the part of the public, and we fear even on the part of many engineers, was one of the most important. Many doubts arose as to the economy and efficiency of the system, and unless these points can be satisfactorily disposed of by the results of actual work on a large scale, it is hopeless to expect that the average surveyor or local board engineer, or even the engineer to a tramway company, would take upon himself the responsibility of recommending electric traction. Nor would this be desirable, for an indiscriminating adoption of new methods must include both bad and good, and in some cases lead to failures, the moral effect of which cannot easily be effaced. We have seen this process in full operation during and after the electric light "boom" of a few years ago, and electrical engineers are still suffering from the effects of it. There is not much probability that a similar thing will happen with electric traction. We have entered into a period of sober and conscientious work, and although the development may seem slow, it is very sure.

In this respect some excellent work has been done quietly by the Electric Traction Syndicate, Limited, of which Viscount Bury, Lord Egerton, of Tatton, Mr. R. Macpherson, Mr. M. Immisch, and many other men of high standing, are members. The members of the syndicate have set themselves the problem of finding by actual trials, on a large scale, the best battery, motor, and gear for automotor cars, and having done so, to introduce electric traction on tram lines. So far as may be judged from a visit to their line at Southwick, they have succeeded with the first part of their programme, and there is little doubt that they will succeed equally well with the second part, and that through their instrumentality electric tram-cars will become familiar objects on some of the metropolitan lines. Those who are still skeptical about this method of propulsion cannot do better than pay a visit to the Shoreham and West Brighton line, and watch the behavior of the electric cars. This line has been chosen on account of the great difficulties it offers to electric, and in fact to any kind of traction; the syndicate rightly judging that if they can succeed on a road having curves of only 30 feet radius, and gradients as steep as one in 20, they will succeed on any other line. On Tuesday last we had an opportunity of inspecting the line and riding on the electric cars. The work of the syndicate began in April last year, and included experiments with a large variety of batteries, motors, and gearing. It is perhaps too much to say that a stage of finality has already been reached, but the present plant is sufficiently developed to answer its purpose in a thoroughly practical manner, and as we said before, the technical part of the problem may now be considered solved. The accumulators used are those of Mr. Roger Tatham, of Rochdale, and the plates consist of a spiral lead grid holding the active material. Originally the inner end of the spiral was free, the current being taken off at the outer end only; but as this caused considerable internal resistance, the distance to be traversed by the current has been shortened by making the upper bends of all the spirals to touch one another by burning them together. The active material is mixed with a certain proportion of unbleached wood pulp, by which means great porosity and storing capacity are obtained. It seems that the vegetable cells of which the wood pulp is composed do not lose their quality of permitting osmose to take place across their walls, even after they have ceased to form part of the tree or plant, and thus the transfer of gases and of the liquid to and from the inner portion of the plate can take place almost as freely as if the pores were not filled by cellulose. Two sizes of accumulators are employed; the larger (A size) contains in each box 11 plates 9 inches by 6 inches, of which five are positive, whilst the smaller (B size) contains 13 plates 7 inches by 4½ inches, of which six are positive. The plates are about one-fourth inch thick, and the storage capacity is respectively 200 and 150 ampere-hours, whilst the weight of each cell complete and filled

Digitized by Google

with acid is respectively 56 pounds, and 40 pounds. The boxes are of paraffined wood lined with lead. For convenience of handling, the cells are arranged in groups, six of the A size being held in a wood and iron cradle, and four of the B size being similarly supported. The cradle adds four pounds to the weight of each cell. The large cells are used in an electric locomotive, and the small cells in the automotor cars. The electric locomotive has been built with the object of hauling exceptionally large passenger cars, and is able to move a paying load of 74 passengers, viz., 60 on the car and 14 on the locomotive. The frame consists of strong angle iron well braced and fitted with shelves for 28 cradles containing 168 boxes in all. The wheels, axle boxes, and springs are of the ordinary railway type, and the power is transmitted from a 10 n. h. p. Immisch motor by means of steel pinions on either end of the spindle to internally geared gun metal rings, bolted to the driving wheels. To insure a constant distance of centres the body of the motor is provided at one end with two sleeves embracing the axle of the driving wheels, and the other end of the motor is suspended from the frame. It is proposed to fix a second motor to the other driving axle, but at the time of our visit only one motor was fitted. This type of gearing, however, will not be used in future. Mr. Immisch proposes to place one larger motor, with a vertical spindle in a well formed between the two tiers of batteries, and to transmit the power by bevel gear to a horizontal shaft, whence four link chains will convey it to the two driving axles. The total rolling weight of the locomotive is about 12 tons, 3 tons to each wheel.

The most important for ordinary tramway work are, however, the automotor cars, of which several are ready for service. These are of the type known as summer cars, seating 21 people—10 in a central cabin and five at each end, besides the driver. The cells, 80 in number, are of the B size, and are placed under the seats, whilst the motor is attached to the under side of the floor, the driving power being transmitted to one axle only. It is a 7 n. h. p. series wound Immisch motor, running at a thousand revolutions per minute when the car travels at the rate of nine miles per hour. The weight of the car was originally one ton, but by the addition of the motor and gear, some structural alterations and strengthening, this weight has been doubled. The accumulators weigh 35cwt., and taking the weight of 21 passengers at 30cwt., we obtain a total rolling weight of 5 tons 5cwt. The wheels are 2 feet 6 inches diameter, and the wheel base is 5 feet. The speed of the car axle as compared with the motor spindle is reduced ten-fold in two steps, there being an intermediate shaft. The gear deserves special notice, link chain being used for both motions. It will certainly surprise engineers to learn that a heavy steel link chain is employed to take off power from a spindle which normally runs at a thousand revolutions, and which at times may run as fast as 1,400 revolutions. With a chain wheel six inches in diameter, this gives a linear maximum speed for the chain of 2,200 feet per minute, and we must confess that we look upon the employment of so high a speed as a bold, not to say hazardous, step. Yet in practice there seems to be no difficulty, and as far as we could see, the chain seemed to work very well indeed. It is of Hans Renold's make, with very broad links 2¼ inch pitch. The slow motion is also worked by a chain of similar type, but correspondingly heavier.

Mr. W. D. Gooch, the engineer to the syndicate, has carried out a large number of experiments to determine the co-efficient of traction on this line. An electric car offers special facilities for such work, since the work done by the motor can at any moment during the run be computed from the readings of an ampere meter and a volt meter, the efficiency of motor and gear having been previously ascertained by brake trials in the shop. In this way it was found that the average co-efficient of traction throughout the line varied between 42 pounds and 55 pounds per ton of rolling load, according to the more or less dirty state of the rails. There are, however, some very heavy gradients, on which the traction would be considerably increased. To vary the tractive force and the speed, a switch is fitted at either end of the cars by which the batteries can be put either all in series or into two parallels of 40 boxes each. In the former case the available pressure is 160 volts, and in the latter case 80 volts. During a run from Shoreland to the depot at Southwick, and from there to West Brighton, we took frequent readings of pressure and current, and found that the energy supplied to the motor with the two halves of the battery in parallel averaged about 5 h. p., and with the whole battery in series about 13 h. p., the speed during the first portion of the run being 9.4, and during the second portion 11.6 miles an hour. The most remarkable performance of the car was its taking a long gradient of one in 20 at a speed considerably faster than walking pace. The current on this occasion was 85 amperes and the pressure 140 volts, corresponding to 16 h. p. electrical energy supplied to the motor. The car appears to be under perfect control, and can be worked from either end. The reversing is done by sending the current through the armature in the reverse direction, there being two pairs of brushes, one for going forward, the other for going backward. Either pair when in position is automatically locked, so as to prevent jarring off and sparking from vibration. The electric cars were inspected and passed by General Hutchinson on the 18th inst. In concluding this brief account of our visit to the Shoreham-Brighton line, we are glad to be able to congratulate the syndicate upon the results they have achieved.—*Industries.*

THE MAGNETIC FIELD.

(On Mr. Carl Hering's "Explorations of the Magnetic Fields surrounding Dynamos" in THE ELECTRICIAN and ELECTRICAL ENGINEER, August, 1887.)

THE papers of Mr. Carl Hering on the "Explorations of the Magnetic Field surrounding Dynamos" reveal some interesting facts concerning the machines dealt with. It is true the tests were made three years ago, and with machines most of which, we presume, have become obsolete, but they are still valuable as showing how machine frames ought or ought not to be constructed with regard to magnetic distribution. The object in all dynamo construction is to obtain a strong magnetic field in the gap, between the poles of the magnet and the armature core, in which the conductor moves, and for the purpose of achieving this end some have attempted to surround the armature itself by magnetizing coils, which thus act directly to produce the strongest field where desired. It is not unlikely that by these means a stronger field may be produced in the gap for a given exciting power, but the disadvantages attending this construction—such as the difficulty of removing the armature and general inaccessibility of parts—are so great as to militate against its general adoption. The additional ampere-turns required for the production of the field is a small matter compared with the great advantages possessed by machines designed with an eye to the prompt execution of repairs. We are, therefore, inclined, these things considered, to wind the magnetizing coils not over the armature directly but on masses of iron brought into close proximity with it, content to sacrifice, in leakage across the poles, a certain portion of the field we create, but keeping the space between polar surfaces and armature core as small as possible that the sacrifice may be a minimum.

The whole of the space, through which the lines of force curve, may be considered as in the magnetic circuit, inasmuch as it serves for their conduction whether filled up with iron, copper, or air. Lines of force always form closed curves, and from Mr. Hering's maps some appear to close in curves embracing a very small area, while others stretch away out into space. It really matters

Digitized by Google

very little where the lines of force stray after they are made to go through the armature. They may go through iron or through air, the only difference being that a greater excitement is required to produce the field where it is wanted in the latter case than in the former. A curious distribution is shown by the "Jumbo" Edison machine, where the-iron part of the magnetic circuit is not of uniform section throughout. On the top side we have two sets of magnet cores, and two massive pole pieces, one above and one below, to guide the lines of force through the armature. But on the bottom side we have only one set of magnets and a thin yoke piece to complete the circuit; a great number of the lines of force going through the armature, stray therefore in the surrounding air to return to the top magnet cores. The bottom magnets and yoke are practically saturated, and on account of the high magnetic resistance resulting therefrom, a large amount of exciting power is needed to produce the requisite field in the conductor gap. In modern dynamos, with one or two exceptions, this defective construction has been avoided, the section of the yokes being always greater than the cross-section of the magnet cores on which the coils are wound. The only way to diminish leakage, and at the same time to create a field with minimum exciting power, is to put plenty of iron in the magnets with a corresponding quantity in the armature core, taking care that the lines of force are not wire-drawn in any part of the circuit.

The map of distribution in the Weston machine seems to show that there is too little iron in the armature and yokes if Mr. Hering's lines can be taken as representing by their closeness the density of the field. The maps of the Van Depoele and Thomson-Houston machines are also very instructive, the former showing how a machine ought not to be constructed, and the latter, "as usual," eclipsing everything in the extraordinary character of its field, and, according to our lights, the worst of the lot.

But these explorations show that much has yet to be learned respecting the magnetic fields. We are, in England, chiefly indebted to Dr. Hopkinson for investigations in this direction and the results he has given us concerning leakage in the two machines with which his name is associated, are very valuable, In exploring the field of an Edison-Hopkinson machine it was found that 24.4 per cent. of the lines of force passing through the magnet cores strayed outside the armature, the zinc base and iron bed-plate on which the magnets rest accounting for 10.3 per cent. In the "Manchester" machine, where the density of force lines in the armature core is much greater, and which has a ring instead of a drum, the total leakage reached as much as 30 per cent. of the lines passing through the magnet cores, showing that a small area of armature core means a greater leakage. Judging from the diagrams we should imagine that the leakage of a Thomson-Houston machine far exceeds this amount, and we trust Mr. Hering at the first opportunity will supplement what he has already done by taking quantitative observations of modern machines. It is impossible to base judgment fairly on note-book sketches, and we must confess to a weakness for seeing everything in plain figures resolved into percentages.

THE ELECTRIC LIGHTHOUSE OF TINO.

The London *Standard* of June 2d, contains the following letter, over the initials "C. P. S.":—In the course of an interesting discussion at the Institute of Civil Engineers, in December last, on the Electric Lighthouse of Tino (an islet at the mouth of Spezia Bay, opposite the beautiful promontory of Porto Venere), it was stated, as an instance of the extraordinary visibility of that light at long distances, that during the official trials in April last year, the rays of its flashes (a group of three flashes every half minute) illuminated the clock on the tower of Volterra, no less than 75 miles distant and at an altitude of over 2,000 feet above the sea level, casting a distinct shadow on the disc. The Tino light, of five or six million c. p., is one of the most powerful in the world, and was put up early last year under the direction of Cav. L. Luiggi, and the late Comm. Parodi, of Geneva, on behalf of the Italian government, the optical apparatus and machinery having been supplied by Messrs. Chance Brothers & Co., of Birmingham, according to the design of Dr. John Hopkinson, M. I. C. E., F. R. S. I have lately had frequent occasion to observe the wonderful illuminating and penetrating power of that light from various points of the Tyrrhenean littoral, and in all weathers. Thus, from a point 3,000 feet above sea level, in the Carrara mountain range, from which, on a clear night, even the oil lights of Viareggio, Leghorn, and of the islands of Capraja and Gorgona, are visible, the flashes of the Tino light shooting across the sea may be seen illuminating the whole coast of the marble district and the lower slopes of the mountains with almost magic effect. Seen from the pier of Viareggio, 30 miles distant, the brilliancy of the light is positively dazzling and the shadow it casts of the Viareggio lighthouse, or of persons walking on the pier, is distinctly observable. Nay, even in the intervals between the triple flashes, the light is clearly visible to the naked eye in the shape of a red spot just about the size and brilliancy of the old Tino oil luminary. Again, though dimmed by heavy rain and thick fog, as it has been during the last few nights, the triple flash is always clear and unmistakable, and then produces, through the quasi-opaque atmosphere, and at a distance of 30 miles, the effect of the blurred disc of the moon on a small scale. This remarkable penetrative power of the Tino light is conclusive proof, not only of how admirably it is designed and suited to its essential purpose as a guiding light under the peculiar atmospheric conditions of the Mediterranean, but also how hazardous it would be to dip—that is, to divert such light, as has been suggested by some—from the horizon to the nearer sea in foggy weather, forsooth, according to the *bene placito* of the man in charge, on the presumption that in such weather the luminous rays could not reach the horizon, and would therefore be wasted. This presumption is wholly fallacious in the Mediterranean; for in the Bay of Spezia, owing to its proximity to the Appennines, the rain fall is much greater than in other parts of the Tyrrhenean Sea, and banks of land fog can often be seen hanging over the bay and Tino, when the horizon as far as Leghorn, Gorgona, and even Corsica is perfectly clear."

PROF. TYNDALL ON LIGHTNING CONDUCTORS.

Prof. Tyndall, writing to the *Times*, says: "Your recent remarks on thunderstorms and their effects induce me to submit to you the following facts and considerations. Some years ago a rock lighthouse on the coast of Ireland was struck and damaged by lightning. An engineer was sent down to report on the occurrence, and as I then held the honorable and responsible post of scientific adviser to the Trinity House and Board of Trade, the report was submitted to me. The lightning conductor had been carried down the lighthouse tower, its lower extremity being carefully embedded in a stone, perforated to receive it. If the object had been to invite the lightning to strike the tower a better arrangement could hardly have been adopted. I gave directions to have the conductor immediately prolonged, and to have added to it a large terminal plate of copper, which was to be completely submerged in the sea. The obvious convenience of a chain as a prolongation of the conductor caused the authorities in Ireland to propose it, but I was obliged to veto the adoption of the chain. The contact of link with link is never perfect. I had, moreover, beside me a portion of a chain cable through which a lightning discharge had passed, the electricity in passing from link to link en-

Digitized by Google

countering a resistance sufficient to enable it to partially fuse the chain. The abolition of resistance is absolutely necessary in connecting a lightning conductor with the earth, and this is done by closely embedding in the earth a plate of good conducting material and of large area. The largeness of area makes atonement for the imperfect conductivity of earth. The plate, in fact, constitutes a wide door through which the electricity passes freely into the earth, its disruptive and damaging effects being thereby avoided. These truths are elementary, but they are often neglected. I watched with interest some time ago the operation of setting up a lightning conductor on the house of a neighbor of mine in the country. The wire rope, which formed part of the conductor, was carried down the wall, and comfortably laid in the earth below, without any terminal plate whatever. I expostulated with the man who did the work, but he obviously thought he knew more about the matter than I did. I am credibly informed that this is a common way of dealing with lightning conductors by ignorant practitioners, and the Bishop of Winchester's palace at Farnham has been mentioned to me as an edifice 'protected' in this fashion. If my informant be correct, the 'protection' is a mockery, a delusion, and a snare."

FAST SPEED TELEGRAPHY.[1]

BY W. H. PREECE, F.R.S.

IN this Jubilee year of telegraphy many papers have been read, articles written, and speeches delivered on the progress made during the past fifty years, scientifically, practically, and commercially, but with very few exceptions has any justice been done to the advance made in England in the scientific direction. Sir William Thomson said, "You have told us how splendidly the land telegraphs are worked; you have pointed out how admirably under the influence of the government system the application of science to telegraphy has been developed. Under government management within these last seventeen years the applications of science to telegraphy have not stood still, but, on the contrary, have been pushed forward with every possible energy and with the most marvellous success." I want to describe the evolution of this system since it left the hands of Wheatstone and Mr. Stroh. The following table illustrates the progress made:

Year.	Words per minute.	Speed to Ireland.
1870	80	50.8
1875	100	70
1880	200	150
1885	350	250
Now	600	462

These results have been the consequences of: (1) Greater perfection of apparatus; (2) the elimination of electro-magnetic inertia; (3) the improvement of circuits; (4) introduction of high speed repeaters. Two reasons exist why these great advances have not received notice: they were not patented, and they emanated from government service. A patent has certainly one great use, it fixes a date and it defines an invention, but it also attracts attention to novelties and improvements, and if the patent be lucrative it incites the immoral to try and do the same thing in another way, and, therefore, often results in still further improvements. There is a very ridiculous conception abroad and widely circulated, that commercial enterprise alone is competent to excite inventive skill.

A complete set of automatic instruments consists of: (1) The perforator, which punches a strip of paper with holes, on the principle of the Jacquard loom, so as to regulate the number, order, and rate at which alternate currents of electricity are sent along a wire by (2) the transmitter, which is the automatic part of the apparatus, sending along the line those currents which at the distant end are recorded as words in the form of dots and dashes, replacing the slow and uncertain manipulation of the hand; (3) the receiver, which is an ink writer of extreme delicacy and great rapidity, recording the words in the Morse character.

(1) The perforator has not been much modified since it left the hands of that accomplished mechanician, Mr. Stroh. Experience has brought out several mechanically weak points, which have been much simplified and strengthened. They have been made to a standard gauge, both as regards the number of perforations per foot (the standard is 120 centre perforations per foot, or, counting the first and last perforation, 121 centre perforations per foot), the strength of springs, and the uniformity of parts, so that interchangeability is possible throughout the whole service. The fact that air pressure for working pneumatic tubes exists in many large post offices besides London has led to its application to punching, which is rather a severe mechanical labor, and it has rendered it possible by constructing double banked perforators to punch eight slips at one time, an invaluable reduction of labor in the transmission of news, which has grown to such gigantic proportions that frequently over 1,000,000 words have been sent in one evening from the Central Office in London. (2) The transmitter is an instrument designed to send as many re-

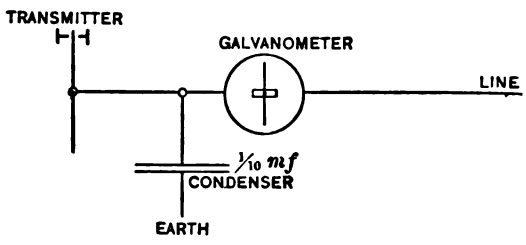
versals of current per second through the line as the retardation and the electro-magnetic inertia of the circuit will allow. These reversals are rapid alternations of positive and negative currents, the former making dots and called the marking currents, the latter making spaces and called the spacing currents. When the transmitter runs free without any paper to guide it, these currents flow through the line with a regular frequency, which is controlled by a beautiful eccentric governor invented by Mr. Stroh. This frequency in the present transmitter can be regulated from 14 up to 240 reversals per second, which means 600 words per minute. When unpunched paper is inserted a permanent current goes to line, the motion of the electrical contact that reverses the current is checked or hindered; when the paper is punched then a dot means a complete reversal, a dash means three complete reversals, but the middle one checked by the paper; a space means three complete reversals all checked by the paper. In the earlier form of transmitter the reversal was effected by a commutating arrangement which involved time, and which could not exceed a frequency of 48 or 120 words per minute. It was a very rapid double current key using one battery. In 1883 this plan was revised, a double or divided battery was used, earth being in the centre, the contacts being simple butt contacts. The mechanism was (see figure 1) much simplified, and the possible speed of working increased to a frequency of 120 or 300 words per minute. Subsequently, in 1886, the divided battery was avoided (see figure 2) by a new form of contact of the same character, but requiring only one battery, and the possible frequency was increased to 240, or a working speed of 600 words per minute. It is evident that with such rapid working the accuracy and perfection of the workmanship must be chronometric in its character. All automatic apparatus is made in the department's own workshops where mechanicians of the highest skill are employed, where standard gauges are carefully worked up to, and where the most rigid system of inspection is exercised. One source of trouble has been sparking at the points of contact which dirties them by disintegrating the metal. Small condensers of $\frac{1}{10}$ microfarad capacity have been applied thus:



which considerably modified the evil; but it has been still further reduced by switching out the galvanometer while the transmitter is at work, for sparking is principally due to the presence of electro-magnetic inertia in the apparatus. (3) The receiver has been entirely remodeled both mechanically and electrically. The principal mechanical improvement has been replacing a spring as a motor by a weight, in order to secure a more rapid and more uniform rate of running at high speeds, and as a receiver may at one moment have to record at 400 words per minute and the next at 25 when working by hand it is clear that unless some governor be used the waste of paper would be excessive. Improved flies have been applied to Stroh's eccentric governor, so as to make it act with equal efficiency at the present high speeds. Thus, the length of the signals made and the length of paper used per twelve words is practically the same at high and low speeds. It was thought at one time that the speed of working was limited by the retardation of the line circuit, but a careful inquiry into the phenomena of electro-magnetic inertia (*Journal of the Society of Telegraph Engineers*, 1887, vol. v., page 27) led me to the conclusion that the principal source of slowness was in the electro-magnet. It is not possible, owing to this electro-magnetic inertia, to establish instantaneously through a circuit containing an electro-magnet a current of the strength due to the E. M. F. producing and to the resistance regulating it. The current strength can be brought up only gradually to its proper value. Every electro-magnet in a telegraph wire becomes an obstruction to the flow of currents, especially when these currents are rapidly intermittent or rapidly reversed. In telegraphs they lower the speed of working, in telephones they blur the clearness of articulation. It is as though the passage for the flow of electricity were restricted, as the clear way of a water pipe would be choked by the presence of a large stone in the pipe, or the efficiency of a gas pipe would be reduced by its being crushed in by a blow from a hammer. But the peculiarity of the electro-magnet is that the currents themselves cause their own hindrance, and the more frequent they are the greater the throttling or choking action. The action is not dissimilar to that of the throttle valve of a steam engine actuated by a centrifrugal governor. Hence, Lord Rayleigh has lately proposed to apply the term "throttling" to this peculiar effect of electro-magnetic inertia. Every electro-magnet has thus a time constant which determines the rate beyond which it cannot work. This time constant can be obtained only by experiment, for it depends on the quality and quantity of iron used, on the form of the core, on the resistance and quality of insulated copper wire, on the number of turns, and on the way they are wound. The battle with self-induction has been a severe one. Years of labor were devoted to determine the proper conditions to reduce these disturbing elements to their minimum point of hindrance combined with efficiency, until fortunately a means was discovered to entirely eliminate their influence. Every electro-magnet wound to a resistance R has its own co-efficient of self-induction L, which determines the rate at which a current rises or falls, and the time constant is expressed by the ratio $\frac{L}{R}$. If the two plates of a condenser of capacity K be shunted by a wire of resistance R_1, then when a current flows the condenser will be charged and the current will consequently gradually rise to its full value, and if the current stops the condenser will discharge and the current will in the same way gradually fall to zero. The time constant of such a condenser is KR_1. This is exactly the same kind of action that takes place in an electro-magnet, and by properly regulating the size of the condenser and the amount of resistance the one can be made to exactly reproduce the former. Now, if we connect up an electro-magnet and a condenser in the way shown in the above diagram (figure 4), then whenever the main current ceases, there is an E. M. F. in the magnet due to L, tending to prolong the current in the direction (l), while there is an E. M. F. in the condenser K due to the charge tending to do the same thing, but in the opposite direction (k). Hence these two effects oppose and neutralize one another when the resistances R and R_1, the co-efficient L, and the capacity K are properly adjusted. Maxwell has shown that when an electro-magnet and a condenser are balanced in a Wheatstone bridge $L = RR_1K$; but in the shunted arrangement

$$L = R_1^2 K.$$

The introduction of the shunted condenser has had the most marvellous effect on the speed of working. It has entirely eliminated any hindrance caused by the electro-magnet, and now the only cause of slow working is the mechanical efficiency of the apparatus and the condition of the circuit. I have pointed out in another paper how copper wire has removed electro-magnetic inertia from the wire, and there remains only the retardation (KR) of the circuit to check speed of working. Four hundred and fifty words a minute is now obtained with ease on circuits of two hundred miles in length, and we have on some circuits reached six hundred words per minute; but 450 is more than we can practically cope with, and, therefore, at present the apparatus exceeds in efficiency the capacity of the staff; but this speed rapidly falls off as the retardation of the circuit increases, and while we can work at the highest speed between London and Leeds, we can only get one-fourth of this speed to Glasgow. If, however, we place at Leeds a repeater, which will respond to and relay on these frequent currents, we ought to get the maximum speed to Glasgow, and this is done by the high speed repeater. The high speed repeater contains on one board all the electrical functions of two transmitters and two receivers. All causes of hindrance are removed from it, and it works at the highest possible speed. Electrically, it is an exceedingly complicated piece of machinery. It owes its efficiency to the perfection of the Post Office standard relay—a relay which has practically no time constant, which responds to exceedingly delicate currents, and which makes perfect electrical contacts—and to the use of condensers. These repeaters are very extensively used. There are special relay offices at Haverfordwest, Nevin and Anglesey to provide full speed to Ireland. The speed to Ireland in 1870 was fifty words per minute. It is now 462 words—a ninefold advance. Leeds, Manchester, Bristol and Preston have also special relay rooms. There are 101 repeaters in use. Some circuits, such as those to Aberdeen, have two repeaters in circuit, one at Leeds and the other at Edinburgh. In fact, these high speed repeaters enable the highest possible speed of working to be obtained to every part of the United Kingdom. They are arranged so as to be used at will either for automatic or for ordinary key apparatus, and either for simple or for duplex working under each class of working. The introduction of high speed repeaters and the use of shunted condensers have marked epochs in the evolution of telegraphy as eventful as the introduction of duplex working or of the telephone. The various stages of improvement which have been narrated in this paper would each form the subject-matter of a patent were it the habit in the government service to patent. Had the telegraph service been conducted under the severe competition of private enterprise, each form of transmitter and of receiver, the relay, the high speed repeater, the shunted condenser, and every other improvement would have been patented, and would have been found worthy of substantial reward. I may add that in bringing about these improvements I have been most ably assisted in

the mechanical department by Mr. J. W. Willmot, now the head of our workshops, and in the electrical department by Mr. J. B. Chapman and Mr. A. Eden, both accomplished practical electricians.

Sir William Thomson, Lord Rayleigh, General Webber, and others took part in the discussion, which was chiefly of an interrogatory character, and in his reply Mr. Preece remarked that the Delaney system of multiplex telegraphy was now being rapidly developed and perfected by the post office authorities, and lines between London, Manchester and Birmingham had already been working on this system for some time. Last week a line between London and Glasgow with repeaters at Leeds was put in operation. The highest speed hitherto reached with the Wheatstone between London and Dublin was 462 words per minute the messages passing in one way, or 231 words when duplexed. Formerly when duplexing a line the total number of words sent in both directions was always greater than the number of words which could be sent in simplex working; but the fact that in the London-Dublin line there was no increase in that number by duplexing proved that the capacity of the line was fully utilized even in simplex working. A speed of twenty complete periods (forty reversals) per second corresponds to fifty words per minute.

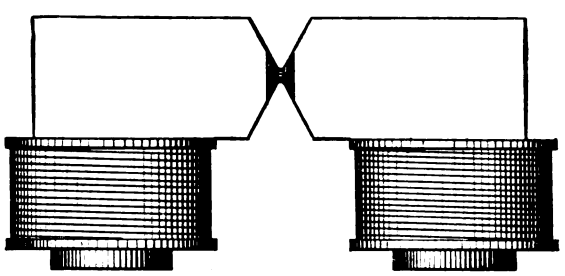
ON THE MAGNETIZATION OF IRON IN STRONG FIELDS.[1]

BY PROF. J. A. EWING, B. SC., F. R. S., AND WILLIAM LOW.

In March of the present year we communicated to the Royal Society ("Proceedings," vol. xlii., p. 200), the results of experiments on this subject, in which the magnetism of a narrow neck or isthmus of iron placed between the pole pieces of a large electro-magnet was examined, by suddenly drawing out the piece, or turning it end for end so that the direction of its magnetization was reversed. The piece examined was in the form of a bobbin with a short central neck, turned to a small diameter and with large spreading conical ends, which were in contact with the pole pieces and provided an easy path for the lines of induction to converge to the central neck. The metal of the neck was in this way subjected to a much greater magnetic force than it would be practicable to produce by the direct action of a magnetizing solenoid. The induction in the iron was measured ballistically by means of a coil of fine wire, in a single layer, round the iron neck. The magnetic force in the air space closely contiguous to the neck was also measured by means of a second or outer induction coil, of a slightly greater diameter than the inner one. This determination of the field allowed a correction to be applied for the air space enclosed by the inner coil, and it also gave what was probably a close approximation to the value of the magnetic force within the metal itself.

The object of the present note is to describe shortly the results of further experiments of the same kind, the details of which may be reserved for subsequent publication.

In the former experiments an electro-magnet with pole pieces 5¼ cms. square was used. The conical ends of the bobbins tested brought the central neck down to a diameter of 0.65 cm. in one form of sample and 0.923 cm. in another form. With this we succeeded in forcing the induction $\mathfrak{B}$ in Lowmoor and Swedish wrought iron up to values lying between 32,000 and 33,000 C. G. S. units, the strength of the magnetic field in the air close to the neck being then about 11,000 C. G. S. units.



Large as those values were, they have been greatly exceeded in the present series of experiments. In the former paper we pointed out that the magnetic induction of the iron examined showed no sign of approaching a maximum, and that the value to which it might be forced by the "isthmus" method depended on the scale of the experiments. Through the kindness of Prof. Tait, in allowing the large electro-magnet of the Edinburgh University Laboratory to be brought to Dundee, we have now been able to subject iron to much higher magnetizing forces, and to secure a much greater concentration of the lines of induction. The Edinburgh magnet is one of exceptional power. Its limbs, which are vertical, are about 60 cms. long, and the cores are 10.7 cms. in diameter. Rectangular blocks of soft wrought iron 9.6 cms. square serve for pole pieces. To allow the old bobbins to be effectively used we added a pair of conical intermediate pieces of soft iron, which virtually formed an extension of the conical ends of the bobbin. Between these the bobbin was placed, the form generally used being that described in the previous paper as sample A. The neck of this sample had originally a diameter of 0.923 cm., and consequently a section of 0.669 square cm., or about $\frac{1}{14}$th that of the pole pieces. As in the former experiments, the highest values of magnetism have been reached with Lowmoor iron, and nearly as high values with Swedish iron.

The same Lowmoor bobbin that had been formerly used (sample A) had its magnetism measured by withdrawing it from the field, while the magnet with all its numerous coils in series was excited by a current which ranged up to 40 amperes. At the highest value the induction $\mathfrak{B}$ in the neck was 38,000 C. G. S., and the outside field, close to the neck, was 18,900 C. G. S. A Swedish sample of the same shape gave an induction of 37,620 with a field of about the same force.

To push the induction to still higher values the Lowmoor sample was then turned down in the central neck until the diameter was reduced to 0.397 cm. This made its section only $\frac{1}{70}$th of the section of the pole pieces. Careful determinations, several times repeated, then gave for the highest induction the enormous value 43,500 C. G. S., the outside field being 25,620 C. G. S. Here, as in the other figures already given, the induction stated is that which is found after the air space enclosed by the inner coil is allowed for; and after a suitable allowance is made for the residual magnetism of the piece. The residual induction is only about 500 C. G. S. units.

The ratio $\frac{\mathfrak{B}}{\text{outside field}}$ in this extreme case is 1.7, and the quantity $\frac{\mathfrak{B}-\text{outside field}}{4\pi}$, which would be the intensity of magnetism $\mathfrak{J}$ if the magnetic force within the metal were identical in value with the outside field, is 1,420. In the former experiments this quantity had values which decreased from 1,680 to 1,620, while the induction increased from about 25,000 to 32,000; here, with an induction of 43,500, it has fallen off to a much more marked extent. We cannot yet speak with any certainty as to the degree of approximation of this quantity to the intensity of magnetism $\mathfrak{J}$; unless, however, the mean magnetic force within the neck is much less than the force at the surface, the results show that $\mathfrak{J}$ is becoming less as the induction is being forced to these extreme values—in other words, that the iron is tending towards demagnetism in the manner Weber's theory leads us to expect. The question is one of the greatest interest, and we are now endeavoring to obtain a better knowledge of the magnetic force within the metal by examining the variation of the force at short distances from the surface of the neck.

A final effort was made to force the induction in Lowmoor iron to higher values, by turning the central neck down still further, until its section was less than $\frac{1}{1500}$ th of the section of the pole pieces, and annealing the bottom carefully before magnetizing it. The value of $\mathfrak{B}$ then reached was 45,350 C. G. S. units, which is the greatest induction recorded in any of our experiments.

With cast-iron the induction has been forced to 31,270 C. G. S., by applying a magnetic force of 16,900.

DISCUSSION.

Lord Rayleigh, being called upon by the president, said he had no experience himself in this interesting subject of induction of very high forces. The interest of it was apparent to all, and until they knew pretty definitely what did happen at the end of the curve, it was obvious that speculations as to the nature of magnetism were very largely premature. He hoped Prof. Rowland would give his opinions upon the matter.

Prof. Rowland—When I first made experiments on this subject I was troubled, as Prof. Ewing says, by a little curvature at the end. I experimented with rings of iron, and I attributed the curvature to the non-homogeneity of the iron. I turned off the offside of the ring, which had been forged originally, and then I turned off some more, and eventually I found that to some extent this curvature at the end disappeared. Therefore I attributed the whole curvature to the cause I have stated. However, my experiments were not sufficient to establish whether there was a maximum for the magnetic induction and for the intensity of the magnetization. I should say from these experiments that there would be a very decided maximum for the intensity of magnetization. When one subtracts the intensity of the field from the magnetic induction the results are very similar, and as Prof. Ewing has remarked, they often decrease in value. I suppose the decrease may be due possibly to an error in the experiments. I think they show a decided maximum of magnetism at a higher value than that I gave, but the maximum is for the intensity of magnetization and not for the magnetic induction. In that case I do not see any reason why this curvature at the end should not

1. Read before the Section of Mathematical and Physical Science of the British Association for the Advancement of Science, *Manchester*, Sept. 2, 1887.

Digitized by Google

be due to the original cause which I gave, which is want of homogeneity in the iron. There may be some particles in the original iron which do not attain their full power at once, and require a very strong field to magnetize them, and one can see very readily if one had a mixture of steel and soft iron that it would give a curve of this nature. I am not at all convinced but that the curving is something very similar to that I recently gave.

Prof. Ewing—I ought to have said with regard to the question of whether this quantity has really passed a maximum and is coming down, that it will require the field to be inaccurate to an extent of at least 12 per cent. to make the quantity really constant instead of apparently a descending one as we have it here. That is to say, the field in the last set of experiments would require to have been 22,000 instead of 25,000 in order to make this quantity constant. I do not myself quite understand why the want of homogeneity in iron should make it possible to get an induction of 45,000 C. G. S. units into it when a piece of pure iron stops at 25,000.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Difficulties of Electric Railways in New York.—The Field Motor on the Elevated Railroad.—The "Bucket Shops"; Arrest of a Proprietor.—An Electric Boy throws up his Job at a Dime Museum.—The Subways.

ALTHOUGH there has been much said and written about electric street cars, there are many obstacles to be overcome before we shall see any number of them in actual use in the down-town thoroughfares of this city. It will surprise no one who is familiar with the ground to learn that the North and East River Electric Railroad Co. are encountering many difficulties in building their conduit. The rails were laid some time ago; the colling stock and motors are ready, but the work of placing the ronduit, which must be carried on at night, progresses very slowly. The vicinity of Washington market is crowded with farmers' wagons at various hours of the day and night; while sewer heads and steam pipes are frequently met in the direct line of the work. All of this delay and the expensive construction appear to offer a strong argument in favor of accumulators, especially for a line of this character. For the welfare of the whole business it is to be hoped that every possible precaution will be adopted to prevent a failure in so conspicuous a location.

The Field motor has gone through the regular cycle of mishaps, but is now likely to be heard from at any moment as flying between the terminals of the 34th street branch of the elevated railroad. The direct action feature is said to have already proved a practical success, and the contact wheel to work without sparking.

There was a ripple of excitement in the principal "bucket shop" of the city a few days ago when the proprietor, E. W. Todd, was arrested by detective Reilly on the charge of keeping a common gambling house. Mr. Todd was a pioneer in the business, and his establishment known as the New York Stock Co., Limited, located at 46 Broad street, has withstood all of the various attempts made by the telegraph companies and the Stock Exchange to suppress what is considered an illegitimate business. The warrant for arrest was sworn out by John A. Hussion, who is said to have lost a considerable amount of money in the place. The telegraph service in connection with the "bucket shops" has always been very ingeniously kept up, and its resources for obtaining prompt quotations appear to be infallible under the most adverse circumstances.

One of the modern electrical mysteries has been disclosed by a city compositor, who is a reformed "electric boy," or would be if a professional printer could be considered as reformed. He was in the employ of Bunnell, not on the corner of Liberty and New Church streets as might be supposed, but in a Bowery museum. During the electric stage of his existence he was enclosed in an oblong stall having a short counter, in front of which was a rail, leaving a passage for the gaping crowd to squeeze through in single file. By means of a sheet of zinc covered with a moist matting, the necessary battery and connections suitably arranged, this depraved youth imparted an electric shock to every person who shook hands with him in passing. The amusement seemed harmless enough until a death curdling statement in the daily papers regarding the dangers from electric wires led to a falling off in the receipts, and the boy's health failing under the strain, he determined to resign before the subway commission put him underground.

At the meeting of the Board of Electrical Control, Commissioner Gibbens called attention to the tearing up of the streets by the Steam Heating Co. The mayor joined him in denunciation of the nuisance, but sat squarely down on the proposition to put the work in charge of the Electrical Board, which he intimated was as much of a nuisance as the one complained of. A resolution was adopted calling upon the various electrical companies to place their wires in such conduits as are ready for them, within 90 days, in spite of the objection of Mayor Hewitt. It would seem to be a wise move to demonstrate practically whether the new conduits and man-holes are suitable for general use, before expending a large amount of money in putting them down all over the city, only to learn that the neglect of certain details has rendered them unfit for the service. Many of the man-holes will no doubt be found too small to permit the proper handling of the multitude of wires which the ducts will accommodate.

A realizing sense of the existence of the state authority was experienced by the management of several of the telegraph companies whose property has been attached, in default of the payment of the assessments made against them by the state comptroller. The largest amount was that of the American District Telegraph Co., $1,500. As it appears quite unlikely that the district messenger wires will be compelled to patronize the subways, they may be considered fortunate in being obliged to incur no further expense than to aid in the support of the Board of Electrical Control.

The combination of gas and the electric light is not giving entire satisfaction in Orange, N. J., and it is reported that Mr. Edison proposes to build a $70,000 plant for the purpose of supplying incandescent lamps in that district, which should be a very good field if the necessary pole rights can be secured.

New York, Sept. 23d, 1887.

PHILADELPHIA.

Dullness in Electrical Matters.—The Centennial Celebration of the Constitution.—Electrical Displays.—The Great Enterprise of Count Mitkiewicz and Mr. Wharton Barker in China.

ELECTRICALLY matters have been extremely quiet in Philadelphia and vicinity during the past month. The Constitutional Centennial celebration being the all-absorbing topic of discussion, interest in other matters seems to have been laid aside temporarily. Last Saturday (the 17th) terminated the celebration and it certainly was a remarkable demonstration of the country's progress in a hundred years. The display of electric light machinery, telegraphic apparatus, etc., was very good, but not so good as it should have been. One float in the procession contained a miniature telegraph pole with wires running down to a desk at which sat an operator receiving and transmitting imaginary messages. Other floats contained dynamo machines, electric light, telegraph and telephone wire, batteries, etc., with linemen in attendance. Another novel feature of the great civic procession was telegraphic stations about half a mile apart along the entire route. A platform with instruments and an operator, perched about half way from the tops of the poles, served this purpose admirably. These stations proved of great advantage in the prompt movement of the parade and would have been of still greater advantage in case of accidents, in facilitating the prompt summoning of ambulances and physicians. Happily no accidents occurred to mar the festivities of the occasion, and it is a very remarkable thing that all went off so smoothly and without mishap, when one takes into consideration the dense crowds which viewed the pageant from the sidewalk and reviewing stands.

It has already been announced that the Chinese government has granted to a Philadelphia syndicate, headed by Wharton Barker, the absolute control for 50 years of a telephone system which the syndicate intends to establish in China.

On Saturday in the United States Circuit Court in Baltimore, the American Bell Telephone Co. filed a bill in equity restraining William Turnbull from making or furnishing to others for use any electric speaking telephones or telephonic apparatus embodying the inventions of Graham Bell. The 1st of November next is fixed for the hearing. This suit is directed against Mr. Turnbull in order to shut off the Chinese telephone scheme with which Count Mitkiewicz and Wharton Barker are connected.

Wharton Barker was seen yesterday afternoon at the house of the Chinese envoy at Jenkintown and was in a happy frame of mind. In response to an inquiry as to the truth of the story that the Bell Telephone Co. through the injunction would hinder the progress of their great project, Mr. Barker said:

"I have carried on all negotiations in an honorable manner and the whole matter has been settled. We have nothing whatever to do with Mr. Turnbull or any other telephone inventor, and I do not care to enter into a public controversy on matters brought up in connection with our negotiations."

Count Eugene Stanistowkostka de Mitkiewicz joined Mr. Barker on the porch dressed to go into the city, and chatted pleasantly on a variety of subjects. In regard to the Turnbull affair, when questioned, he smiled, dropped his eyelids and with a deprecatory gesture waved Turnbull and all other obstacles out of existence. "The decree is signed," he said, "and the Imperial envoy is here to finish the negotiations. No efforts by anybody in this country can change what has been decreed. The Viceroy alone can revoke the decree." The count related the remark of Ma Kien Chang, made on Saturday night at the banquet to President Cleveland. As Dr. Pepper spoke of the tri-

Digitized by Google

umph of a century in America the great Chinaman said with emotion: "Ah, how I hope that 100 years from now China may be celebrating a like jubilee."

Count Mitkiewicz remarked that he did not care to enter into a newspaper discussion, but added: "What is the meaning of all this talk about myself and the plans of the syndicate? It means that the Bell company, who through Hubbard, the father-in-law of Bell, were trying to get these very concessions now granted to Wharton Barker and his syndicate, are grasping like drowning men at straws, and are doing all in their power to upset the scheme. It cannot be done. They can no more restrain Viceroy Li from manufacturing telephones or what he wants in China than they could stop the course of Niagara. Mr. Barker has stolen no one's money, has stolen no one's brains. He will use the best telephonic system he can get, Bell to the contrary notwithstanding. The grant is really a Chinese form of patent forbidding anyone else from manufacturing a like article in the empire. These new accusations are only part of a great scheme in which England, France, the Bell telephone company and the Western Union joined to defeat the Barker syndicate and obtain the franchises for themselves.

"The obtaining of the franchise," continued the speaker, "means the commercial and financial separation of Great Britain and China. The gravity of the situation is fully recognized in diplomatic circles, and the endeavors made to undermine the decree confirm the matter beyond doubt. Hitherto the banks of Shanghai and Hong Kong have controlled the banking system of that vast empire, and England, through them, has kept American enterprise out. The so-called American institutions have not been American, they have been against us. This decree means more than mere banks or telephone systems; it looks to full commercial union of China and America. The Viceroy Li, who is a learned and brilliant man, and who is thoroughly acquainted with America, has decided to break down all barriers, and, moreover, chose Americans as those above all to whom he would grant such valuable franchises.

"China is secured," continued the speaker firmly, "as she is to be half partner in the enterprise. The people of this country will soon wake up to the magnitude of the plan."

Mr. Barker in discussing this enterprise, said:

"The telephone privilege has been granted us for 50 years, whereas it was only recommended for 30 years, and we have every reason to believe that our other plans will be as well received. Our plan is simply this: To establish long and short-distance telephone systems throughout the empire, to develop the coal and iron fields, establish iron mills for the manufacture of rails and locomotives, and to introduce a banking system.

The enterprises differ from all previous efforts to establish foreign interest in China, in that the government was the first to move in this case, whereas all previous attempts have been initiated by foreign interests.

PHILADELPHIA, Sept. 19, 1887.

BOSTON.

Mr. Stockton assumes the Presidency of the American Bell Telephone Co.—Reports of the Erie Telephone Co.—An Electric Railway for Quincy.—An Electric Car Tried in Cambridgeport.—New Drawing-room Cars on the Boston and Albany.—Contentions between Gas Companies and existing Electric Light Companies.—The Introduction of Police Signals.—Yachts Lighted by Electricity.—The Club House of the Boston Electric Club.

MR. HOWARD STOCKTON assumed the chair of the president of the American Bell Telephone Company on the 1st day of this month; no changes are expected in the offices of the company. Many of the employés who came in with the original Bell Telephone Company are still in its service.

The Erie Telephone Company continues to report substantial increase in earnings in comparison with last year, as will be seen from the statement for July and the first four months of the current fiscal year, herewith tabulated—

July—	1887.	1886.	Increase.
Gross earnings	$49,571.93	$43,946.23	$5,625.70
Gross expenses	33,557.37	29,448.33	4,109.04

At a meeting, held last night, of the citizens' committee of Quincy, recently appointed to consider the advisability of building a street railway, a sub-committee, which had made investigations, recommended that the road be laid with T rails weighing forty-two pounds to the yard, and that some form of electrical propulsion be employed. A formal application to the state authorities for a location was drawn up, the route to extend from the boundary line between Quincy and Weymouth at the Quincy Point Bridge to the boundary line between Quincy and Milton in the westerly section of the town. It is not proposed to build this entire distance at once, the route as at present laid out being from 4½ to five miles in length. The capital stock is placed at $40,000.

A trial of the electric-motor car was made on the 30th ult., from Cambridgeport to Harvard square with about twenty-five persons on board. Much faster time was made than could possibly be done with horse power. Julien batteries are used.

The Boston and Albany Railroad Company has just succeeded in a laudable effort to lessen in a considerable degree the discomfort of railroad traveling between here and New York. It took much money to do this; in, fact it cost this company $72,000. For that sum the Wasson company of Springfield has built four drawing-room cars, which were tested on a trial trip to Worcester recently by a company of about fifty gentlemen. The Roman lamps with which the cars are lighted are especially attractive. These lamps are distributed about the cars, and in each an electric light is set The effect is very pretty. Each car will accommodate thirty-six persons, and is provided with a stateroom that can be curtained off from the rest of the car for the convenience of persons who desire privacy. The Martin system of steam heating is to be used. These cars are designed to run on the 4.30 P.M. "limited" between Boston and New York.

In the Supreme Court on the 2d inst., before Judge Holmes, lawyer Dudley presented a bill in equity brought by Matthew Burns against the Newton Electric Light Company, upon which the court issued an order of notice returnable Sept. 13. The plaintiff lives on Crafts street, Newtonville, and the defendant has its machinery and buildings on the same street, within a short distance from the plaintiff's house, parts of the building being not more than twelve feet distant. The plaintiff alleges that the operation of the works creates a great noise and disturbs his rest at night, and he therefore asks for an injunction to restrain the defendant from running its machinery.

The board of gas commissioners gave a hearing on the 18th ult., on the application of the New Bedford Gas Lighting Company for authority to furnish electric light. This company, under authority of section 9 of the act of last June, authorizing gas companies to purchase or lease the property and franchise of any electric lighting company, has bought out the New Bedford Electric Lighting Company, and consequently has not been required to apply to the city government for power to maintain and operate the wires. The hearing was for the purpose of obtaining from the commissioners an authorization, under section 1 of the same act for engaging in the business of generating and furnishing electric light in the territory now operated. This was the first instance of an application in the interest of two companies jointly.

The Gas Lighting Company was represented in the hearing by president Gilbert Allen and counsel L. L. Holmes, and the Electric Lighting Company by president William Lewis and general manager S. C. Howard. The Edison Electric Illuminating Company, which was the remonstrant, was represented by president J. W. Macomber and attorney H. H. Knowlton. The latter entered the objection that if the authorization applied for were granted, the gas company would probably enter into the business of furnishing not only arc but incandescent light, although the latter is the Edison specialty. It was claimed that the Electric Light Company whose franchise had been purchased had begun to operate in New Bedford previous to the passage of the act which required the authorization of the city government. The capital stock of the gas company is $225,000, the Electric Lighting Company $100,000, and the Edison Illuminating Company of New Bedford $75,000.

The commissioners reserved their decision.

A hearing was also given by the gas commissioners on the petition of the Clinton Gas Light Company for authority to furnish electric light in Clinton and Lancaster. The company was represented by its counsel, John W. Corcoran, and there was no remonstrant. It was stated on behalf of the company that a plant for arc electric lighting already exists in Clinton, and is about to come into its possession by purchase. And later in the day an adjourned hearing was given to the Chelsea Gas Company. And on the 7th inst., there was a hearing on the petition of the Lawrence Gas Light Company for authority to purchase and unite with the Lawrence Electric Lighting Company. Mr. C. J. R. Humphreys, who represented both of these companies, stated that the gas company had a capital of $400,000 and the electric lighting company $16,000 and 110 arc lights. He claimed that the public interest would be furthered by the union. President F. E. Clarke, of the Edison Electric Illuminating Company,

Digitized by Google

argued that the consolidation would tend to destroy the field for the company he represented, which had a capital of $65,000 and about $100,000 in plant. This company is now furnishing light for Lawrence. The commissioners reserved their decision.

The Gamewell Fire Alarm Telegraph Company obtained an order from the city government, on the 23d ult., to set up and maintain police signal stations in division 4 for telephone and telegraph signal service. Two boxes were set up on the 30th inst. One of the boxes at the corner of Lincoln and Kneeland streets attracted the attention of a crowd of South Cove roughs last evening. They didn't like it, and so proceeded to knock it down.

There will be thirty boxes in this police division on trial, with the permission of the police commissioners, who were authorized by the Massachusetts general court at its last session to expend $75,000 on a system of police signals. The stations will be on two circuits, each having its head at the Lagrange station. One circuit will cover that part of the district lying east of the station, and the other circuit that part lying west. A break in either circuit will not affect the operation of the other.

Inside of each box is the call, which in appearance is like an alarm clock of the common nickel-plated style. In the centre of the dial of the call is a pointer. Around the rim are points marked with the different calls. By placing the pointer on the call wanted and pulling down the lever notice is immediately given at the central station of what is wanted by means of a system of telegraphy.

For example: Should an officer want an ambulance, he would simply have to place the pointer on the ambulance call and pull the lever. None but officers will be in possession of keys to these inside boxes, which, in addition to the signal apparatus, contain a complete telephone outfit. Inside of each station is a small iron case containing an automatic signal instrument, by means of which citizens who hold keys can summon police aid by simply pulling down a lever.

The advantages claimed for this system are its great simplicity, speed in making a call, and the advantage of the privacy which the signal house affords an officer when using the telephone. It is the oldest system of police signals in the country, and is in successful operation in Brooklyn, Washington, Chicago, Detroit, St. Louis, and many other large cities. Whether or not it will be used in Boston remains to be decided by the police commissioners. The Gamewell system has a competitor in the Wilson system, which has been in use in division 6 in South Boston for nearly a year, and which has given very satisfactory service. Both have been put in a district where there is plenty of work to test their efficiency. Time will show which is the most efficient of the two.

Mr. J. Montgomery Sears has fitted up his private summer residence at Southboro with 50 electric lights, fed by storage batteries, which are charged by a dynamo driven by a hot-air engine. He is so well pleased that he will probably fit up all his property in Boston with electric lights.

The Hospital Life Insurance building on State street has 112 accumulator cells, which are charged for four hours in the day with enough electricity to supply the entire light needed in the building during the succeeding 20 hours.

The elegant steam yacht "Cora" of the Sound Yacht Club of New York, owned by John A. Morris, of Throgg's Neck, Westchester, N. Y., has been fitted up with 54 cells of storage batteries which supply 56 lamps 16-candle power, burning seven hours, by the Electrical Accumulator Company of New York. The "Cora" made quite a sensation at Bar Harbor. The same company put in cells to feed 80 16-candle lights on the steam yacht "Susquehanna," owned by Mr. Stickney, the Philadelphia coal magnate, while she was at Hull.

There are now over 100 members on the list of the Boston Electric Club. A representative board of officers has been elected as follows:

President—Mr. Frank Ridlon, Boston, agent for the Brush Electric Light Company.

Vice-presidents—Messrs. W. B. Hosmer, of the Thomson-Houston Electric Light Company; Frank A. Houston, attorney of the New England Telephone Company; W. J. Hammer, general manager of the Edison Electric Light Company of Boston; Henry J. Pettingill, superintendent of the United Lines Telegraph Company.

Secretary—Allan V. Garratt, electrician.

Treasurer—Herbert H. Eustis, superintendent of the Eastern Electric Cable Company of Boston:

Executive committee of 15—Col. C. M. Ransome, chairman.

Membership committee of five—Mr. A. H. Chapman of the New England Telephone Company, chairman.

House committee—Mr. P. H. Alexander, of the Thomson-Houston Electric Light Company, chairman.

The following is a list of the honorary members—Prof. Alexander Graham Bell, of Washington, D. C.; Prof. John Trowbridge, of Harvard College; Prof. Charles R. Cross, of the Institute of Technology; Prof. A. E. Dolbear, of Tufts College; Prof. Elihu Thomson, electrician of the Thomson-Houston Electric Light Company; Prof. Holman, of the Institute of Technology.

The club will meet on the first Monday evening of every month, when scientific papers will be read having special reference to electricity. Exhibits of inventions and other things which would particularly interest its members will be given from time to time at the club rooms, which are located at No. 66 Boylston street. The club have the use of two whole floors, which are connected by an electric passenger elevator, the only one in use in the city. Upon the first floor is located a fine large reception room, elegantly furnished with costly carpets, rugs, pictures, etc. It is finished beautifully in polished oak. There is also the secretary's office, coat room and cigar stand on this floor. The second floor is given up to a billiard room, and contains three tables. There will be no liquors for sale in the club. The rooms will be fitted up with electric lights, electric bells, electric clocks and an electric piano, which is the only novelty of the kind in Boston. Wires will run from this piano to another in the rooms of the Edison Electric Company in Bumstead court. Music played upon this will be transmitted to that in the club rooms. Other electrical wonders will be introduced from time to time in the rooms, and the visitors will be met with surprises on every hand. The club will have a grand house warming upon the opening of its rooms, which will take place about October 1. The members of the Boston Press Club will be invited to be present.

BOSTON, September 16, 1887.

CHICAGO.

The Industrial Exhibition.—The Chicago Electrical Club.—The Pullman Palace Car Co.—Experimenting in Electric Lighting.—A Large Hotel Contract for Electric Apparatus Including Lighting.—The Western Electric Co. at Work on the River Front.

EVERYBODY goes to the exposition this month. The big building is brilliantly lighted and seems to be filled with samples of the best of everything, from the cider press to the art gallery. But for some reason or other (they would all probably say they are too busy) the Chicago electrical supply houses have not put in exhibits. The only exception is the electric lighting, and the dynamo stand attracts a good deal of attention from visitors. In a space inclosed by a railing and neatly carpeted are a 13 x 16 Buckeye engine, driving three 35-light dynamos, and a 10 x 12 Porter engine driving two 30-light dynamos. Eighty-two of the lights are hung in and around the building, the remainder being distributed among the various exhibits and booths. As perfectly lighted spaces as can be imagined are the art rooms, where 38 lamps are hung above canopies in such a way that none of them are visible from the floor. The effect of this evenly distributed light is most pleasing, the pictures showing to much better advantage in the evening than during the day time.

Two regular meetings of the Chicago Electric Club have been held this month at the club rooms, 223 Dearborn street. On the evening of the 5th the members listened to a paper read by C. C. Haskins, on the subject "Peculiarities of Electric Currents." In connection with his essay Mr. Haskins illustrated some of the peculiarities of currents by means of experimental apparatus. These experiments, and the discussion of the physical effects of currents, made the meeting one of the most interesting that have been held. Last night an interesting paper was read by E. A. Sperry, on the subject of protection of dynamos from lightning, after which electric light, telephone and motor interests were well represented in a discussion upon lightning arresters. Messrs. Sprague and Harding, of the Sprague Electric Railway and Motor Co., were present, and spoke to the members of the successful operations in their field of business.

Now that the club is an assured success it has become evident to all the members that rooms for permanent quarters should be selected and furnished at the earliest possible moment. There are at present two eligible suites of rooms in view, and a committee from the board of managers have been appointed to decide the matter. It is proposed to have billiard and reading rooms, besides the large assembly room.

The Pullman Palace Car Co. are experimenting with apparatus for lighting their cars by means of dynamos connected with the car axles. It is proposed to use small 30-light machines in connection with accumulators, each car to have a complete outfit, the power to be derived from the axle by means of a reversible clutching device. Automatic regulators are to be provided, also automatic mechanism for disconnecting the dynamo from the lighting circuit, or accumulators, whenever the speed of the car shall fall to a certain point. We understand that it is the intention of the Pullman company, as soon as this system is perfected, to take out the oil lamps and equip all of their cars for electric lighting.

Mr. John Young, general agent of the Western Electric Co., has secured within the past week the contract for a complete electric outfit for the Grand Avenue hotel, a palatial hotel now building in Kansas City and which expects to open the 6th of next May. The contract, which it is claimed is the largest of the kind ever given, covers annunciators, with bells and return calls in every room; also an improved system of automatic fire alarm,

Digitized by Google

and wiring for both arc and incandescent lights throughout the building. This hotel will contain many novel features and promises to be one of the finest in the country. The kitchen and dining rooms will be located on the upper floor, and the main building and two wings are arranged so that there will be no inside rooms; electric lights will be used exclusively. The W. E. Co. are busy making cables and electric light apparatus for the lighting of the river. They have recently closed contracts for arc outfits for the south side cable railroad shops and for Keyport, N. J.

The Pennsylvania R. R. Co. opened bids last week for two large electric light plants to be erected in Chicago, one for the Union depot, to consist of 50 arc and 900 incandescent lights, and the other for freight houses and tracks, requiring 700 incandescent and 200 arc lights. The contract may be awarded any day, and the decision is anxiously awaited, as such a large contract with this company is a most desirable one, and most of the lighting companies have put in bids.

Referring again to telephone matters in Indiana, we may say that in view of recent developments the prospect is not very encouraging for peace and prosperity in the Central Union Telephone Co.'s business in that state. The accident, or blunder, on the part of the telephone company in letting the repeal of the obnoxious law slip through their fingers, after it had been practically secured, was a most costly one, and postponed for at least two years that measure of relief. The firm stand taken by them of either toll service or else no service at all, has resulted in quarrels with municipal councils in almost every city in the state, and infringing instruments have been freely put in use. In a former letter we spoke of the situation particularly at South Bend, the council there ordering the telephone company to leave the city. The result was that the street commissioner went to work to cut down the poles and wires, and managed to do considerable damage before he could be enjoined. Judge Noyes has now denied the motion for a permanent injunction, on the ground that the question is one of municipal power, and that he can find no law to sustain the council in granting a permanent right to any corporation to occupy the streets and alleys of the city.

Another move against the Central Union company in Indiana is in the nature of a suit begun in the name of the state for $40,000, back taxes and penalties. This is on account of a law passed in 1881, requiring foreign telephone companies doing business in the state to report annually the gross amount of their receipts and pay into the state treasury 25 cents for each $100. It seems that this law has been ignored by the telephone company.

CHICAGO, Sept. 23, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

THE REIS TELEPHONE.

[76.]—The enclosed open letter to Dr. Theodore Stein is in reply to an open letter to me which appeared in your issue of July of this year. As my former article appeared in the *Journal of the Franklin Institute* I have thought it more in accordance with custom to publish in that journal. If it is not inconsistent with your usage to publish reprints, I would be glad to have my reply appear in your October number simultaneously with the October issue of the Institute Journal.

Very respectfully yours,

Philadelphia, September, 1887. EDWIN J. HOUSTON.

WAS PHILIP REIS THE INVENTOR OF THE ARTICULATING TELEPHONE?

BY PROF. EDWIN J. HOUSTON.

THERE appeared in the January number of the *Journal of the Franklin Institute*, for 1887, a short article by me entitled "Can the Original Reis Telephone transmit Intelligible Articulate Speech?" In this article was published some correspondence from Dr. Theodore Stein, of Frankfort-on-the-Main, in reference to certain experiments made by Mr. Jno. R. Paddock with old and original Reis instruments. In this correspondence Dr. Stein denies that the apparatus in question can transmit articulate speech, but acknowledges that certain other forms of Reis apparatus can transmit intelligible words or short sentences.

Dr. Stein has published in THE ELECTRICIAN AND ELECTRICAL ENGINEER for July, 1887, an open letter to me, which I have only just seen, since its author omitted sending me a marked copy of the same, and since he preferred to publish his letter in a different journal from that in which my article appeared. It is true that I am a subscriber to the excellent journal in which Dr. Stein's open letter appeared, yet, from great press of professional work, my journals had accumulated during the summer, unread, in a manner which I am sure not infrequently happens to busy men. I have therefore only just seen Dr. Stein's letter, and if it has remained unanswered so long, he has only himself to blame therefor.

Since Dr. Stein has chosen the form of an open letter, I may perhaps be pardoned for replying in this somewhat questionable style of conducting a scientific controversy.

PHILADELPHIA,

To Dr. Theodore Stein: September 14, 1887.

It is only at this late date that your open letter to me of May 25, 1887, has come to my notice. Had you seen fit to publish the same in the *Journal of the Franklin Institute*, in which the statements to which you object appeared, or had you sent me a marked copy of the paper in which you did publish, you would not have been kept waiting so long for my reply.

The burden of your objection appears to rest on my understanding of your letter of October 23d, in which certain remarks are made concerning the platinum contact and its opposing contact piece on the telephone membrane.

I quite agree with you that "such a nonsensical arrangement is against all common sense," and, indeed, as you will probably recall, I stated in my article in the January number of the *Journal:* "It is difficult for us to believe that Dr. Stein could have so blundered as to experiment with an open-circuited apparatus." Nevertheless, your letter of the 23rd of October is open to this interpretation, and I do not understand that in your open letter to me of May the 25th, you deny the correctness of the translation of said October letter, since you say in your open letter: "The sentence in my letter to you of October 23rd was intended to mean that through the vibration of the membrane, while speaking or singing in the wood cube, the *platinum point* was lifted from the membrane and thus a transmission of sound through an interrupted circuit was made." You will, of course, recognize the fact that you can hardly hold me responsible for what you *intended* to say, but only for what you actually said.

I am quite willing, however, to accept your explanation as to what you intended to say with respect to the platinum contact and its position in relation to the telephone membrane, but would here call your attention to the unfortunate antithesis you made between this form of Reis instrument and that other form of Reis instrument in which the platinum contact "rests directly on the membrane by gravity." If your meaning is that in the apparatus in controversy, the platinum contact *when not in use* rests on the membrane, but *when in use is thrown off from the membrane*, thus producing the breaks or interruptions in the circuit, which you allege prevent the transmission of articulate speech, then I am presumably correct in assuming that in the later form of Reis apparatus the platinum contact *not only rests on the membrane when not in use, but also when in use*, otherwise there would be no significance in your contrast of the two pieces of apparatus: or, as you say in your letter of October 23d: "By reason of this, there are here no interruptions of the current, but only fluctuations (undulations) in it, which is the desideratum for the production of articulate words or sentences." If you have been correctly translated here, you may, perhaps, understand my surprise at your failure to appreciate that just here lies the quintessence of the entire controversy. If Philip Reis did this, then he was the inventor of the articulating telephone, since he devised an apparatus that enabled articulate speech to throw electrical undulations on a circuit, which I suppose you will admit can transmit articulate speech.

It would appear then, from your own testimony, that Reis was the true inventor and Bell merely the improver. The question is not, as you appear to think, who invented "The first useful apparatus for the practical far-speaking telephone," but who invented the articulating telephone? No one can deny that, taken as a whole, Mr. Bell's apparatus is better suited for practical work than that of Mr. Reis, but Mr. Bell's apparatus constitutes, in the opinion of many well-known and reputable physicists in this country, mere improvements on an apparatus already invented, and was not a new discovery or invention.

Since your open letter tacitly implies a wilful misunderstanding on my part of your letter of October 23d, I will here reproduce the original letter and the translation of the same, and leave the verdict concerning the matter to such of the scientific world as may be interested therein:

Digitized by Google

ELEKTROTECHNISCHE RUNDSCHAU,
Redaktion: Kaiser Strasse, 25, Frankfurt a. M.
FRANKFURT A. M., den 23, October, 1886.

Herrn Professor Edwin J. Houston, in Philadelphia.

SEHR GEEHRTER HERR!—Ich habe durchaus nichts dagegen einzuwenden, wenn Sie den Ihnen am 21. Juli d. J. geschriebenen Brief veröffentlichen.

Trotz Ihrer gefälligen Mittheilung, dass Sie selbst keinen Zweifel in die Angaben des Herrn Professor Paddock setzen, muss ich bei meiner Behauptung stehen bleiben, dass man mit dem Apparate, welchen ich Herrn Professor Thompson überlassen habe und den Professor Thompson an die Overland Telephone Company weiter gegeben hat, nicht, wie mit den neueren Bell-Telephonen, Worte oder ganze Sätze, auf irgend eine Entfernung, auf die man nicht durch direkte Sprachvermittelung hören kann, zu übertragen vermag. Solches ist nur mit den Reis'schen Telephonen zweiter Form möglich (abgebildet in Thompson's Buch: *Philip Reis, Inventor of the Telephone*, Seite 86), weil man an diesen Apparaten die Membran beliebig spannen kann, und weil hier der Platinkontakt nicht, wie bei meinem, Herrn Professor Thompson überlassenen Apparate, etwas von der Membran absteht, sondern direkt nach dem Gesetze der Schwere auf der Membran ruht, mithin hier keine Stromunterbrechungen stattfinden, sondern nur Stromschwankungen, wie solches das Desiderium bei Hervorbringen von artikulirten Worten oder Sätzen ist.

Die kürzlich publicirte Beobachtung von Francis E. Nipher, dass man bei einer bestimmten Spannung der Membran mittelst des Reis'schen Telephons Worte übertragen könne, halte ich für volkommen richtig und bin überzeugt, dass jedes Mal, wenn, wie vor 25 Jahren, Worte order kleine Sätze mit dem Reis'schen Telephon zweiter Ordnung übertragen haben, die Membran richtig gespannt war; es war immer ein Zufall, wenn dies geschah, da Reis selbst in den Vorträgen über sein Telephon auf die richtige Spannung der Membran kein besonderes Gewicht gelegt hatte.

Wenn Sie auch diese Mittheilungen im *Journal des Franklin Instituts* publiciren wollen, habe ich nichts dagegen einzuwenden.

Ich bin mit vorzüglicher Hochachtung.

Ihr ergebenster,
DR. STEIN.

[*Translation.*]

ELEKTROTECHNISCHE RUNDSCHAU,
Editorial Office: Kaiser Strasse 25, Frankfurt a. M.
FRANKFURT A. M., October 23, 1886.

To Professor Edwin J. Houston, in Philadelphia.

DEAR SIR:—I have not the slightest objection to the publication of my letter to you, dated July 21, 1886.

Notwithstanding your statement, that you have no reason to doubt the accuracy of the declaration of Professor Paddock, I must stand by my assertion that with the apparatus which I gave to Professor Thompson, and which he subsequently gave to the Overland Telephone Company, it is not possible, as it is with the more recent Bell Telephone, to transmit words or whole sentences to any distance beyond that at which the spoken words may be heard directly. Such transmission is only possible with the Reis telephone of the second form (illustrated in Thompson's book; *Philip Reis, Inventor of the Telephone*, page 86), for the reason that in this apparatus the membrane may be tightened to any extent, and also because in this, the platinum contact does not stand off somewhat from the membrane, as in the apparatus which I gave to Professor Thompson, but rests directly upon the membrane by gravity. By reason of this, there are here no interruptions of the current, but only fluctuations (undulations) in it, which is the desideratum for the production of articulate words or sentences.

I consider the recently-published observation of Francis E. Nipher, that, by giving the membrane a certain tension, it is possible to transmit words with Reis's telephone, to be quite correct; and I am convinced that every time we succeeded, 25 years or more ago, in transmitting words or short sentences, with the second form of the Reis telephone the membrane had just the right tension. It was always an accident, when this happened, for Reis himself, when lecturing on his telephone, attached no particular importance to the proper tension of the membrane.

Should you wish also to publish this communication, you are at liberty to do so.

I am with high esteem, etc.,
DR. STEIN.

I note what you say as to the bored-block transmitter, etc., "Nevertheless, neither Philip Reis himself, nor I, *nor any other German experimenter* (my italics) has ever been able to converse with a Reis bored-block transmitter and a Reis knitting-needle receiver, as is claimed to have been done by Mr. Paddock." I presume the italicized statement as above is intended merely as an expression of your own belief, since you can hardly speak with such positiveness for the very numerous experimenters of Germany.

As regards the statement made by me in the article in the January number of the *Franklin Institute Journal*, viz: "Although the author has not personally repeated the experiments of Mr. Paddock with the original apparatus of Reis, yet he is disposed to give full credence to the statements of Mr. Paddock, because he (the author) had, prior to the publication of Mr. Paddock's letter, held an almost uninterrupted and quite intelligible conversation, continuing for some five or six minutes, in which questions and answers were given and received, by the use of a transmitter, which was an exact reproduction of the Reis bored-block transmitter, and employed the platinum contacts found on the Reis apparatus; and also because he does not see any essential structural differences between this form of transmitter and that in extensive commercial use to-day by the Bell Telephone Company."

Concerning the above, you say: "It is plain, assuming the correctness of the statements, that while using a Reis transmitter, you MUST have used a Bell Telephone RECEIVER. You cannot well venture to deny this fact, although you ignore it in your article." Permit me to suggest that this statement by you seems to me to prove conclusively that you have failed to appreciate the real question at controversy. If you will read the title of my paper of January, 1887, you will see that it is: "Can the Original Reis Telephone *transmit* Intelligible Articulate Speech." The entire question as a matter of invention is limited to the *transmission of speech*. I did use a Bell telephone receiver, but that has nothing to do with the question as to whether the apparatus, figured in figures 1 and 2 of my article, as in figures 1 and 2 of your open letter, are capable of *transmitting* articulate speech. The controversy is as to whether certain forms of Reis transmitters can transmit speech. You argue that they cannot, because you allege they produce interruptions or breaks in the circuit. I argue that they did, can, and will transmit speech. So far as this question is concerned, what matters it as to the particular form of receiver employed?

The following statement is made by you in reference to the tension of the membrane as described in Mr. Paddock's letter, viz.: "But more remarkable is the story of Mr. Paddock, which you, a scientific physicist, adopt, that he obtained the required tension of the membrane in the wood-cube telephone of Reis through the action of *sunlight*. What an imputation is involved in producing such scientific nonsense before the physicists of the whole world. Do not the two gentlemen know that every animal membrane is very hygroscopic, and that in speaking against such a membrane the moisture of the breath is absorbed, and the membrane must lose its tension, even though Mr. Paddock let the sun shine in his mouth while using the apparatus." The above is such a remarkable illustration of your apparent failure to understand the meaning of a plain statement, that I will rest satisfied with clearing myself before "the physicists of the whole world" by *simply quoting the only remarks* in Mr. Paddock's letter in which any reference to sunlight is made.

Mr. Paddock says on this point "The requisite tension of the membrane I have found to be necessary as Dr. Stein remarks. But in the absence of any mechanical means, such as is furnished by the later forms of the Reis apparatus, I have obtained the desired tension of this membrane by exposing the instrument for a short time to a dry and warm current of air, or still better, to the direct rays of the sun, without detaching the membrane in any way from the wooden block to which it is secured. Under these conditions any degree of tension can be obtained which is desired, and care only has to be exercised that this tension shall not be *too great!*"

I must take very decided exception to your charge of my suppressing facts—you say: "How is it that in your criticism of my communication you suppressed the fact that Mr. Paddock changed the Reis apparatus and did not experiment on the basis of the mode of the inventor, Ph. Reis." If Mr. Paddock made any such changes as you claim, or any changes at all, I was and still am entirely ignorant of the same, beyond what you state, since I have not at hand the report of the Overland case to which you refer. I will, therefore, leave it to Mr. Paddock to answer you in this regard, if he should think it necessary.

In a subsequent paragraph you say: "I will in your favor and to your honor believe, that you had no knowledge of *the changes which I made* on the original bored-block telephone, which went to the United States through the agency of Prof. Silvanus P. Thompson, of London." I note the necessity which has again arisen for an explanation on your part as to the correct meaning of the portion of your letter above which I have italicized, and the very careful explanation you have given in THE ELECTRICIAN AND ELECTRICAL ENGINEER for September 1887, in which you state that the above phrase, as translated for that paper, should read, "I will in your favor and to your honor believe, that you had no knowledge of the changes which WERE *made* (in America) on the original bored-block telephone, which went to the United States through Prof. Silvanus P. Thompson, of London."

If this is what you mean, then permit me to ask with which of

Digitized by Google

the statements quoted below you wish to be credited, viz.: "How is it, that in your (my) criticism of my (your) communication you (I) suppressed the fact that Mr. Paddock changed the Reis apparatus;" and "I will in your favor and to your honor believe, that *you had no knowledge of the changes* which WERE *made* (in America) on the original bored-block telephone, etc."?

Quite on a par with the lack of courtesy displayed in the above, is your statement: "That the first principle of German science is *truth*." The slur you here attempt to cast on American science is not worthy of being answered.

In conclusion, permit me to say that I am quite willing to have the scientific world pass judgment between us, as to "the manner in which we use our scientific weapons."

SUB-DIVIDED TRANSFORMERS.

[77.]—Having read the very interesting and valuable article on the development and history of transformers by Mr. Kennedy, reprinted in THE ELECTRICIAN AND ELECTRICAL ENGINEER, I should feel obliged if you would find space for insertion of the following note in your columns.

Some months ago Mr. Kennedy described in chronological order the different patents, in the *Electrical Review*. At that time the complete specification of my transformer had just been lodged, and consequently Mr. Kennedy could neither know the contents of this patent or mention it. It is not surprising if several people have similar ideas and independently arrive at similar results in the scientific world, as is the case here. I preceded Mr. Kennedy in this idea by about five months, and working on a somewhat different line arrived at the sub-divided transformer.

While Mr. Kennedy tried to develop the iron core by reducing the magnetic resistance, I gave my principal attention to the conductors which I wished to place in such a manner as to obtain equal distribution of work in each layer, and, therefore, throughout the whole induction coil.

This type of sub-divided transformers which is the first patented in England has several advantages over those previously described, and they will easily be recognized if I state before describing the apparatus its fundamental points of construction.

1. Equal distribution of work throughout the transformer.
2. Suppression of self-induction from one primary layer on others, and from one secondary on its neighbors.
3. Greatest possible work with smallest amount of copper.
4. Great radiating surface.
5. Simplicity in construction and repair.

The first and third conditions are attained by keeping all layers equally close to the core, they will, therefore, all have equal length (the shortest possible), and are placed in the most intense magnetic field. (Figure 3.) This is contrary to all former types, in which the superposed layers do less work per inch of conductor owing to their greater distance from the core (thereby being placed in a weaker magnetic field) and to the self-induction of the neighboring layers.

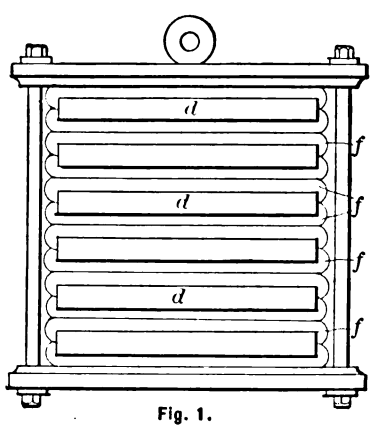

Fig. 1.

The second and fourth conditions are fulfilled by reducing the superposed layers to a minimum (or nearly so) and so arranging the core or cores, that the different systems of conductors are separated by iron (figures 1 and 2).

The fifth condition is achieved by the forms described below.

Figures 1 and 2 show two induction coils built of spirals.

Figure 3 represents cross-sections, figure 4 end views, figures 5 and 5*a* top views of some spirals or layers, and figure 5*b* a side view of the two last spirals. In all figures *d* indicates a system of primary and secondary layers, *f* cores of iron wire or strips, the latter with a flat side towards the spirals, *h* cores of strips standing on edge (figure 9), P primary, S secondary wires.

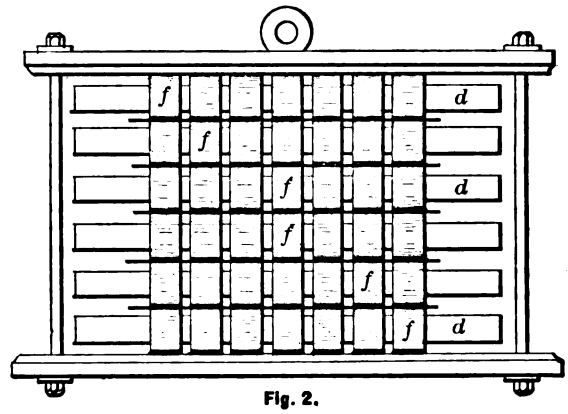

Fig. 2.

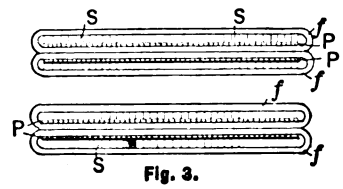

Fig. 3.

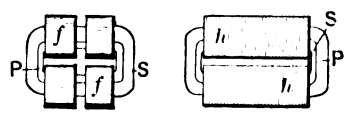

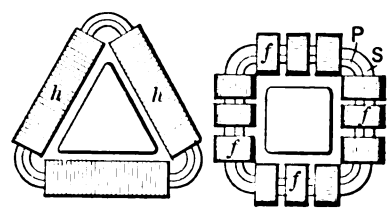

Fig. 4.

Figure 5*a* shows a new form of an iron core stamped out of sheets of iron or made of two strips forming a cross, figure 6, of which the band *aa* is passed over the outside of the layer *d* and *bb* lying in the central hollow space is connected to it, as shown in figures 7 and 8. If it is desired to place the cross on edge the modified form, figure 10, must be chosen, *aa* forms a complete loop which is slipped over the spiral *d*, and the arms *bb* are bent through the central hollow part of *d* and connected to *aa*. Another modification developed out of form figure 10 is shown in figure 11.

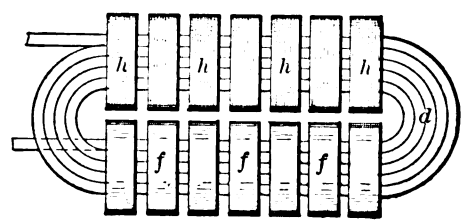

Fig. 6.

To make this apparatus a commercial success it ought to combine simplicity and efficiency with cheapness, and the question arises which is the core that combines these qualties.

Theory proves that iron wire, or strips placed on edge are most efficient, and bands put flat on the spirals or layers are not so good; but practice shows that the latter cores are by far the cheapest (being less than one-quarter in price compared with the former), and the difference in efficiency is but trifling if the width of the strips is not large.

My system compares very favorably with that described by Mr. Kennedy.

Digitized by Google

In the type described by Mr. Kennedy the sub-division is hardly complete as there are 6 or more systems of coils on one core, besides the magnet is complicated and requires a great deal of work. It is a drawback to this system that the magnetic circuits are not complete in each core, especially if the closing is affected by placing the strips on edge. To obtain good contact in this way is difficult. As is well known, inefficient connection causes the development of heat, and if the apparatus is not well bolted together the magnetic reversals tend to cause an oscillating motion at these points, which produce a loud humming noise; it is, therefore, evident that if great care is not taken in the manufacture of such a core the power wasted will be much

Fig. 5a.

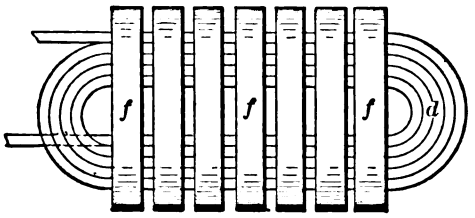

Fig. 5b.

greater than that lost by Foucault currents in magnets like *f*. It is necessary, furthermore, that the core should be complete in order that both the primary and secondary wires may be wound on it.

In the Gutmann transformers the primary and secondary layers are wound independently of each other and the core, and if the core is made of flat strips, *f*, it requires simply the bands to be cut to the desired length, a certain number after being insulated laid one over the other, passed through the central hole of *d* (figures 1, 3, 4, 5), and connected in form of concentric

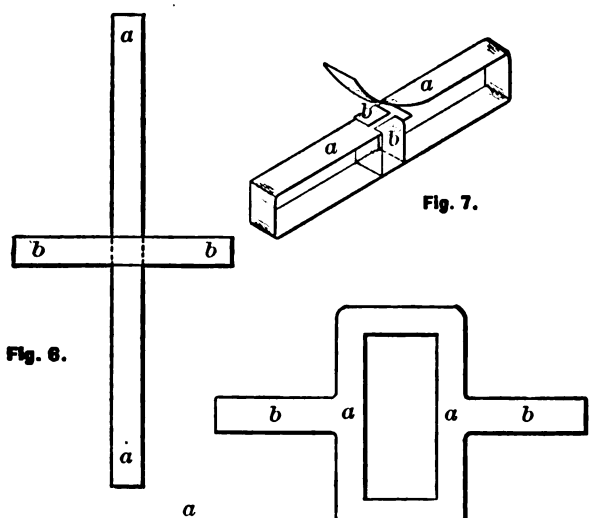

Fig. 6.

Fig. 7.

Fig. 10.

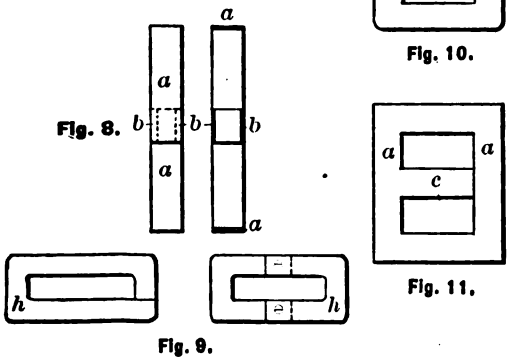

Fig. 9.

Fig. 11.

rings, or of a spiral; no bolts or screws are needed if the ends of the outside strips are well attached to each other.

Each layer is a safety fuse for the other part of the apparatus, and in case of a break-down the burnt coil can easily be disconnected and replaced without affecting any other part of the transformer.

The manufacture is very rapid and inexpensive because the work of each transformer can easily be distributed amongst several men and very few tools are required. Finally, I may state, that sub-divided transformers do not require greater space than types with a core common to all layers for coils like figure 1, working with 2,000 or 1,000 volts in the primary, and 100 or 50 volts respectively in the secondary capable of supplying two to three horse-powers remain within the space of 15″ × 6″ × 4½″. They work well and silently, and the temperature of the apparatus is negligible.

ELECTRICAL NEWS AND NOTES.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

FIRST MONTHLY MEETING.—SEASON 1887-88.

THE monthly meetings of the American Institute of Electrical Engineers were resumed September 20th, at Martinelli's Fifth avenue. Dinner was served at half-past six o'clock. After coffee and cigars the president, Mr. T. C. Martin, called the meeting to order with the following remarks:—

It is with much pleasure that we resume our meetings for the winter season with a paper so important and unquestionably so interesting as that to which we are about to listen. The attendance this evening is large and very gratifying. We are not merely a New York society, our membership extends over all the country. At the present time we have members in between 30 and 40 states and territories of the Union, and no fewer than 10 countries of Europe, the West Indies, South America and Canada. Under these circumstances it can be imagined that it is rather difficult to get all the members together when a paper is read here, no matter how important it may be.

The subject before us this evening is "Electric Street Cars with Special Reference to Methods of Gearing." Mr. Reckenzaun, our distinguished guest, as you are all aware, has made a special study of this branch of the electric motor question, and it was through his genius and ability that the remarkable trip was made across the English channel, the first of the kind on record. Not long after that trip Mr. Reckenzaun presented a paper before the London Society of Arts on a subject somewhat similar to that which he brings before us this evening, and so meritorious was it and such was the interest excited by it that the society felt justified in awarding Mr. Reckenzaun its silver medal. Mr. Reckenzaun soon leaves us to return to England to receive that medal. (Applause.)

In bringing this subject of electric cars before us this evening, it was thought possible that the paper might cover the whole subject, but after a little consultation Mr. Reckenzaun determined to restrict it more specifically to the subject of gearing, and I think you will all agree with me that there is no more important department of the subject of electric locomotion than that.

I now have the pleasure, gentlemen, of introducing to you Mr. Anthony Reckenzaun.

Mr. Reckenzaun then read his paper. (See page 387.)

DISCUSSION.

The President—Gentlemen, the valuable paper to which you have listened is now open for discussion. It is natural, under the circumstances, as we have Mr. Reckenzaun with us now, and as he is shortly to leave for Europe, that we should, so to speak, put him in the witness box and puzzle, perplex and annoy him with questions. In that way, I have no doubt we shall greatly add to our stock of information on the subject before us. But I know Mr. Reckenzaun would prefer a discussion rather than a series of interrogations, and I think that on the matter presented before us to-night, and with half the gentlemen in attendance directly interested in street railways as run by electricity, the subject should not lack ventilation; and I venture to believe that should any gentleman desire to discuss some of the points presented with Mr. Reckenzaun, he will find a foeman worthy of his steel.

Mr. R. W. Pope—There is one point in connection with the worm gearing that I have heard referred to before, and I presume, as Mr. Reckenzaun's name was mentioned in connection with it, that he can give us further details, and that is the matter of lubrication. I understood, when this question was up before, that in his use of worm gearing the worm was run in oil, and if so, I would like for one, to hear a little more about it.

Mr. Reckenzaun—The worm wheels are the first bearings. The first bearings are generally made of several collars. There is a tin box around the whole, completely around it, just having a hole with a very light stuffing box. You have the whole gear-

Digitized by Google

ing closed almost air tight. If you use ordinary lubricators, just to start the thing—the thrust bearings—and if you place two or three inches of oil at the bottom of the tank you will find that there is a perfect, continuous, automatic lubrication. The teeth of the worm wheel will lift up just sufficient oil to lubricate the worm and there will be sufficient oil always running around—flying about in the tank—to keep the whole thing well lubricated. There is hardly any waste of oil going on through leakage at the shaft or at any other points. Here you have a perfect lubrication that cannot fail at all. I believe this is the only question that Mr. Pope asked, with reference to the lubrication. Of course you can use any lubricant you wish. Some lubricants are far more efficient than others. Naturally we should use the most efficient lubricant we can get in the market. With regard to the friction surface of the worm wheel, I have mentioned that that is made of phosphor-bronze and the worm is made of steel. These two metals have a very low coefficient of friction between them. The worm is moreover turned out of a solid piece of steel and perfectly polished. The phosphor-bronze wheel is a toothed wheel thoroughly trimmed and also polished inside. Therefore, they have a perfect wearing surface to start with. The worm gearing works for a considerable length of time without any appreciable wear on the teeth at all. I think a perfectly constructed worm gear ought to run 20 years without renewal if properly lubricated. The prejudices against the worm gearing will soon wear away. Up to the present time worm gearing has been constructed on anything but scientific principles. The teeth were at a very small angle. The material used for the worm was frequently cast-iron. The worm wheel was sometimes made also of cast-iron. Sometimes they made wrought-iron worms and cast-iron wheels. Altogether the worm gearing has been constructed on anything but scientific principles.

Mr. Wetzler—I would like to ask Mr. Reckenzaun if he ever has tried to use a worm which instead of being cut cylindrically has been cut radially so as to conform to the radius of the wheel into which it geared.

Mr. Reckenzaun—I do not quite understand what Mr. Wetzler means by cutting a worm radially.

Mr. Wetzler—What I mean to say is instead of cutting your worm cylindrically have you cut it so that its outer curvature conforms to that of the wheel!

Mr. Mailloux—The hour-glass form.

Mr. Wetzler—Yes, the hour-glass form.

Mr. Reckenzaun—All the worm gearing I have constructed has been made on the plan of cutting it out cylindrically.

Mr. Wetzler—Those cut in the curved or hour-glass form are said to be more efficient according to Prof. Thurston's experiment.

Mr. C. O. Mailloux—I would like to add by way of information that this form of worm was the very first that was used. If I mistake not it was the celebrated mechanician or engineer Hunter who first devised the worm, and it was in that form that he gave it to the world—the hour-glass form as he called it. The shape of the teeth is varied as they go toward the end near which they point inwardly in a radial form as Mr. Wetzler has said.

With regard to the worm, I have watched with interest the evolution of means of transmission from the motor axle to the car axle and I am very well prepared to agree with our friend Mr. Reckenzaun that it is undoubtedly one of the most important problems that we have to deal with to-day. In fact I may say that it is the only remaining unknown quantity in the problem of electrical traction. The problem of designing and constructing electric motors has advanced by the assistance of workers, mathematicians and others, until it is to-day a question of engineering purely; but the manner in which we should dispose of the energy in order to render it available for moving the car is, unfortunately, not so well taken care of; and the very fact that we see so many diversified attempts to meet the severe requirements which Mr. Reckenzaun so well placed before us, shows that a satisfactory solution—at least one that is satisfactory to everybody, has not yet been reached. Some are very much predisposed in favor of belting, others in favor of gearing, friction appliances, etc., etc. Now there is, I think, going to be a certain amount of competition between different forms of gearing, leaving aside for the present other forms than gearing—namely, belting, etc. There is going to be some divergence of opinion for some time to come as to which is the best form of gearing. Experiments have been made by very able persons on the subject, and so far nearly all of them concur in ascribing to the worm a much lower efficiency than to spur gearing. I have in mind some experiments which were made under the auspices of Messrs. Sellers, of Philadelphia, in which they sought to go to the bottom of the problem thoroughly and to arrive at some conclusion as to the relative efficiencies of the various forms of gearing. The results attained, showed first that the efficiency did increase with the speed, as Mr. Reckenzaun has stated, but that this efficiency did not increase indefinitely with the speed; that it reached a certain maximum, and a very curious circumstance was that the forms giving the highest efficiencies were those two direct ordinary spur gearings in which the shafts are parallel with each other. Starting from that, they made experiments in which the angle of the two shafts was gradually increased so that there was a gradual transition from the form in which the two shafts were parallel to that in which the two shafts were at right angles to each other as in the worm gear. We may say, in fact, that worm gearing and spur gearing are the two extreme forms, intermediate between the two extremes being placed the so-called helical gearing in which the teeth are placed at an angle in spirals. The results obtained by the Messrs. Sellers showed that the nearer they approached the form *of the worm* the lower was the efficiency. I have not in mind the figures of the efficiencies, but the experimenters themselves rather left us in doubt as to the value of their results by referring to very many circumstances which, in their opinion, would vitiate some of the results obtained, and there were certain conditions of the operation of their apparatus which they were not exactly satisfied with. I must say that I have always looked upon the worm with more or less suspicion. While I was not predisposed against it, particularly after seeing the beautiful results obtained with it by Mr. Reckenzaun, in England, yet I felt that it was to be taken under probation. There are some disadvantages, I think, which are connected with the use of the worm, and one of them which occurs to my mind just now, is the difficulty when the worm is fastened to the motor shaft in running down hill. When an electrically propelled car runs down a grade it is found possible to shut off the current in a great many instances, and this, of course, results in a certain saving of energy. Now, unless the pitch and the general design of the thread be properly adjusted, it seems to me that it would be somewhat difficult for a car to move down hill with ease, because of the well-known difficulty of moving such an arrangement backward. It is very well known that a thread can be used to turn a toothed wheel, but it is very hard to turn the thread by means of the toothed wheel. I understand that Mr. Reckenzaun has met this difficulty, though I do not know whether he still considers it one of the things to be remedied, or whether he deems the remedy that he has proposed sufficient.

Now, turning back to the other form of transmission, namely, the pinion, which I have said is likely to be one of the opponents or rivals of the worm system, I have in mind some form of that kind which I saw in use a year or so ago, which it seemed to me was very well adapted for the purpose. Recognizing the fact, of course, of a great tendency to wear in the pinion or in the gear wheel, and also the great tendency to the production of noise, a special form of pinion had been devised. This was made by taking a number of thicknesses of raw hide, and closely packing them and threading them on the shaft with knots to hold them in place; then cutting a thread so as to make a pinion of these thicknesses of raw hide. The gear wheel, I understand, was of phosphor-bronze. I made some experiments with that system—the Bentley-Knight—at Providence at the shops of the Rhode Island Locomotive Works. I found the working of it to be satisfactory. It was entireley noiseless and the only doubt that there was in my mind as to its success was the question of durability of the pinion. I have no doubt that if there is any wear it must necessarily come on the pinion, that being the softer substance of the two; but I have no data by which I could arrive at the comparative durability of the raw hide pinion.

With regard to the chain, I may say that my experience with it goes to show that the loss from its use is not nearly so great as might at first be supposed. In that respect the pinion is placed in very nearly the same position that the worm gearing is. In other words, it depends largely on who is using it and how it is used. Mr. Reckenzaun has obtained excellent results—nobody will deny that—with the worm gearing, which has always been looked upon as the bane of the mechanic. Now, the same may be stated with regard to the chain belt. It is capable of giving excellent results, but in order to obtain them, a special form of chain must be used and the secret of the success which Mr. Van Depoele has achieved in this country is due largely to the special form of chain which he has used. The connecting piece between the links has a thimble around it which acts as a roller, so that instead of having a frictional action on a toothed wheel, it has more of a rolling action, and by taking care to keep the chain properly lubricated, not only is the noise greatly reduced, but the loss from friction is also very largely diminished.

Mr. Reckenzaun—I think there is only one point which requires observation on my part and that is in regard to running down hill with worm gearing. I make the angle of the thread so that the car runs down hill very easily if we once start the worm. You can with your hands turn around the worm wheel almost at any speed you like and I know from experience a car which is provided with worm gearing will run down an incline of one in seventy to one in a hundred—it depends on the roughness of the track—very easily. If it were not for that, if the pitch or the angle of the worm thread were not sufficiently great there would be more danger even in the case of running on the level road than running down hill, because as soon as you cut off the current from the motor the momentum of the car would strip off all the teeth of the wheel. If you make that angle

Digitized by Google

sufficiently large you will find there is no trouble at all with reference to the point to which Mr. Mailloux has called attention. If you take the formula which I have given on the black-board, and which I suppose will be published some day, and if you take the dimensions I have put down you will find the exact angle of the worm thread, and you will find that its angle of repose is so low that the worm wheel is bound to revolve with the greatest of ease.

As regards spur gearing I have pointed out in the course of my observations in the paper that I have been very well satisfied, in fact, astonished with the ease with which that spur gear which we use in Philadelphia is working.

In respect to chain gearing, I have been rather unfortunate with it, but if I had employed such appliances as Mr. Mailloux or Mr. Van Depoele, no doubt I might have been more successful. Mr. Van Depoele uses rollers, and we know that rolling friction is much easier than what I call grinding friction where the links of the chain have to grind over the teeth.

I agree with Mr. Mailloux that there will be a great competition between the different forms of gearing, and it is only that form of gearing which lasts longest and gives the least trouble which will be eventually adopted generally. But at the present time we are still in the dark as to the best form. Everyone believes his own the best because he has had the greatest experience with it. Any discussion of the description we have had to-night will greatly advance the subject.

Mr. Wheeler—I want to ask Mr. Reckenzaun how the gear was connected to the motor? If the motor was mounted directly on the shaft, did not the jarring of the car shake the motor up a good deal and prevent the brush resting on the commutator? I do not think he has explained that.

Mr. Reckenzaun—No, sir, I have not explained that. The worm and its couplings are generally forged in one piece. I employ a slightly flexible coupling, and between the bearings are springs, which take off the jarring from the bed of the motor. There is very little jarring going on—comparatively little, and we have never had any trouble with the jumping off of the brushes from the commutator. If the springs on the commutator brushes are sufficiently strong there will be no trouble. In some cases I have tried—taking the brushes of the commutator to be almost horizontal—I have tried to put a counter-balance on the brushes so that the jarring, instead of shaking the brush off, jars it on or puts pressure upon it. I found at last that there was no necessity for such balances. There is very little trouble in that respect if all is properly adjusted in the first place. With the coupling flexible in the first place and the wheel flexible to the bearings that support the frame of the commutator you will find very little trouble on the points Mr. Wheeler has mentioned.

Mr. Wheeler—If the motor jars up and down at all it either must twist on the foundation or else there would be a fault in the shaft. That is to say, the shaft would either have to go one way or the other.

Mr. Reckenzaun—Yes, there will be a slight fault in the shaft; but if there is a flexible coupling it will compensate for that. Of course, we do not expect it will be at fault half an inch at any time, but it will allow a variation of an eighth of an inch.

Mr. Mailloux—I would like to call attention to another point. I do not wish to see it passed by, because I think it is of some importance and perhaps throws light on these discrepancies relative to the efficiency of the worm which have been observed in the results of the best experimenters. I have reference to end-thrust in the motor. My own study of the theory and practice of the worm wheel has convinced me that at least a large proportion of the waste of energy due to friction in worm gearing must have been due to end-thrust. Now, the question arises why did not Mr. Reckenzaun employ means by which this end-thrust could be reduced, if not eliminated, and in that way obtain a much better efficiency than the others who had preceded him? I wanted to mention particularly that in analyzing the experiments made by Messrs. Sellers I was not satisfied with the precautions that they seemed to have taken to eliminate that end-thrust, and perhaps that may have been the cause of considerable loss of energy by friction.

Now, there is another point which occurs to me and which I will beg the privilege to discuss while I am up. The problem of electrical traction involves a very important requirement in the matter of securing adhesion between the rails and the wheels in climbing up grades, going around curves, &c. The electric motor has not been found successful in enabling us to climb grades higher than 6 per cent., or at the outside 7 per cent. I have succeeded in going up a grade of 6 per cent, with a car having another car attached to it. But these are *tours de force*, so to speak, which, perhaps, we would not care to repeat every day. Then if we admit the necessity for a certain amount of traction—adhesion between the motor and the car, we arrive at the consideration of the importance of having the power transmitted to both axles. In a great many cases I have found that the transmission of the motion to one axle was insufficient in certain kinds of weather when the tracks were not in the right condition. There would be a very severe and annoying amount of slipping which would greatly interfere with the progress of the car and the success of the experiment.

Now, another requirement which has presented itself in my study of the problem is this—the difficulty of starting easily, smoothly, and without hesitation. That is a more important item of the problem than people generally imagine, and I have in mind several systems of electrical traction which are successful in almost every respect but that. They start with a certain jump which is likely to strain, if not to rupture, some part of the mechanism of transmission, and in connection with this it has suggested itself to my mind as being an eminently desirable end to attain to have means by which the motor could be started independently of the car. There is a certain amount of inertia to overcome in the motor itself and a certain amount of energy must be expended in giving it the velocity at which it is to be run. Now, if we could do that first and not have to do it at once or simultaneously with the overcoming of the inertia of the car itself you will see that we will have made some gain. It would be very much like dividing a load into two portions instead of having to lift it all at once, lifting a small part of it and then going on to lift the rest. That suggests itself to me as an important matter, and I believe that the successful system will be one in which that feature is present. I would like to hear the opinion of Mr. Reckenzaun.

Mr. Reckenzaun—With regard to eliminating the end-thrust of the motor in the case of worm gearing, I use no special precautions whatever excepting that I employ several thrust collars. I believe Mr. John Pendleton has a system of worm gearing in which the thrust is eliminated by having two worms, one right-handed worm and the other a left-handed worm, so that the thrust of the one counteracts the thrust of the other. But it has this little disadvantage that the gearing comes very near to the ground. There are two worm wheels and the motor shaft is at a tangent to the two wheels, and the motor is between. By this means the two driving wheels have to revolve in the same direction. The two worms revolve in the same direction, and being right and left-handed the thrust is entirely eliminated. I have made one kind of worm gearing for a special purpose where two worms were attached to a motor which drove two worm wheels, and on the same shaft with the worm wheels were two large spur wheels which were used for climbing up a rack. In this case also the thrust was eliminated, so that there was only the friction of the thread of the worm and the worm wheel teeth.

With regard to the problem of adhesion it is perfectly natural that the more driving wheels you have the better will be your adhesion because each wheel will have the same effect in assisting to start the car. I never use less than four driving wheels on my cars. I would use six if it was convenient.

Mr. Mailloux—How do you connect them, Mr. Reckenzaun?

Mr. Reckenzaun—I use two small trucks and two motors. There are four driving wheels and two driving axles. By extending the shaft we could have a second worm wheel; but that would complicate matters very much unless it was absolutely necessary for very steep grades.

It is nonsense to attempt to run cars on a grade of more than six per cent. in wet weather. It is impossible. No electric car or steam car or any self-propelled vehicle will with absolute certainty climb grades of more than six per cent. in slippery weather. If we go beyond six per cent. we must have some artificial adhesion; we must introduce some rack on the road, or cables which have a positive motion. Any one who attempts to guarantee a self-propelled vehicle whether propelled by steam or any other means on grades of more than seven per cent. will most certainly lose his reputation.

With reference to starting I have always found that electric cars start with remarkably facility; that is to say with remarkable quietness. There is very little jerk. Mr. Mailloux mentions that most electric cars start with a jerk, I know that steam cars, cable cars and horse cars start with a jerk, but I have very seldom found it on electric cars, and I have had the privilege of riding on a good many electric cars in various parts of the world. There is a gentleman here, Mr. Stein, who I think might give an opinion on that subject. He has been on our car in Philadelphia, and I think he would say how easily it starts. You can hardly feel the starting; it starts gradually, and that is perfectly natural. When the current is transmitted to the motor, the motor has no counter-electromotive force. Therefore the whole of the current that goes through is determined by the actual wire resistance of the motor. As soon as the motor is started, as soon as the armature revolves the current decreases, immediately, in proportion to the relative speed of the armature. As the counter-electromotive force is created in the armature by its revolution so the current is reduced, and it is almost impossible to start an electric car suddenly with a great jerk.

I think those are the main points Mr. Mailloux touched upon.

Mr. Pendleton—In regard to the electrical propulsion of cars, while the first efforts were being made in Paris by Mr. Philipart, in the celebrated omnibus feat, with which he paralyzed the residents of Paris, by the exhibitions made on the Boulevard, and also the run from Paris to Versailles and return, my attention was

Digitized by Google

drawn to the question of power contained in the accumulator for the purpose of car propulsion; and while an examination of that apparatus failed to satisfy me as to its being a mechanical arrangement affording the best efficiency, yet the results attained in that demonstration convinced me that the value of the accumulator and motor would find a better application in the replacing of horses than in anything else, and as I was devoting my attention to experiments with the accumulator during those years, I gave a good deal of study to improving the mechanical devices then adopted, which were simply to put in a D2 Siemens dynamo connected to the counter-shaft and from the counter-shaft connecting to the wheels of the omnibus which was borrowed for the purpose, and my recollection is that the apparatus weighed about nine tons. We are all familiar with the demonstration made and a good many are familiar with the devices used, but when I made the attempt to find something better it appeared that according to the experience of car men, and in the opinion of those who had employed various devices with compressed air or steam, it was a very difficult subject. Our oldest car builders in conversation told me that the experiments had so far demonstrated that horses were the best things to put on cars and nothing else would do; that engines would not stand the pounding of the rail. They were very rapidly destroyed. Occasionally some invention would run smoothly for awhile, but that inevitably it came to grief in a very short period. Notwithstanding this discouragement, various devices such as have been spoken of to-night were reviewed one after the other, and the device which Mr. Reckenzaun has alluded to was the final result after discarding some dozen or more. But the necessity of using the worm and worm-wheel running in oil was very evident to my mind. It may be remembered by a good many here that in May, 1886, I exhibited at the New York Electrical Society, a design for this system of car traction, having eliminated from it all the objectionable features, so far as could be well done on paper. I exhibited it for the purpose of getting the opinion of those who were engaged with me in investigating mechanical and electrical questions. I was discouraged afterwards by the opinion of many—some of whom are here present—as to the efficiency of the worm and the worm-wheel, and it is with the greatest pleasure that I hear so well defined and so thoroughly proved by practical experiments what I may say was a chance choice more than a scientific result on my part. It came to me intuitively as it were; it seemed to satisfy me better than any other. I have had the apparatus in model for a good many months past but other engagements have prevented my doing as much work in that line as I wished. The interest has increased from week to week. It is only a fortnight ago that I visited Philadelphia, and had the opportunity of riding upon a car which Mr. Reckenzaun had in charge at the corner of Washington avenue and Twenty-fourth street. I saw there a car under thorough control, mounting grades of five feet in 100 easily, stopping in the centre of the grade and starting without any difficulty. The starting from a dead stop was with ease—much more than we would experience in a horse car—and although I had been so many years a believer and exponent of electric traction, and particularly of accumulator traction, for street cars, I will state to you that I was surprised and gratified at the practical demonstration of its value that I saw. The car was run by a motor attached only to to one pair of wheels. It had always been a great doubt with me whether on grades of five to the hundred or four to the hundred a car would have sufficient bite upon the rail to enable it to mount grades of that degree. I saw the car stop on a grade, start on a grade without any slip and go over it and I felt that a very important question was solved by the manner in which it performed its work. Gentlemen, there is no doubt in my mind to-day in regard to the value of electrical propulsion or of accumulators acting in replacing horses. After the demonstrations that have been made it is only a matter of a few months when we will find one or two lines of horse cars in this city adopting the electrical propulsion, and then you may expect it to come like the roll of the sea. There will be no supplying the demand that will arise for electrical cars. I had the pleasure that day I was in Philadelphia, of being associated with two presidents of horse railways who were witnessing the experiments and they both expressed their surprise and delight at the behavior of the car and of the thorough control which it was under. We have but a brief period to wait before we shall find the advantages which the adoption of a new and better system will give to the general public and to the welfare of our cities.

The President—There is one branch of the subject which has not been touched upon this evening, yet it merits our attention. We have so far confined the discussion to street cars, whereas this whole discussion might refer more largely to electrical cars in general. It may not be within your knowledge generally that within the last month or two an electrical road, the largest of the kind in this country, has been put in operation in the coal mines of Pennsylvania. We have with us this evening Mr. Schlessinger, who has put that road in operation and who has it successfully running to-day. He there handles trains of many tons weight, and his experience in dealing with the particular question that was touched upon of moving off easily and quickly without any jarring of the machinery would be very valuable in this connection. I think it would afford us all a good deal of pleasure to hear of his experience in the Lykens Valley coal mines.

Mr. Schlessinger—In the Lykens Valley coal mines we entered into competition with one or two lines of horses and also with the steam engine. The mules were taken off the second day entirely, and I think that the steam engine has seen its last days also in those coal mines. It is proposed wherever steam locomotives are being used to change them for electric motors in a very short period. The trains we have to handle are sometimes as large as 100 tons. We have to take them over grades of about one per cent. to two per cent. and around 90 degree curves, one of them being 25 feet radius. We have got to start trains on these curves. The mode of transmitting the power from the motor to the wheel is chain gearing. I found that wherever the train stands the starting is very easy or would be very easy if it were not for the fact that the cars generally are bumped together, and the load is not put all at once on the motor but gradually. One car starts after the other, and this is an objectionable feature so far as the easy starting is concerned. If the whole train would start as one then it would move off very nicely and easily without any jar at all, and that is another reason why I think it is always preferable to have the motor geared in such a manner to the car that both start together, not the motor first and then the car. There will always be a jar if this is not the case. It is the same thing as if the chain gearing should have stretched; it will always be noticeable that the car starts far more heavily and with a greater jerk than if the chains are perfectly tight. Outside of that the weight and power required to start the motor are so small as compared with the power required to start the whole thing that there is very little gained in starting one, especially the motor, before the other. The chains we are using in the Lykens Valley coal mines are the chains Mr. Van Depoele is using, and side by side with them a chain that I have specially constructed for the purpose. The links are made of phosphor-bronze and the pins are steel having a wearing surface of two square inches. The chain with a thimble is not giving much satisfaction up there. I suppose it is because of the very heavy strain on it.

Capt. O. E. Michaelis—A remark that Mr. Schlessinger has just made in regard to the increased shock due to the successive movement of the cars constituting the train brings to my mind a remark that the reader of the evening also made in his paper, which I saw was clearly founded on experiments and not simply the result of theory. That remark was that the duty upon the motor was greater in starting the train than afterwards, and Mr. Mailloux continued somewhat in the same manner. Now, during the present year there was a series of remarkable experiments made at Burlington, Iowa, under the auspices of the Master Car Builders' Association, which will bring about, I think, an entire revolution in the method of connecting trains, and I am fain to confess that these experiments appear to upset all our pre-conceived theories as to the duty of the motor in starting trains. I speak on the subject because I am at present engaged on this coupler question and therefore take some interest in it. These experiments showed that the greatest duty upon the locomotive in this case was actually after the whole train had been started, and it is very curious. I am willing to admit that I was entirely mistaken myself, because at the very time almost of my receiving the account of these experiments I had taken great pains to explain to a friend of mine the theory by which a train was moved by the successive picking up of the cars, a theory which was of course upset by these experiments. The result has been that the Coupler Committee of the Master Car Builders' Association—all prominent railroad men in active practice—unanimously agreed at the convention in Minneapolis, that the future coupling of cars shall be tight and not loose, and have recommended the abolition of the pin and link coupler and the substitution of a close vertical hook, which coincides, I think, with what Mr. Schlessinger has said.

Mr. Mailloux—I stated that one of the difficulties was the sudden starting of electric cars. Now, I should have said that circumstances were responsible for that. It depends very much on the way in which the energy is given to the car, and when you are dealing with accumulators it is not often possible to apply the electrical current to the car in a manner sufficiently gradual and slow to prevent that sudden onslaught of motion, so to speak. That is what I had in mind in speaking of the sudden motion. If the current is supplied over circuits with devices by which it can be put on more slowly or more rapidly according to circumstances the case is different, but with storage batteries generally it is far more convenient to have as few combinations as possible, as little mechanism in the regulating apparatus, so as not to complicate things. Now, with regard to the starting of the motor shaft first the opinion I expressed was the result of experiments. I have seen the value of that point demonstrated quite recently by means of a system in which the motor is started first giving free scope to the full electromotive force of the battery and allowing it to run at a very high speed and accumulate energy in the form of momentum, so that not only that part of the work has been done but we have even stored a certain amount of energy there which when a device is applied shall enable us to make use of that stored energy to start the car itself. I have seen the results demonstrated by a gentleman who has a system of traction, and I must say that it

Digitized by Google

struck me very favorably indeed. He used a frictional device in the connection between the motor and the driving wheels, also combined with spur gearing, but when I saw the ease with which he started and stopped and overcame grades, &c., I was convinced there must be something in it.

Mr. Pendleton—I called Mr. Mailloux's attention to the value of the electric motor, particularly for the purposes which we are now discussing; and that the electric engine has its greatest traction at the time of starting and, therefore, is more particularly valuable for the purposes of car traction than any other engine we know of, and in order to get this momentum of a small armature for the purpose of moving a heavy car it would only invariably bring about the result of a jerk which we have none of us noticed so far in the actual tests and experiments made. I have noticed particularly in regard to the cable cars that it is very disagreeable for obvious reasons; but where we are using a 10 h. p. motor weighing 700 or 800 pounds for the purpose, and the armature of which is but a fraction of the weight, the momentum there can amount to very little in a car weighing six tons.

Mr. Mailloux—It is very apparent that when a motor is permitted to run very fast its counter-electromotive force approximates very closely to its source of energy. Consequently the current is very little from it If you put on a force like a brake that tends to slacken that motor and to gradually couple it with the driving axle you will have a variable velocity ratio between the two, which ratio is gradually approaching unity. As you put on a greater and greater effort you are slacking the motion of the armature and getting the benefit of its momentum, while at the same time the current is increasing through it, and in that way you have the most gradual putting on of the current that you can hope for. I have seen the experiment made so many times that I for my part do not doubt it any more.

The President—There being no further discussion I will ask Mr. Reckenzaun to make such closing remarks as may occur to him.

Mr. Reckenzaun—I was merely going to reply to Mr. Mailloux. On the very first car which I constructed in 1882, which was worked by storage batteries, I used the momentum not only of the armature of the motor but also the momentum of a fly wheel which weighed between three and four hundred-weight. I put the fly wheel upon the counter-shaft and I used that gearing which I have described to-night—that peculiar gearing with the discs and a wedge shaped band. I employed the friction clutch. I thought that by starting the motor to its full speed, and with a heavy fly-wheel, that it would be a great advantage in the starting of the car, but I was greatly disappointed. The car started with a jerk, and when I did away with the fly-wheel I found that the car started with the greatest of ease, and I believe from actual experience which I have had in this direction that it is far better to start without the momentum of the armature or the momentum of any fly-wheel connected with the armature. It is perfectly natural that an electric motor must start gradually. Take the motor off the car altogether and put it upon a table and send through it any current from any battery you like or from any source of energy you like—fifty volts, one hundred volts, or five hundred volts—and you will find that the armature cannot start suddenly. It must take a few seconds to take up its speed, and, therefore, it is perfectly natural that a car propelled by electric energy must start gradually. It is a perfectly natural consequence.

Our worthy chairman has requested me to make some concluding remarks, but the time is getting very late, and I believe gentlemen will be very glad to get off. I have nothing more to say. I have been exceedingly interested in the various remarks which have been made to-night, and I must own that I have learned a great deal. With regard to the general application of electricity to street car propulsion, as Mr. Pendleton has pointed out very forcibly, there is a very great future in store for us, and the time is very near when horses on street cars will be entirely abandoned. We have, I might say, almost passed the experimental stage, and we are now entering the more profitable stage of manufacturing and supplying street railways with electric motors. The advantages in electric motors are not only economy but cleanliness and great saving of space at the depots, and great saving of space in the streets. If you take crowded streets like Broadway, New York, and many other thoroughfares where every square inch of space, you might say, is of value, if you do away with horses you save in length about twelve feet, and in width, of course, the width of the track. Now, it would seem ridiculous for me to make such a remark, but if there are hundreds of cars running in a crowded street it makes many thousand square feet of space saved, and in that space other vehicles can pass. Another great advantage in electrical propulsion will be (apart from economy, which is certain to be a result) that we shall be able to travel at a greater speed. Horses cannot pull a car at a greater speed than six miles an hour. The average speed of all the horse cars in America and Europe is five miles an hour including stoppages. Now, if we can travel at the rate of eight or ten miles an hour a great deal of time will be saved and passengers will avail themselves more of the new mode of traction. They will save a great deal of time. The traffic is constantly increasing. I have heard recently that the street car traffic of New York alone has increased in the last ten years fifty per cent. If it increases in the next ten years again fifty per cent. it would be impossible to cope with the traffic if we employ horses at all. The elevated railroads it appears are doing a large amount of business—almost as much as they are capable of doing—and the only loophole, it seems to me, out of the difficulty is either by building underground railways or by propelling the street cars at a greater speed so that the same number of cars will carry double the number of passengers in the same time.

With these remarks, gentlemen, I close, and I thank you very much for your kind attention. (Applause.)

Mr. Wheeler—I move a vote of thanks to Mr. Reckenzaun for his interesting and instructive paper.

The motion was seconded by Mr. Wetzler and carried.

LIEUT. ZALINSKI'S PNEUMATIC DYNAMITE GUN.

On Tuesday, the 20th, in the presence of the secretary of the navy, the naval committee of the House of Representatives, and many representatives of the army and navy of this and other countries, an exhibition was given in New York bay of the destructive capabilities of the Zalinski pneumatic dynamite gun. The results of the tests made at the time prove conclusively, that, with the present experimental and necessarily imperfect gun, a shell containing 55 pounds of explosive gelatine may be thrown with accuracy a distance of one mile, and exploded at the proper moment for producing the maximum of destructive effect. The target used was a two-masted schooner "Silliman," 80 tons' burden, late of the United States coast survey, but recently condemned, and reserved to be used in torpedo experimenting. She was anchored 1,980 yards from Fort Lafayette, where the gun was stationed. After two trial-shots with blank cartridges, a loaded shell was fired, which struck the water a few yards short of the target. The explosion threw a column of water nearly a hundred feet into the air, and the concussion jarred the vessel so that the mainmast was broken off a few feet above the deck. The next shot struck the vessel at or below the water-line, with an instantaneously destructive result. The schooner was lifted up, fairly torn apart amidships, and the rails were under water in less than 30 seconds, only the foremast and its standing rigging being left in view. All around this floated small fragments of the schooner. In each of these instances the gelatine was exploded by percussion in this way: a small electric battery was affixed to the side, the only thing lacking to start its operation being moisture. A thin piece of blotting-paper kept this out. When the shell was immersed, the moisture admitted generated sufficient electricity to fire a detonator of fulminate of mercury, which exploded the gelatine.—*Science.*

SYMPTOMS OF FURTHER LITIGATION OVER ALTERNATE CURRENT DISTRIBUTION.

The following correspondence between the Westinghouse Electric Co. and the United States Electric Lighting Co., in relation to the United States company's proposed use of the alternating system of electrical distribution has been made public.

July 27th, 1887.

THOMAS B. KERR, ESQ.

Dear Sir: We enclose herewith a copy of a letter written to-day by THE UNITED STATES ELECTRIC LIGHTING CO. to THE WESTINGHOUSE ELECTRIC CO. We assume that you will of course represent THE WESTINGHOUSE COMPANY in this matter and if you decide to commence a suit, we are authorized to appear for THE UNITED STATES CO. and will accept short order of process. We will also give you a stipulation admitting the construction of the apparatus made by our clients and facilitate a speedy trial of the suit in every way we can.

The apparatus referred to consists substantially of a dynamo machine generating an alternating current of high tension, and induction coils at the point of consumption for converting it into currents of lower tension to be used for incandescent lighting. The primaries of the induction coils are connected in multiple arc with the circuit from the dynamo. Incandescent lamps are connected in multiple arc with the secondary coils, which are shorter and thicker than the primaries so as to make the secondary currents of lower tension than the primary. Both coils are wound on the same iron core. This will, we think, enable your clients to decide whether they consider this apparatus to be covered by the patents referred to in their advertisements, but should you require any further information in this regard, we shall be pleased to give it to you.

We think it proper to say that in case you do not bring a suit at present, we shall feel at liberty to make use of this correspondence in any subsequent litigation against our clients on the patents referred to.

Yours, very respectfully,

DUNCAN, CURTIS & PAGE.

NEW YORK, July 27th, 1887.

THE WESTINGHOUSE ELECTRIC CO.,
Pittsburgh, Pa.

Dear Sir: Our attention has been called to your advertisement on page xiv of the *Electrician and Electrical Engineer* for June, 1887, in which you assert that you are the owners of patents that cover broadly, "the distribution of high tension alternating currents and their reconversion to low tension currents for incandescent lighting and running of motors," and in which you plainly indicate your intention of bringing suit against other persons found using this system of distributing electric currents for the purposes indicated.

While it is our settled policy to respect the rights of others as secured by valid patents, we deem it proper to notify you that we do not admit your right to maintain any claim of the character indicated in your advertisement.

Digitized by Google

We also take this occasion to notify you that we are engaged in the manufacture and sale of electric light apparatus in which alternating currents of high tension are converted by inductive action at the points of consumption into currents of low tension for incandescent lighting; and, in order to prevent future misunderstanding, and to secure a speedy determination of our rights in regard to such apparatus, as against the claim which you set up in your advertisement, we are ready to respond at short notice to any suit that you may be pleased to bring against us on the patents on which you base your claim. In case such a suit is brought, it will afford us pleasure to give you a more detailed description of our apparatus, and we promise to do whatever else can reasonably be asked to facilitate a trial and obtain a prompt adjudication of our relative rights.

In view of the peculiar character of the claims that you assert, we think it proper to say that our object is to secure to ourselves an early opportunity of contesting such claims in a suit for the proper defense of which we can be held responsible, and to prevent any possible prejudice to our interests by the outcome of any suit brought by you against other parties.

Yours respectfully,

THE UNITED STATES ELECTRIC LIGHTING CO.
BY G. W. HEBARD, *President.*

PITTSBURGH, July 29th, 1887.

MESSRS. DUNCAN, CURTIS & PAGE,
120 Broadway, New York.

Dear Sirs: Your favor of 29th inst. enclosing the copy of a letter of that date, written by THE UNITED STATES ELECTRIC LIGHTING CO. to THE WESTINGHOUSE ELECTRIC CO., came duly to hand.

I cannot have a consultation with Mr. Westinghouse in regard to the matter until the latter part of next week, and so I will not attempt to reply fully at the present time. I will, however, say, that we have been informed that THE UNITED STATES ELECTRIC LIGHTING CO. were preparing to enter into the manufacture and sale of alternating current plants, and that I have instructions to bring suit against it as soon as any definite case of infringement was brought to our notice.

I will further add, that the apparatus described by you is, in my opinion, a clear infringement of our Gaulard and Gibbs patent, number 351,589. As soon as I can have a consultation with Mr. Westinghouse, I will send a suitable reply, but it may as well be clearly understood by your client, that its threatened infringement of the rights of THE WESTINGHOUSE ELECTRIC CO. to the alternating system will not be tolerated an instant, and will be resisted by the use of all legal measures at our command. The course adopted by your client in regard to this matter, and its abandonment of the system of electrical distribution which it has always heretofore used, in order to adopt the alternating system which we have not only patented, but actually created in this country, is hardly to be justified by the labored and unusual notice which you have favored me with.

Very respectfully,

THOMAS B. KERR,
Attorney for the Westinghouse Electric Co.

PITTSBURGH, August 8th, 1887.

THE UNITED STATES ELECTRIC LIGHTING CO.
120 Broadway, New York.

Dear Sirs: Your letter of July 27th, * * * * came duly to hand.

You do not and cannot deny that the use of the apparatus you are making is covered by our patents, and that your manufacture and sale of it will expose your customers to the liability of a suit by us. Your letter is, therefore, an admission of infringement of our rights, while your action in abandoning the system of distribution which you have heretofore used, for the wholly different system of distribution which we have patented and introduced into use in this country, although an unqualified admission of its merit, is regarded by us as a flagrant disregard of our rights and without warrant on your part.

Your notice would have more of real candor and fairness if it had been given at the time when you first decided to embark on your course of infringement, instead of after a secret and systematic preparation, whereby you are enabled to say that you are now engaged in the business.

We do not concede that you have any rights in the matter, as it is well known and universally admitted that Gaulard and Gibbs, the patentees of our Letters Patent No. 351,589, first introduced and demonstrated the utility and commercial value of their alternating system by the erection of working plants in England in 1883, in the face of the ridicule and opposition of all existing electric lighting interests.

After a thorough investigation into the merits of the system, and after fully satisfying ourselves of the rights of the inventors, we purchased their interests in this country, and since that time have introduced the system extensively here in a field which had not been successfully and profitably occupied by you or any other company; and now, after we have thoroughly demonstrated its value and importance, you propose to abandon your former practice and to benefit yourselves by the unlawful appropriation of our invention. We do not propose to submit to such a course on your part without making use of every lawful means at our command to vindicate our rights. We will, therefore, be obliged to you if you will give us a detailed description of the apparatus you are making and selling, as you have kindly offered to do, together with such other information as may be necessary for the bringing of a suit or suits for the infringement of any of our numerous patents which we may find embodied therein. When we have this information we will accommodate you with one or more suits, as the facts may warrant.

We deem it proper to notify you that in addition to the patents which we have already obtained, we have a large number of applications for patents now pending in the Patent Office, covering important details of the apparatus, some of which will possibly be used by you in your attempted utilization of our system. If such should prove to be the case, your customers will be called to account for using them as soon as we obtain the patents.

In conclusion, we would ask you to contrast your deliberate invasion of our rights in this matter with our conduct in reference to your three wire patent, when, without question and at considerable expense and trouble, we changed several plants rather than have the appearance of infringing upon your rights.

Respectfully,

THE WESTINGHOUSE ELECTRIC CO.
GEO. WESTINGHOUSE, *President*

NEW YORK, August 17th, 1887.

THE WESTINGHOUSE ELECTRIC CO.,
Pittsburgh, Pa.

Dear Sirs: We have yours of the 8th inst. Our letter of July 27th, was not, like yours, written to influence public opinion, or to cover up any facts. Our purpose in writing it was, as we frankly stated, to facilitate an early decision by the Courts of certain questions in dispute between us, after a full investigation of the controversy, and to avoid any prejudice to our rights from suits you might bring against other parties. We assumed that you would be at least as anxious as we were for an early adjudication of our respective rights, and we are therefore surprised that instead of frankly accepting the opportunity we offered, you should so entirely misconstrue our letter and adopt so violent and discourteous a tone in your reply.

We are also surprised, in view of the sweeping assertions of your advertisement, that you should require further information before deciding whether you will bring a suit or not, and particularly in view of the reply of your Mr. Kerr, under date of July 29th, to a letter from our counsel describing somewhat more fully than we did the apparatus we are making, in which he says: "I will further add that the apparatus described by you, is, in my opinion, a clear infringement of our Gaulard and Gibbs patent, No. 351,589."

Should you still, however, be unable to decide without further information whether to bring the suit, we shall be pleased to allow you to examine our apparatus.

While we prefer to try such controversies in the courts rather than to attempt to discuss them by correspondence, there are certain statements contained in your letter which we can hardly pass over in silence without risk of misapprehension in regard to our position.

We do deny that the use of the apparatus we are making is covered by your patents, although we frankly admit that it is covered by the claims you make in your advertisements. So far as we have knowledge of your patents, we do not believe that you will seriously make any claim of infringement except with respect to the Gaulard & Gibbs patent above referred to, and we are advised by our counsel that our apparatus is not covered by any proper construction of this patent, such as would be sustained by the courts.

We have no means of knowing what applications you have in the Patent Office, but if it turns out that we are using anything which you can fairly claim as your property, we shall pursue the course you did when you became convinced of the justice of our position in the suit on the three wire patent, and cease using it at once. You must not expect us, however, to acquiesce in any attempt such as we believe you are making with reference to the Gaulard & Gibbs patent, to appropriate what has so long been public property.

We are wholly unable to see where you found your assumption that we have abandoned the system of distribution we have heretofore used. We have not abandoned, and we have no intention of abandoning, either of the systems we have been using, but shall continue to use them largely.

Your reference to our "secret and systematic preparation" for introducing the system referred to in our letter, seems to us, to say the least, hardly ingenuous. Although our preparation has been systematic, there has been nothing secret about it, as you well know. Several months since, we informed you that we were preparing to introduce such a system, and, if we are not mistaken, your counsel were fully apprised of our intention in that regard some months before that time.

We cannot agree with you in regard to the value of Gaulard & Gibbs' system or their experiments to which you refer. On the contrary, it is generally conceded, as we understand, that the system devised by Gaulard & Gibbs, and used in the experiments referred to is wholly impracticable for commercial use. It has, as we understand, been abandoned by you for a radically different system, and is not, so far as we can ascertain, in commercial use anywhere at the present time. We certainly have no intention or desire to use it.

Nor can we suppose you seriously think that we have no rights in the matter After a very careful investigation of the subject we ascertained that the fundamental features of the system of distribution by means of induction coils or transformers were invented by Mr. Paul Jablochkoff. As you are well aware, we have purchased his invention for this country, and the Patent Office has already decided in an interference proceeding between Jablochkoff and Gaulard & Gibbs that Jablochkoff was the prior inventor.

The liability incurred by our customers from using our apparatus, to which repeated reference is made in your letter, need cause you no uneasiness. It will not, we feel sure, disturb them. We are abundantly able to protect them and shall certainly do so.

In conclusion we think it proper to say, not by way of threat, but merely to avoid any possible misapprehension in regard to our position, that we also have numerous patents and pending applications covering important inventions. We have reason to believe that you are using several of these inventions in the apparatus you are making, and we shall in due time, take proper steps for enforcing our rights.

Yours, very respectfully,

THE UNITED STATES ELECTRIC LIGHTING CO
BY G. W. HEBARD *President.*

NEW YORK, Sept. 19th, 1887.

THE UNITED STATES ELECTRIC LIGHTING CO.,

Dear Sirs: The report of Messrs. Byllesby and Shallenberger, of our company, of their inspection of your alternating current apparatus, which was kindly shown them at your shops by your Mr. Curtis, is to the effect that at present you are not in position to do business in that line, or in other words that your devices and arrangements are not of a character to operate commercially without radical change. We are not informed that you have any alternating current plant in operation. It would therefore seem that your notice to us its premature, and that, as you are not at present, so far as we can ascertain, injuring us by illegal competition, a suit for infringement would be entirely out of place. While we do not care to waste time and money in useless suits, we will defend our rights by all legal means in case you should hereafter actually invade them.

Yours respectfully,

GEO. WESTINGHOUSE, Jr., *President.*

THE TELEPHONE IN GERMANY.

The use of the telephone in Berlin is rapidly extending. At the beginning of last month, the number of subscribers was 6,262, and there were seven exchangers in the town and 21 in the neighborhood. The postal authorities have some difficulty in keeping pace with the public requirements as regard the telephone service. At the present moment there are 1,000 applications lodged at the office, and new applications are coming in at the rate of 150 per month. The total number of separate circuits is about 10,000, of which 8,000 are above ground. The placing of wires underground is being opposed by the town council, who object to the frequent disturbance of the pavement, and are endeavoring to levy from the post office a tax for the use of the streets in the same way as they levy a tax from the electric lighting companies who use the streets. Generally the town authorities raise no objections to over-head wires, and are even disposed to consider them as an element of safety. It has been observed that during recent thunder storms those portions of the town which are most thickly covered with telephone wires enjoyed complete immunity from strokes of lightning, whereas damage was done in other districts. The explanation of this fact is that a large number of the posts supporting the telephone and telegraph wires have purposely been connected with earth, and these posts formed, together with the net work of wires, a fairly efficient protective system.

QUARTERLY REPORT
OF
THE WESTERN UNION TELEGRAPH COMPANY.
FOR THE QUARTER ENDING SEPTEMBER 30TH, 1887.

EXECUTIVE OFFICE,
WESTERN UNION TELEGRAPH COMPANY.

New York, September 14, 1887.

The following statement will show the condition of the Company at the close of the quarter ended June 30th, 1887:—

Surplus, April 1, 1887, as per last Quarterly Report..		$6,815,932.36
Net revenues, quarter ended June 30, 1887.....		1,100,782.03
		$7,916,714.39
From which deducting for—		
Dividend of 1 per cent. paid July 15, 1887..	$811,864.43	
Interest on bonded debt	122,664.85	
Sinking funds	20,000.00	
	$954,529.28	
Less—		
Portion of the sinking fund for the bonds of 1900 (which was set aside previously) returned to the Company by the sinking fund trustees, because of the drawn bonds not having been presented for redemption	40,000.00	$914,529.28
Left a surplus, July 1, 1887, of.		$7,002,185.11
The net revenues of the quarter ending September 30th, instant, based upon nearly completed returns for July, partial returns for August, and estimating the business for September, will be about .		$1,400,000.00
Add surplus, July 1st, as above.....		7,002,185.11
		$8,402,185.11
From which appropriating for—		
Interest on bonds.....	$122,500.00	
Sinking funds.....	20,000.00	$142,500.00
Leaves a balance of		$8,259,685.11
It requires for a dividend of 1 per cent. on the capital stock.....		812,000.00
Deducting which, leaves a surplus after paying dividend, of.....		$7,447,685.11

In view of the preceding statements, the committee recommend the adoption by the board of the following:

Resolved, that a dividend of one per cent. on the capital stock of this Company be hereby declared payable on and after the 15th day of October next, to stockholders of record at the close of the transfer books on the 20th of September, instant.

Resolved, that for the purpose of the Annual Meeting of Stockholders, to be held on Wednesday, the 12th of October next, and of the dividend hereinbefore declared, the stock books of the Company be closed at three o'clock on the afternoon of the 20th of September, instant, and be reopened on the morning of the 15th of October next.

Respectfully submitted,

NORVIN GREEN, *President.*

SUBMARINE CABLES.

The government of Formosa, at the end of last year, decided to connect this island with the mainland by means of a submarine cable, and asked for tenders for the carrying out of the work. Messrs. Jardine Matheson & Co., were the successful tenderers, and placed the orders for the manufacture of the cable and the fitting of the cable steamer with the Silvertown Company. The *Fee Chew* was built at Messrs. Doxford's yard, in Sunderland, and as well as being fitted with cable tanks and cable gear, she carries four guns of light calibre, and on account of her speed will be used, when not employed as a cable vessel, as a despatch boat. The cable will be laid under the superintendence of Mr. Joseph Rippon, assisted by Mr. Daley, both of the Silvertown Company's staff, and by Captain Lugar, who formerly commanded the cable steamer *Mackay Bennett*, and served for a considerable time in the repairing steamers of the West India nad Panama Telegraph Company.

ELECTRIC RAILWAYS IN AMERICA.

Now in Operation.

APPLETON, WIS.—Appleton Electric Street Railway; overhead conductor, 4½ miles, 5 motor cars. Van Depoele system.
ASBURY PARK, N. J.—Sea Shore Electric Railway; overhead conductors, 4 miles. Daft system.
BALTIMORE, MD.—Union Passenger Railway Co.; overhead conductor. Daft system.
BINGHAMTON, N. Y.—Washington Street and State Asylum Electric R. R.; overhead conductor, 5½ miles. Van Depoele system.
DENVER, COL.—Denver Tramway Co.; conduit, 4 miles. Short-Nesmith series system.
DETROIT, MICH.—Detroit Electric Railway Co.; overhead conductor, 2 miles, 4 motor cars. Van Depoele system. Highland Park Railway Co.; overhead conductors, 3 miles, 2 motor cars.
GRATIOT, MICH.—Gratiot Electric Railway Co.; overhead conductor, 1 motor car. Van Depoele system.
KANSAS CITY, MO.—Kansas City Electric Railway Co. Henry system.
LIMA, O.—Lima Street Railway Motor and Power Co.; overhead conductor, 6½ miles, 7 motor cars. Van Depoele system.
LOS ANGELES, CAL.—Los Angeles Electric Railway Co.; overhead conductor, 5 miles, 4 motor cars. Daft system.
MANSFIELD, O.—Overhead conductors. Daft system.
MONTGOMERY, ALA.—Capital City Electric Street Railway Co.; overhead conductor, 11 miles, 20 motor cars. Van Depoele system.
PORT HURON, MICH.—Port Huron Electric Railway Co.; overhead conductors, 2¾ miles, 3 motor cars. Van Depoele system.
SCRANTON, PA.—Scranton Suburban Railway Co.; overhead conductor, 2¼ miles, 3 motor cars. Van Depoele system.
WICHITA, KAN.—Wichita, Riverside and Suburban R. R. Co.; overhead conductor, 4 miles, 6 motor cars.
WINDSOR, CAN.—Windsor and Walkerville Electric Railway Co.; overhead conductor, 1½ miles, 1 motor car. Van Depoele system.
WOONSOCKET, R. I.—Woonsocket St. Railway Co.; overhead conductors.

CHICAGO, ILL.—THE VAN DEPOELE ELECTRIC MANUFACTURING CO. have asked for a franchise from the Lake View city council to run overhead wires from Diversy street north six miles. The company agrees to go underground in one year. If this line proves satisfactory to Mr. Yerkes, the president of the North Side system of street railways, it is thought he will adopt the Van Depoele electric railway upon other lines.

RICHMOND, VA.—THE RICHMOND UNION PASSENGER RAILWAY CO. expected to complete their road and to have it running before this time. They have 13 miles of track, of 4 ft. 8 in. gauge, 45 lb. rail, and will use 40 cars with Sprague electric motors, two on each car. The cars are to be heated by an electric apparatus invented by Dr. W. Leigh Burton, of Richmond.

BROOKLYN AND CONEY ISLAND.—This company which operates a horse railroad from Brooklyn to Coney Island, will reconstruct its road-bed before next season and will substitute electricity for horse-power.

THE VAN DEPOELE ELECTRIC RAILWAY AND POWER CO. has been incorporated with a capital of $2,000,000 for the purpose of purchasing the good will and street railway patents and plant of the Van Depoele Electric Manufacturing Co. The new company will proceed at once to build a new factory, costing not less than $500,000, and with the increased capital will be able to cover the field in a thoroughly satisfactory manner.

NEW YORK NORTH AND EAST RIVERS RAILWAY CO., which has laid double tracks on Fulton street, has secured permission from Arthur Leary, president of the Bleecker street line, to relay the tracks of the latter company on Fulton street. When this is done the electric conduit, on the Bentley-Knight system, which is in process of construction at Pittsburg, will be put in place. The stationary engines and boilers are ready and awaiting shipment from Providence. The J. G. Brill Co., of Philadelphia, have notified the company that the 20 cars they ordered some time ago are almost ready. The Eighth Avenue R. R. Co. and the Belt Line Co. have given the electric company the right to run the cars over their tracks on Fulton and West streets.

THE NATIONAL TELEPHONE EXCHANGE ASSOCIATION.—ANNUAL MEETING.

The National Telephone Exchange Association assembled at Pittsburg on the morning of September 26th, and continued its sessions till afternoon of the following day. President C. N. Fay, of Chicago, presided. The reports of committees showed the affairs of the association to be in a flourishing condition. An amendment to the constitution making October the time for paying annual dues instead of July was adopted.

Henry Metzger, of Pittsburg, was unanimously elected president for the ensuing year. The following officers were also elected :—William D. Sargent, of Brooklyn, vice-president ; H. L. Storke, New York, treasurer. E. J. Hall, Jr., of New York, was elected a member of the advisory committee in place of W. A. Jackson, of Detroit, whose term had expired.

Several papers of much interest were read during the sessions, among which were the following :—Telephone Subscribers *vs.* Knights of Labor, by Mr. C. N. Fay ; Notes on Long-Distance Telephoning, by Mr. Ed. J. Hall, Jr.; Ten Years Progress in Practical Telephony, by Mr. T. D. Lockwood ; The New System of Designating and Ordering Wire, Devised by a Committee of the National Electric Light Association, by Mr. A. V. Garratt ; Underground Work, by Mr. W. D. Sargent.

The members of the association spent Tuesday afternoon, after adjourning at 1 o'clock, in the pleasures of an excursion up the Monongahela, as far as Braddock, hospitably arranged for them through the kindness of Mr. Henry Metzger.

AN IMPORTANT ELECTRIC LIGHTING COMBINATION.

Some months since the Thomson-Houston Electric Co., of Boston, commenced the installation of a number of incandescent electric lighting plants, in which the distribution was effected by means of alternating-current generators and converters, upon which legal proceedings were instituted by the Westinghouse Electric Co., of Pittsburg, alleging infringement by the former company of the Gaulard-Gibbs patent which is owned and controlled by the Westinghouse company. The suit referred to was brought in the Massachusetts district of the United States Court, but no testimony has as yet been taken. It is now authoritatively announced that the suit has been withdrawn, and that an amicable arrangement has been entered into between the two companies, by which they will hereafter operate in harmony and in close business relations. It is learned that by the terms of the agreement, the Thomson-Houston company acknowledge the validity of the Gaulard-Gibbs patents relating to electrical distribution by alternating currents, and will hereafter work under a license from the Westinghouse company. The Thomson-Houston company acquire the right to install the Westinghouse system in the six New England states, and also in connection with the arc lighting plants which it has established in the principal towns and cities throughout the United States, some 200 or more in number, most of which are operated by local companies ; while on the other hand, the Westinghouse company will install the Thomson-Houston arc system, wherever a plant of that kind may be needed in connection with the Westinghouse stations. This practical union of two business interests between two of the strongest and most energetically managed electric lighting corporations of the country cannot fail to have an important influence on the future of the electric lighting industry in the United States. It cannot be otherwise than mutually beneficial to the stockholders of both companies, not only in greatly facilitating the rapid extension of electric lighting, but in relieving them from the annoyance of a tedious and expensive course of litigation. The joint product of the extensive manufacturing establishments of the Westinghouse Electric Co. at Pittsburg, and the Thomson-Houston company at Lynn, will amount to several thousand lamps per day together with the necessary dynamos and converters, and the present indications are that the facilities of both factories will be taxed to the utmost to supply the immediate future demands for the extension of electric lighting.

MR. STEPHEN D. FIELD'S MOTOR ON A BRANCH OF THE ELEVATED ROADS.

The Field electric motor has been running experimentally with a good degree of success on the branch of the Third avenue elevated railroad which runs from the Thirty-fourth street station in Third avenue to the station at the Thirty-fourth street Ferry nearly every day of the latter part of September. The trials are made on the north track, usually between 10 o'clock a.m. and 12 m. They are well worth the careful attention of engineers and others interested in electrical traction.

Mr. Stephen D. Field, the inventor, conducts the experiments in person. Mr. Field is working at considerable disadvantage, being obliged to locate his dynamo at a point more than half-a-mile from the end of the section of track used. His large motor directly connected to the driving wheels, and, therefore, running at a relatively very low rate of speed, works satisfactorily. The sparking at the brushes is very slight indeed. The dynamo used to supply the current is of the very interesting design of Mr. R. Eickmeyer, and of the "iron-clad" type described by Mr. Eickmeyer at the Electric Club some months ago. Mr. Field's success thus far is very promising, and it is to be hoped that his plans for electric traction on the elevated roads will be carried out on a sufficient scale to demonstrate their utility thoroughly.

ELECTRIC LIGHT AND POWER.

AT NORTHAMPTON, MASS., the local electric light company has made a contract with the city authorities to light the city hall with 53 incandescents and three arcs ; two of the arcs are to go in the main hall. The city will pay $225 a year for the bulk of this lighting, and by the night for the hall lighting. Northampton has now 58 miles of electric lighting circuits.

THE PITTSFIELD ELECTRIC ILLUMINATING CO., of Pittsfield, Mass., are changing their plant from the old direct current system to the Westinghouse alternating system Their first installment is for 1,300 lights, and they have received the contract for the city lighting for the ensuing year. Twenty-five c. p. lamps will be used. They are also preparing to run a line to Lenox, Mass., a distance of six miles, for the purpose of lighting the summer residences in that town.

THE GREENVILLE (S. C.) GAS LIGHT CO. will introduce electric lights. The Brush system has been adopted. Sixty lights will be started out with, and the number will be increased as required.

MESSRS. PAINE AND FRANCIS, New England agents of the Edison United Manufacturing Co., announce the following new business ; Farmington Electric Light Co., Farmington, Me., 300 lights; S. S. Pierce & Co., 450 lights ; American Rubber Co., Cambridgeport, Mass., 1,200 lights ; Tremont and Suffolk Mills, Lowell, Mass., 50 lights ; F. E. Reed, Worcester, Mass. (increase), 100 lights ; Bates Manufacturing Co., Lewiston, Me., 300 lights.

THE LAWRENCE (MASS) GAS CO. has decided to put in a complete steam plant for running electric lights in connection with its gas supply.

THE CAPITAL GAS CO., of Sacramento, Cal., which succeeded the Pacific Thomson-Houston Electric Light and Power Co., is now increasing its plant, and adding a 180 h. p. Corliss engine. Mr. J. D. Coleman is the superintendent of the electric light department.

NEW ORLEANS.—The bids opened September 1st, for lighting the public buildings in 1888 were : Brush Electric Light Co., $7,350 per year ; New Orleans Gas Light Co., $4,999.68 per year ; Louisiana Electric Light Co., $81 per light for incandescent lights, $600 per light for arc lights for five years, or a total of $30,864 for the five years.

THE RACINE (WIS.) GAS LIGHT CO. has put in a hundred 2,000 c. p. arc lights, and expects to begin lighting November 1st. The rates will be $75 per light for all-night lighting, and $50 per night till midnight per annum for the city. The rate for commercial lighting will be $8 per month till midnight.

THE SOUTHERN ELECTRICAL CONSTRUCTION AND SUPPLY CO. is putting in a 650-light Westinghouse incandescent plant at Waco, Tex.; also, a similar plant, with 50 arcs, in Dallas, same state.

THE ASHTABULA WATER WORKS CO., of Ashtabula, O., will add electric lighting to its water works business. It has begun by ordering 60 lights from the American Electric Manufacturing Co., which it expects to increase considerably during the coming fall.

THE ROME GAS LIGHT CO., Rome, N. Y., will supply incandescent electric lamps.

THE NEW HAVEN (CONN.) ELECTRIC LIGHT CO. is about to erect another engine, this being the eleventh one, and two more boilers, making eight in all, in order to supply the demand for both arc and incandescent lights furnished by them. The engines were all built by Armington & Sims, and the boilers are tubular.

THE WALTHAM GAS AND ELECTRIC LIGHTING CO., which has been in operation about six months, is now running two 200-light incandescent machines ; one 45-light and one 50-light arc machines. It has two Armington-Sims engines, and expects to put some motors in in the fall.

THE WASHINGTON GAS LIGHT CO., Washington, Ind., has gone into the electric lighting business, and will run its plant by the aid of an Otto gas engine.

THE PLAINFIELD ELECTRIC LIGHT CO., Plainfield, N. J., has nearly completed the enlargement of its station to a capacity of 3,000 lights on the Westinghouse alternating system.

THE HEISLER ELECTRIC LIGHT CO., of St. Louis, of which Messrs. Hyer and Montgomery, Aldrich Building, New York city, are the agents for New York state, has recently put up a line of its incandescent lights for the lighting of the streets of the villages of Fishkill Landing and Matteawan, N. Y., and on Monday evening, August 28th, the people of those places (which are virtually one village) had a celebration in honor of the inauguration

Digitized by Google

of the system. This company has put up these lights in a number of cities in various parts of the west, but has never until now put its system into practical operation in the east. In the Heisler system the lamps which are from 20 to 200 c. p., and are said to be very steady and white, are run in series. The streets of the towns mentioned have 18 miles of wire, from which 183, 20 and 30 c. p. lights are furnished. The wire is of copper, No. 8 or 9 B. and S. gauge.

Foreign.

Belgium.—Railway Station Lighting.—Tenders have been received for lighting the Schaerbeck railway station which affords a useful means of comparing the cost of gas lighting and electric lighting. The St. Josse ten-Noode gas works propose 37 burners each of 110 c. p., and using 32 cubic feet per hour, the cost of gas would be about 73 cents per thousand, and the cost of the installation would be $4,480. Schuckert, of Nurnberg, represented by M. Bouckard, proposes 24 arc lights of 550 c. p., at 9¾ cents per lamp-hour for 3,000 hours guaranteed; at 8½ cents for the following 500 hours, and 7½ cents for any further time, the cost of the installation would be $21,825, and the railway management at the end of the term of 10 years would have to take it over at $7,420. The Societe Anonyme d'Eclairage du Center has submitted three alternative tenders: [a] 11 arc lamps of 1,000 c. p., at 12¼ cents per hour for the first 3,000 hours, 10¼ cents for the next 500 hours, and 8½ cents for the remainder, the cost of installation would be $11,150, the plant being taken over at the expiration of the term for $3,580; [b] 16 lamps of 850 c. p., at 10¼ cents for the first 3,000 hours, 8½ cents for the next 500 hours, and 6½ cents for the remainder, the cost of installation would be $12,610, and the sum to be paid for same at the expiration of the term $4,750; [c] for lighting the two combined stations, 21 arc lamps of 1,000 c. p., at 12½ cents for the first 3,000 hours, 10½ cents for the next 500 hours, and 8 cents for the remainder, the cost of installation would be $19,875, to be bought at the end of the term for $7,370. The engineers of the railway are considering these proposals, and on a decision being come to the contractor will have to complete the installation within six months.

Buenos Ayres.—Mr. Chas. V. Boisot, agent of the Edison Electric Light Co., is arranging to make a large installation of the Edison incandescent light in the city of Buenos Ayres. In the Buenos Ayres *Herald*, it is stated that the plant is to be laid down for a capacity of 7,000 16 c. p. lamps, and that the service will include domestic lighting as well as streets, theatres, public buildings and stores. The price of gas at Buenos Ayres is given at $4.50 per thousand feet by the *Herald*. Such a rate for gas offers a tempting opportunity for the introduction of electric lighting.

PERSONAL MENTION.

From October 15th, Mr. C. J. Kintner, of Wiedersheim and Kintner, of Philadelphia, will be located in New York, at 265 Broadway, where he will establish a New York office of the firm. The presence of Mr. Kintner in New York, will no doubt prove advantageous to the general patent business of the firm, and it will surely be gratifying to his many friends here.

MANUFACTURING AND TRADE NOTES.

UNION SWITCH AND SIGNAL CO.—This company is putting in two large interlocking systems on the Pennsylvania at Pittsburg, and is at work on a number of new towers on the Philadelphia and middle divisions of that road. In addition to the roads named in several former notices, the company has contracts from the Atchison, Topeka & Santa Fe; Chicago, Milwaukee & St. Paul; Chicago & Northwestern; Pittsburg, Cincinnati & St. Louis; Philadelphia & Reading; Central of New Jersey; Baltimore & Ohio; Lake Shore & Michigan Southern; Kings County Elevated (Brooklyn, N. Y.), and the Wisconsin Central. The business of the company bids fair to largely exceed that of any previous year.

THE BALL ENGINE CO., of Erie Pa., is running night and day to supply the demand for its high speed automatic cut-off engine. The greatest demand for these engines comes from the electric lighting interests. This company has turned out during the first half of this year in the neighborhood of 15,000 h. p.

THE JARVIS ENGINEERING CO., of Boston, has received the order for the third Armington & Sims Co. engine for the Newton Electric Light Co., of Newton, Mass.

THE ROCHOW COMPOUND ENGINE.—F. Rochow, manufacturer, Brooklyn, N. Y.—is used in the machinery department of the Murray Hill Hotel, in New York city, where can be seen two of the largest size, and one medium sized Rochow engines, furnishing the power for the immense electric light and refrigerating systems, besides the passenger and freight elevators. All the other power required in this great hostelry also comes from the same source.

THE INDIA RUBBER AND GUTTA-PERCHA INSULATING CO., 159 Front street, New York, W. M. Habirshaw, general manager, are supplying India-rubber covered leads for electric light service in sizes varying from 316 to 2½ circular mils of conductor, both solid and stranded. They have prepared, for the use of purchasers, a table of the sizes of their electric light leads showing the circular millage, weight, insulation, nearest B. W. G. and price per foot.

CATALOGUES AND PAMPHLETS RECEIVED.

The Treatise on Medical Electricity and Catalogue of Electro-Medical Apparatus, a new edition of which we have received from the Jerome Kidder Mfg. Co., has grown to a considerable volume of 112 pages. Besides Dr. Kidder's Researches in Electro-Allotropic Physiology, Uses of Different Qualities of Electricity to Cure Disease, it contains many abstracts from medical books and papers touching electrical therapeutics and directions for all ordinary applications. Dr. Kidder's study and practice, together with the excellence and variety of the electrical appliances devised and manufactured by him and the company bearing his name, are too well known to require enumeration at this time.

Mr. J. H. Guest, of Brooklyn, N. Y., sends us a circular setting forth his Automatic Fire Telegraph System. Mr. Guest gives a list of twelve patents—from 1870 to 1887. The circular contains the following announcements:

"The automatic transmission of fire-alarm signals from one station to another, by means of thermostatic devices operating upon closed electrical circuits; or, the combination with a battery, one or more alarms, and a main circuit, of one or more branch circuits containing thermostats, the closure of the circuit in any branch by its thermostat operating all the alarms, infringes the rights secured to me by the above patents, the infringement of which, by either *manufacturing, vending or using*, by unauthorized parties, renders such parties responsible for such unlawful use, and all the consequences thereof, and liable to suit therefor.

"The subscriber claims to have been the pioneer in the invention and introduction of automatic electric fire-alarm systems, thermostatically operated, as the records of his past business in this field plainly show: and all or any of the closed circuit thermostatic fire alarm systems at present in use infringe his rights, and such infringement will be noticed, and parties so infringing will be dealt with according to law for such cases made and provided."

From the information conveyed in the circular, Mr. Guest appears to have elaborated a very comprehensive system of fire-alarms, applicable to many conditions, and capable of use over existing lines, such as those of district telegraph companies.

Horace Van Sands, 733 Broadway, New York, sends us a catalogue of his electrical goods, under the title "Electrical Appliances, How Made, and How Used." Mr. Van Sands gives much fuller description and information concerning electric bells and similar appliances, with their connections very clearly illustrated by neat cuts and diagrams, than are often found in such lists. The pamphlet should prove very useful to the large number of people who have to put up or use signalling apparatus in localities where the services of electrical workmen are not readily at command. Perhaps careful attention to the information and directions furnished in Mr. Van Sand's pamphlet, would improve the service rendered by many regularly engaged in such work. The very simplicity of electric bell work tempts into it many careless hands, whose slip-shod work annoys the purchaser and discredits electricity in domestic service.

The Edison Electric Light Co.'s new circular is a handsome pamphlet of 38 pages, and is devoted chiefly to setting forth the advantages of their central station lighting system and its growth during the past few years. A list of 103 companies, running or organized in various parts of the country is given. The parent company announces its intention to continue its practice of receiving stock in local companies as a consideration for its franchises or licenses under its patents. The circular is illustrated with handsome cuts of the stations at Detroit, Mich., Harrisburg, Pa., Milan, Italy, and others.

The Baxter Electric Manufacturing and Motor Co., in their catalogue, give very full information concerning the construction and the capacities of their motors. The catalogue contains a very concise and forcible statement of the advantages of electric motors for the supply of power in relatively small amounts, illustrated by figures of the cost of steam power in similar amounts. The practical skill and business energy of the Baxter company have, in a relatively short period, placed them in the front rank of producers of electric motors.

AN INFRINGEMENT SUIT DECIDED.

U. S. CIRCUIT COURT.—SOUTHERN DISTRICT OF NEW YORK.

LA RUE *v.* WESTERN ELECTRIC COMPANY.

Decided May 16, 1887.

EDWARDS.—Telegraph Keys.

Letters Patent No. 270,767, granted January 16, 1883, to Edgar A. Edwards for an improvement in telegraph keys, construed, and held to be for a patentable invention.

Mr. Arthur v. Briesen, for the complainant.
Mr. George P. Barton, for the defendants.
COXE, *J.*:

This is an equity action for infringement of letters patent No. 270,767, granted to Edgar A. Edwards, January 16, 1883, and by him assigned to the complainant.

The invention relates to instruments used for transmitting telegraphic signals, and is said to be an improvement upon the well-known Morse key, the inventor substituting as the lever fulcrum a torsional spring or strip of metal for the trunnions or pivots which were before in use. The patent contains four claims. In the first, second and fourth, "the circuit-breaking lever" is distinctly made an ingredient of the combination. The third claim is in these words:

3. The combination in a telegraph-key, of the lever fulcrumed upon the torsional spring with the adjusting screws H H_1, for regulating the amplitude of the lever movement and retractile resistance of the torsion spring, substantially as described.

It will be observed that this claim omits "the circuit-breaking lever" as an element, and in this respect is broader than the other three. The infringing instrument is called a "sounder," and contains no circuit-breaking lever" as this term is generally

Digitized by Google

understood in the art. The complainant, however, insists that the sounder has a lever which breaks not an electric but a magnetic circuit, and is therefore within all the claims of the patent. What the patentee invented, and unquestionably intended to secure, was a flat torsional spring, ribbed or otherwise, upon which a lever is fulcrumed, when in any electrical instrument, it can be substituted for the pre-existing trunnions and spiral spring and perform the two-fold function of a supporting-fulcrum and retractive spring. He distinctly says that he does not limit himself to the application of the spring to the key alone, as it is obvious that it may be used to replace the trunnions of the relay and sounder. He may, however, have so restricted three of his claims that they do not cover the instrument used by the defendants. It is not essential in the present action to decide this question. If it is held that the third claim is infringed the complainant will derive the same advantage as if the decree declared the infringement of all.

The defendants insist that the patent is void for want of utility and invention, and that they do not infringe. But a word need be said regarding the first defense. Several instruments embodying the invention have gone into practical operation, and have apparently been received with favor by telegraphists. In fact, it appears that an employé of the defendants, Charles D. Haskins, has, since the commencement of this suit, secured a patent, dated November 9, 1886, for an improvement in telegraph receiving instruments, one element of the combination being a torsional spring, substantially identical with the patented spring, the only difference being in the manner in which it is fastened to the lever. This patent was assigned to the defendants. It can hardly be said, then, that Edwards' invention is without utility. That which is used is useful. A thing to be useless can have no utility whatever. A patent is never declared invalid upon this ground at the instance of one who is deriving benefit by infringing upon its claims. (Gibbs *v.* Hoefner, 22 Blatchf., 36, and cases cited.)

Is the patent void for lack of invention? The defendants, for the purpose of illustrating that art at the date of the invention, have introduced in evidence a number of exhibits showing the manner in which telegraph keys were constructed prior thereto. It is unnecessary to refer to these, as they do not contain the torsional spring and add very little to the light thrown upon the prior art by the statements of the patent itself. The exhibits which are the nearest approach to the invention are the magnetic "pole-changer" and the "adjustable torsional spring." In the "pole-changer," first known in 1881, there is a lever which oscillates between fixed points and is fulcrumed upon the free end of a non-adjustable torsional spring. The principal office of this spring is to form a supporting fulcrum for the armature lever. The retractile force exerted by it is very slight. If one of the supporting posts in the patented apparatus were removed, its similarity to the "pole changer" would be apparent. The "adjustable torsional spring" exhibit is an enlarged model of an instrument made by one of the witnesses in 1878. It consists of a fine wire connected at each end to adjustable brackets, a lever suspended in the centre of the wire. It is not the purpose of the wire to cause repeated and regular oscillations of the ends of the lever. That it performs any torsional function is strenuously disputed. The wire is very fine, and as its ends are not firmly fastened, but to some extent are permitted to rotate in the holes of the brackets, it is not easy to see how it can be twisted to exert any appreciable force. It is enough to say that the matter is involved in doubt. Neither of these exhibits can be said to anticipate or otherwise to defeat the patent. It follows, therefore, that the patentee has made an invention, not a great one certainly, but one entitling him to a position far above the plane of the skilled mechanic. Torsional springs were of course well-known, so were telegraph keys and sounders minus this spring; but the combination of the patent was never before used, and there is nothing in the prior art to suggest it except to an inventor—to one who was a skilled artisan only it would never have occurred.

Do the defendants infringe? They argue in the negative, for the reason that the combination of the third claim is confined to a telegraph key, and by implication, to a "circuit breaking lever," and as they use the combination in a telegraph sounder and not in a key they do not infringe. They insist, further, that they do not employ the adjusting screws, H H_1. In regard to the latter suggestion, the defendants' expert testifies:

> I find two adjusting screws having a relation to the lever of the sounder similar to that of the screws, H H_1, to the lever of the key in the patent; but in the sounder they do not practically have any effect upon the retractile force applied in the lever.

The complainant's expert considers the functions the same in every particular. The court is satisfied that he is correct.

As has been seen, the third claim does not contain the element of a "circuit breaking lever," and in view of the clearly expressed intention of the patentee to include other telegraphic instruments it must be held to include the lever of a sounder. Fairly construed, the claim should read: "The combination in a telegraph key or sounder," &c. To restrict it to a "key" alone, as that word is known in telegraphy, would be most illiberal, and would unduly circumscribe the invention. No better illustration of this can be found than the following statement from the Haskins patent, before alluded to:

> The invention has been described in connection with a telegraph sounder, but it is evident that the torsion-spring may be applied to the armature lever of any telegraphic receiving instrument or to the lever of any telegraphic key without departing from the spirit of the invention.

Equally it is true that the Edwards spring may be applied to a sounder without departing from the spirit or the letter of the invention.

As the question of infringement was carefully examined by this court upon the motion for a preliminary injunction (28 Fed. Rep., 85; 36 O. G., 453), it is unnecessary to repeat what was then said.

There must be a decree in favor of the complainant upon the third claim for an injunction and an accounting.

As the motion to punish the defendants for contempt will probably turn upon a question of fact, which ought not to be determined upon affidavits, it is thought that this issue should also be referred to the master and the motion held in abeyance until the coming in of his report.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions, 11 Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From August 23d to Sept. 13th., 1887 (inclusive).

Alarms and Signals:—*Fire Alarm Telegraphic Repeater*, C. Burgher, 368,907, August 23. *Electric Call Bell*, J. G. Noyes, 369,808. *Electrical Annunciator Call System*, F. J. Patten, 369,810. *Electric Bell*, H. P. F. Jensen, B. Webb and J. Jensen, 369,989, September 13.

Clocks:—*Controlling Device for Clocks*, W. S. Scales, 368,689, August 23. *Electric Synchronizing Attachment for Clocks*, E. F. Bard, 369,386. *Electric Alarm Clock*, A. G. Woolley, 369,672, September 6.

Conductors, Insulators, Supports and Systems:—*Conduit for Electric Railways*, F. Euphrat, 368,576. *Connecting Device for Electrical Conductors*, W. J. Hammer, 368,764. *Support for Electric Conductors*, M. J. Hart, 368,766, August 23. *Conductor Tip*, S. S. Wheeler, 368,987. *Method of Making Impervious the Joints of the Lead Pipe of Electric Cables*, W. R. Patterson, 369,121. *Manufacture of Electrical Conductors*, J. J. Williamson, 369,144. *Joint for Telegraphic Wires*, D. P. Emminger, 369,238. *Insulating Telegraph Cables*, W. R. Patterson, 369,259, August 30. *Underground Electric Cable*, J. H. Dalzell, 369,320. *Lead-Armored Conductor and Process of Making the Same*, T. G. Turner, 369,372. *Electrical Conductor*, H. F. Campbell, 369,394. *Insulator*, E. T. Greenfield, 369,447. *Manufacture of Bunched Electric Cables*, J. H. Dalzell, 369,592. *Bunched Electric Cables*, same, 369,593. *Manufacture of Diminishing Electric Cables*, same, 369,594, September 6. *Manufacture of Insulated Electrical Conductors*, J. T. Jaques, 369,793. *Underground Conduit for Electric Wires*, G. Rader, 369,813. September 13.

Distribution:—*System of Electrical Distribution*, T. A. Edison, 369,280, August 30, same, 369,439, 369,441, 369,442, and 369,443, September 6.

Dynamos and Motors:—*Electric Generator*, L. G. Woolley, 369,219, August 30. *Dynamo-Electric Generator*, R. Eickmeyer, 369,400. *Regulator for Dynamo-Electric Machines*, E. Place, 369,655, September 6. *Dynamo-Electric Machine or Motor*, E. Thomson, 369,754. *Regulation of Electric Motors*, S. S. Wheeler, 370,000, September 13.

Galvanic Batteries:—*Electrical Battery*, T. W. Bryant, 368,806, August 23. *Galvanic Battery*, J. A. Seely, 369,034, August 30. *Galvanic Cell*, L. Drescher, 369,505, September 6. *Galvanic Battery*, H. J. Brewer, 369,769, September 13.

Lamps and Appurtenances:—*Electric Safety Lamp for Use in Mines* M. Settle, 368,857, August 23. *Mast-Arm for Hanging Electric Street-Lamps*, F. H. Lacey, 368,955. *Manufacture of Incandescent Electric Lamp Filaments*, A. Bernstein, 369,091. *Electric Arc Lamp*, O. P. Loomis, 369,194. *Process of Treating Filaments for Incandescent Electric Lights*, E. P. Thompson, 369,267, August 30. *Electric Lamp*, O. P. Loomis, 369,319. *Electric Arc Lamp*, H. Lemp, 369,456. *Feed Mechanism for Arc Lights*, W. W. Street, 369,568. *Arc Lamp*, D. J. Hauss, 369,640. *Carbonizing Mold for Incandescent Electric Light Filaments*, E. P. Thompson, 369,664. *Method of Testing Electric Light Filaments*, same, 369,665. *Carbonizing Mold for Incandescent Electric Light Filaments*, same, 369,666, September 6. *Apparatus for Making Carbons*, J. T. Lister, Reissue, 10,866, September 13.

Miscellaneous:—*Electrical Resistance*, W. H. Knight, 368,596. *Electric Hose Coupling*, E. H. Crosby, 368,654. *Electrical Apparatus for Voiding Water Pipes*, J. W. Kent and R. Orr, 368,674. *Process of Tanning by Electricity*, J. W. Aborn and J. Landin, 368,745. *Safety Catch for Electrical Circuits*, W. J. Hammer, 368,765. *Portable Electric Propeller for Boats*, G. Trouvé, 368,796. *Electrical Resistance Coil*, C. D. Baker, 368,804. *Combined Electric Receiving and Transmitting Device*, F. S Carter, 368,809, August 23. *Electro-Magnetic Dental Mallet and Plugger*, P. Helmer, 368,948. *Ship's Course Corrector*, C. Rouget, 368,973. *Lightning Arrester*, E. A. Sperry 369,036, August 30. *Electrical Heating Apparatus*, A. H. Buckelew, 369,432. *Lightning Arrester*, A. B. Depuy, 369,436. *Sediment-Trap and Solution-Clarifier*, M. H. Levett, 369,457. *Magnetic Register-Connection for Water Meters*, A. S. Dietzman, and G. Cressey, 369,595, September 6. *Apparatus for Backing Electrotypes*, R. Gnichwitz, 369,706. *Electric Valve Controller*, W. H. Markland, 369,801. *Electrical Cut-Out*, N. F. Stoddard, 369,889. *Lightning Conductor*, W. Brown, 369,915. *Electric Heat-Regulating Apparatus*, W. A. Connelly, 370,007, September 13.

Railways and Appliances:—*Stop-Cock for Electro-Pneumatic Brake Systems*, J. F. Carpenter, 368,650, August 23. *Apparatus for Lighting Cars by Electricity*, S. H. Short, 369,561, September 6. *Railway Telegraph*, L. J Phelps, 369,880. *Governor for Electro-Magnetic Brake Circuits*, G. F. Card, 369,917. *Electric Railway-Signal*, J. H. Farrar, 369,929, September 13.

Storage Batteries:—*Secondary Battery or Accumulator*, A. E. Peyrusson, 368,608, August 23.

Telegraphs:—*Printing Telegraph*, R. J. Sheehy, 368,692, 368,858, and 368,859, August 23. *System of Synchronism for Telegraphy*, G. A. Cassagnes, 368,931, August 30. *Printing Telegraph*, W. B. Wood, 369,577, September 6.

Telephones, Systems and Appliances:—*Telephone*, H. L. Todd, 368,628, August 23. *Test-Circuit for Telephone Cables*, W. R. Patterson, 369,122. *Electric Speaking Telephone*, M. Martin, 369,256, August 30. *Telephone*, F. C. Watkins, 369,376. *Krotophone*, same, 369,377. *Krotophone-Receiver*, same, 369,378. *Telephone Transmitter*, same, 369,379, September 6.

THE ELECTRICIAN
AND
ELECTRICAL ENGINEER.

Conducted by F. L. POPE. G. M. PHELPS, JR., Associate Editor.

PUBLISHED MONTHLY BY

THE ELECTRICAL PUBLISHING CO.,

115 Nassau Street, New York city.

European Agent, F. H. WEBB, 4, The Sanctuary, Westminster, London, S.W., Eng.

TERMS OF SUBSCRIPTION.

United States and Canada,	per annum,	$3.00
Four or more Copies, in Clubs (each)	"	2.50
One Copy, Four Months,		1.00
Great Britain and other Foreign Countries within the Postal Union	"	4.00
Single Copies,		.25

[*Entered at the Post Office at New York, N. Y., as second class mail matter.*]

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

NEW YORK, NOVEMBER, 1887.

SOME OF THE RESULTS OF TELEGRAPHIC COMPETITION.

NEARLY a year since, in a discussion of the commercial prospects of the telegraph business in the United States, under the conditions then prevailing, we expressed the opinion that the competitive organizations were suffering a greater proportionate loss of revenue than the Western Union company, for the reason that the non-remunerative rates then and since in force applied to a greater share of their entire business. Commenting upon the probable result of such a state of affairs, we said:

It is wholly improbable that the competitors of the Western Union company will be able to inflict any greater damage upon its revenues in future than they have done during the past year, while at the same time it will be seen that even under these conditions its net earnings have not gone below four per cent. upon its present capital. As Western Union is well known to be controlled by a small group of strong capitalists, of whom Mr. Gould is the chief, there is no apparent reason why those astute gentlemen cannot if they choose, afford to let the present condition of affairs go on indefinitely, or until their competitors are exhausted, and then take them in upon some basis which will be remunerative to themselves. Such a consummation must necessarily result in a restoration of the rates to a reasonable and remunerative figure, but we have already shown that such an increase would, as far as the public is concerned, amount to but a trifling sum on each message transmitted.

Our views as to the ultimate outcome of the situation are proven, by the subsequent progress of events, to have been singularly accurate. Mr. Jay Gould and his fellow capitalists have waited, with their accustomed patience, until the Baltimore and Ohio company became sufficiently "exhausted," and they then proceeded to take it in "on a basis remunerative to themselves." As to the truth of the last part of the proposition there can be no doubt, if as generally understood, the price paid was only some $4,000,000, reckoning Western Union stock at its market value. If, as officially stated, the plant purchased embraces about 58,500 miles of wire, this would amount to about $70 per mile. It was by no means a bad purchase, especially in view of the facts that the plant is nearly new and of first-class construction, and that many of the franchises and rights of way, such for example as that over the West Shore and Nickel-plate railroads, are extremely valuable, and that the capitalization of the present Western Union plant is about twice as great, viz., $140 per mile.

It is stated apparently by authority, that during the last year the business of the Baltimore and Ohio amounted to 7,500,000 messages, for which it received $2,983,506, or approximately 30.9 cents per message, as against the 30.25 cents per message reported by the Western Union. It is difficult to understand how this can be true, unless, as is probably the fact, the estimates are made upon the basis of a different number of words per message. For if the figures are made on the same basis there is no apparent reason why the Baltimore and Ohio company could not have earned a profit of over half a million dollars, in which case it could scarcely have gone begging for a purchaser as it did, at $4,000,000.

The fundamental error originally committed by the Baltimore and Ohio company was in adopting the suicidal policy which has been the direct cause of the failure of every competitive telegraphic enterprise from the beginning. We refer to the policy of cutting rates. If the Baltimore and Ohio, with its superior equipment and excellent personnel, had maintained a minimum 25 cent rate from the start, and had at the same time given the business public an ideally prompt and accurate service, such a service as every experienced telegrapher knows can be given if only the proper inducements are offered to the employés, the outcome would, in our opinion, have been a very different one. Such an experiment remains to be tried, and we sincerely hope to see it done. It is manifestly impossible to transmit messages at a profit at such absurdly low rates as 10 and 15 cents, if the labor employed is to be reasonably or even fairly remunerated. President Green sums the matter up in his accustomed pithy and epigrammatic way, when he says, in his annual report, "Our greatest competitor is time, and just in the proportion that we can overcome time in transmission and delivery of messages will our business be increased." It is to be hoped that he may be enabled to carry out the policy which he has thus indicated.

ELECTRICITY ON STREET RAILWAYS.

THE recent convention of street railway managers at Philadelphia discussed little else than the question of the application of electric power to street railway service. The able and exhaustive paper of Mr. Wharton, which we print elsewhere in this issue, based on the results of experimental work carried on under his own directions, must have opened the eyes of some of the more conservative brethren who are waiting, in various parts of the country, to find out whether electricity "is going to work" before committing themselves to its use. We infer that Mr.

Digitized by Google

Wharton is of the opinion that the direct-supply method although well adapted to a small traffic, will not answer for a large traffic, as, for example, on the Third Avenue line in New York. In this he is, of course, in error, but in the main his conclusions are eminently sound and satisfactory. Mr. Richards, of Boston, who is admitted on all sides to be one of the ablest street-railway managers in the world, puts himself on record as an enthusiastic believer in the immediate utility of the electric system. The accumulator method, which at first was regarded with little favor, at least by electricians, is giving surprisingly good results in Philadelphia and Boston, and its future is apparently full of promise. The direct-supply method has already more than fulfilled the expectations of its friends. An electric street car "boom" is certainly upon us.

EFFICIENCY OF THE DIRECT VS. THE ALTERNATING SYSTEM OF DISTRIBUTION.

In a public hearing before the Massachusetts Gas Commissioners a few weeks since, Prof. W. D. Marks, of Philadelphia, made the somewhat amazing statement that the maximum efficiency of the alternating dynamo is about 70 per cent., and that the efficiency of the converter ordinarily used in connection with it is 80 per cent.; from which he deduced that the total maximum efficiency of the alternating system is 56 per cent., as against 85 for the direct system of the Edison type. He also asserted that the economy of the direct system, within the distance of two-thirds of a mile, is from 60 to 100 per cent. greater than that of the alternating system. At the same hearing Mr. W. F. Jenks, of the Edison company, stated that at Brockton, Mass., seven and a half 16-candle lamps per horse-power were obtained. The company furnishing the alternating system guarantee ten 16-candle lamps per horse-power. The problem that we would like to have solved is this: How is it that a system having a maximum efficiency of only 56 per cent. furnishes 160 candles per horse-power, while another system having an efficiency of 85 per cent. can furnish only 120? It would be interesting to electric light engineers to know the authority for the figures of the eminent professor.

The demand for trained skill in electrical engineering continues to increase faster than the supply, notwithstanding the influx to that vocation of large numbers of young men during the past few years, and the successful establishment of electrical courses in many of our high class technical schools. It is not too much to say that no extensive corporation or firm engaged in the fields of electric light and electric power is able to man its work adequately. It is easier to get business than it is to execute the work. The need is felt most in respect to the higher classes of service—service properly coming under the designation of electrical engineering. Although experimenters and scientific investigators have demonstrated many principles underlying the correct construction of dynamos and motors, and have published their researches and results, so that they are free to all, their systematic and thorough application is in many cases neglected, or, if not overlooked, fails of accomplishment perforce, because the men to apply them intelligently are not at hand. Badly designed dynamos or motors, insufficient or needlessly large conductors used in wiring, in short, failures to apply well-known principles in the design of apparatus or in the installation of plants, result in the loss of money to somebody. We feel very sure that the managers of leading manufacturing and contracting companies fully realize the situation and desire to have their designing and construction executed under the supervision of trained skill and accurate knowledge. The money value of such knowledge and skill is doubtless growing in their eyes, and will, we trust, lead to such ample compensation as will increase the attractiveness of electrical engineering as a calling to capable and energetic young men.

The reforms in the Patent Office embodied in the bill prepared by the legal committee of the National Electric Light Association (which we reprint in another column) for submission to Congress, commend themselves at once to all acquainted with the needs of the office and its shortcomings in serving the best interests of inventors and the general public. In a circular pamphlet, the Association sets forth many considerations in favor of the proposed legislation, supplementing the able statement of Mr. Arthur Steuart, chairman of the legal committee, by opinions of much force and cogency, in contributions by Mr. Albert H. Walker, of Hartford, Mr. Benjamin Price, of Baltimore and Mr. Ephraim Banning, of Chicago.

The Association earnestly requests its members as well as all other persons who approve the proposed reforms, to make personal efforts in developing opinion in favor of the bill, particularly among members of Congress. If their request be heartily responded to, nearly every member of Congress can be made acquainted with the merits of the bill before its presentation next winter.

The American Institute Electrical Exhibition, as was expected, affords an excellent opportunity for the general public to become acquainted with the generation, operation and application of the force that now serves so many of their daily wants. The field is well covered by the numerous and various displays, ranging from electric railways and electric lighting plants to annunciators and push buttons for house calls. The exhibition will prove useful in spreading information, and was wisely undertaken by the New York Electrical Society.

The appeal of the National Electric Light Association, to its members for contributions to a fund of $2,500 for printing the proceedings of the last three semi-annual meetings and for printing and circulating the congressional bill for Patent Office reform, and documents in furtherance of that measure, seems fully justified by the significance and value of the work, and will doubtless lead to the raising of the required amount at an early day. As at present constituted, the annual receipts of the Association from membership dues are quite inadequate for the provision of such a fund.

There is no finer drive, for its length, in America, than the ten miles of the old Albany Post road, along the east bank of the Hudson from Yonkers to Tarrytown. Flanked by magnificent villas and country seats, with their smoothly shaven lawns, and exquisite ornamental plantations, shaded by rows of venerable elms, and surrounded by evidences of wealth and taste on every side, it may well be as it is, the pride of Westchester County. But in the vicinity of Tarrytown, the electric light fiend has been let loose with results which literally beggar description. Rough, unpainted poles, set in an irregular and scattering manner, thick, white wires, strung in a slack and slovenly way, zigzagging across at inelegant angles; bracketed to the branches of the fine old elms, nothing could be imagined better calculated to excite the disgust of the average inhabitant against electric lighting, than this wanton and utterly unnecessary disfigurement of a magnificent avenue.

Those of our readers who may be annoyed by the delay in issuing this number of The Electrician and Electrical Engineer, will please reserve their disapproval for the striking printers.

ARTICLES.

USES OF ELECTRICITY IN MILLS.

BY C. J. H. WOODBURY.

ATTENTION is frequently called to the extent to which the devices operated by electricity are becoming a necessity in commercial affairs, or a convenience held no less essential in matters of domestic life. Few persons have any idea as to the extent to which electricity is used in large manufactories, particularly in textile mills where the utmost regularity of operation is essential to every detail of the organization. These large establishments with numerous buildings enclosed in an extensive territory, form a community of their own where the labor toils under circumstances of such close competition that the difference between prosperity and failure is obtained by the skill with which the utilization of the waste material is accomplished.

For example, suppose that a visitor should pass through one of these large cotton mills with eyes closed to everything except where electricity plays a part, and this method of eclipsing more prominent matters would of necessity reveal a large number of features in which electricity forms an essential condition.

In the first place, stepping into the office of the manager, there are the usual methods of signaling and communication by the ordinary electric push button and bell with wires leading from the desk of the manager to other portions of the building and to his numerous lieutenants on the premises.

The telephone is being introduced and is continually developing into a more important place in such surroundings, for in addition to the ordinary telephone connection with the central station of the system, a number of mills are equipped with telephones leading from the overseers and superintendents of various departments to the main office, and there by means of the small switch-board, they can communicate with each other. An arrangement of the kind has been found to be of the greatest utility in the saving of time and also prompting the more rapid and absolutely confidential transmission of messages between various portions of an establishment. In case of fire, the telephone would serve a most important and valuable purpose; not merely in giving the alarm but accompanying it with more detailed information than would be possible by an alarm bell, and at the same time affording a vehicle for receiving orders transmitted over the wire.

In the textile manufacturing, regularity of speed is essential in obtaining uniformity of fabric in various processes of production, and the manager can at any time ascertain the velocity of the various water wheels, or engines, by moving a suitable electric switch in the office, and the impulses caused by the revolution in any one of the prime movers in the establishment.

A number of switches are in this manner arranged to throw in various circuits and the impulses received from any one of the engines or water wheels, and the record of the motion accomplishes more than merely affording an opportunity of hearing sounds concurrent with the revolutions measured; but in combination with the clock work the electric impulses are used in connection with an escapement for one minute so that the special dial on the clock will record the number of revolutions made during one minute. In this manner a few moments time serves as a means of obtaining an inspection of the work of all prime movers in a large establishment comprising a number of different mills.

On passing into the mill, the visitor is at once impressed with the extent of the precautions taken against fire; and in this matter electricity is of paramount importance in the protection against fire where the value of a few seconds in its incipiency will determine whether the fire is to become a trivial matter or a disastrous conflagration, and it is here that electricity plays its great part, in the saving of seconds.

In addition to the ordinary fire alarm box, whose station is placed at some salient part in the yard, there are other manual stations connected with it at various points in the mills where any person by taking a suspended hammer can break open the glass covering a manual alarm, and in this way transmit a warning to the fire alarm in the yard.

Within the mill there is another class of fire alarms entirely of an automatic nature, which are operated by a rise in temperature to some predetermined point above the normal heat; the usual temperature selected for this purpose being 120 degrees.

This will affect the thermostats so that the electric circuit will be opened or closed, according to the nature of the system employed. Some of these thermostats are operated by the expansion of mercury or by the dissimilar expansion of two metals, others by the fusion of a joint or link of alloy fusing at 162° Fahrenheit. Later forms use the expansion of a reservoir containing either a hydro-carbon or some other liquid volatile at the desired temperature.

A great deal of ingenuity has been spent, both on these thermostats and the whole electrical system with which they are connected, with a view of obtaining promptness in the operation of the thermostat and also that the electrical organization of the system shall be so arranged that it shall not be impaired without notice by deterioration of the battery, interference with the wires, by accident or malice, and at the same time to prevent the sounding of false alarms. The question of thermostats cannot obtain other than a passing reference in this connection, merely stating that the practical results are of a most satisfactory nature.

The alarm from the thermostats is also localized by visual numbered tags as in an ordinary annunciator, in addition to the sounding of the alarm, so that the fact of the fire and its detailed location is promptly announced in the office or the headquarters of the watchmen. A recent instance of a hot bearing on the machinery of an elevator, showed the delicacy of these fire alarms, for a thermostat caused an alarm to be sounded before the bearing had become hot enough to produce fire; and an automatic sprinkler near by was not opened as the heat radiating from the warm bearing was merely sufficient to cause the thermostat to sound the alarm in advance of the occurrence of fire. Thermostats are also used in connection with electric apparatus to indicate where the temperature of main journals exceeds the usual temperature, and in this manner give warning of conditions tending to produce hot bearings.

Electricity is also used in connection with the automatic sprinkler systems which are in universal use for the protection of such property; for in some instances it is not feasible to allow the water to remain in these sprinkler pipes during the winter months on account of the danger of freezing in buildings which are not artificially warmed, and one of the methods in such cases is the use of electrical apparatus which will cause a valve to be opened and water let into the pipes whenever the temperature of the room rises sufficiently to open any one of the sprinklers.

On account of the many contingencies and necessary mechanical complications from the various dry pipe systems hitherto in use, it has been found preferable either to warm the buildings in winter, or even shut off the water altogether during cold weather than to rely upon automatic appliances which introduce such mechanical complexities into the matter. It is in this direction that there is a fine chance for inventors to produce an article for which there is an extensive demand which has not been met by any of the numerous devices produced for this purpose.

Digitized by Google

Mills are patrolled by watchmen on an hourly circuit day and night for the year round, and the record of such work is made by electricity as the watchman visits the several stations, which are so arranged that it will record the patrolling of the whole of the predetermined route which will oblige him to traverse the whole of the property entrusted to his care.

There are two classes of these electrical watch clocks, both of which make their records upon circular paper dials which can be filed away and used for reference, showing the time at which each station was visited. One class of these clocks use a circuit for each station and the closing of the circuit by an ordinary push button or its mechanical equivalent which causes a perforation, pencil mark or stamp number, upon the paper dial in the position indicated by that of the registering device on that circuit; while the time at which such a registration is made is indicated by the circumferential position of the paper registered when the circuit was closed.

The other class of electric watch clocks use an arbitrary broken circuit, corresponding to the strokes of the fire alarm; instead of ringing a bell, it perforates the numbers upon a circular paper disc revolved by clock works. These paper discs in both instances are measurable alike, being attached to some portion of the clock mechanism which revolves once in 12 hours, and with suitable radial and circumferential lines, so that the locus of the various perforations may be readily determined and the position is more easily noted by bordering the paper dial with figures representing the hours, similar to the clock dial.

One of these watchmen's electrical clocks requires no battery, the electricity being generated by the magneto operated by the watchman in the act of making his record at the several stations.

In some cases the watchmen's clock is placed at the headquarters of the district telegraph company, and if the watchman is fifteen minutes late at any of the stations in the mill, an alarm bell at the mill is rung from the district telegraph, and if no answer is signaled back by the watchman a policeman is summoned to the mill on the presumption that assistance is needed. Of two instances where such delays occurred, in one the watchman had been hit by a rock thrown through a window and was lying insensible, and in the other he was in a dying condition from a fit, and medical assistance was summoned barely in time to save his life.

It is quite possible that the arrangement may seem complex to those not personally conversant with its details; but the contrary is the case; a very few patents seem to control the whole business.

Considering other matters of electrical applications in a mill, the first and most valuable is that of electric illumination which has been of great value wherever used, by affording a perfect lighting when arranged with good judgment, which gives results comparable to that of the day light; allowing the suitable distinction of colors by the flood of light furnished, enabling the detection of imperfect work at the time that it occurred in the process of manufacture, keeping the health of the operatives in better physical condition, an advantage alike to humanity and also to the more sordid demands of manufacturing; and in every respect seems to relieve manufacturing from the disadvantages attendant upon artificial light.

In certain classes of textiles there is known to the trade a difference between the quality of summer and winter goods; a distinction which owes its origin, not to questions of temperature, but solely to the fact that during a large percentage of the hours of labor in winter artificial light is used, while in summer it is not used at all.

Electricity is also used in the course of manufacturing in several devices which are of great importance in the production of perfect cloth; as in the first drawing out of cotton as it comes from the card before any twist has been applied to it, one of the most efficient eveners is operated by electricity. In the warping room where a breaking of the thread, if undiscovered, would be an injury to the fabric, the mechanical alarms for such mishaps have been to some extent displaced by more sensitive and accurate electrical alarms; and in the weaving room there are devices recently introduced, in place of the mechanical arrangements formerly used for the purpose, by which a broken thread is immediately made known and the loom automatically stopped.

There are other matters of great importance in the manufacture of textiles in which it is assumed that electricity will eventually be of far greater recognized importance than at present.

In the operations of dyeing and bleaching, not to mention the chemical processes for supplying the agents which are there used, it can not be otherwise than that electricity will in the immediate future occupy a very much larger field in that department of industrial chemistry.

A few years ago careful experiments were made in the attempt to bleach cotton fabrics on a large scale by means of ozone, generated by means of an induction coil, but while the results were never pushed to commercial sequences, the manager of the bleachery, a gentleman who has received the advantage of chemical instruction in some of the best European polytechnical institutions in addition to the practical experiences of many years in this country, always felt confident that this method of bleaching would eventually be found to be the cheapest and most desirable method.

There is a class of troubles of the most serious nature in textile mills arising from the static electricity generated by belts, and especially during the operations of spinning; at certain states of the atmosphere, these difficulties become more aggravated and are sufficiently severe at times to cause the operation of the mill to be unprofitable or not even feasible; for instances have been known where it was actually necessary to shut down the mill on account of the dog days.

The success of those communities such as Oldham, in England, where cotton manufacturing has proved to be extremely successful and always at an advantage over their competitors elsewhere, has been shown to be due to the uniformly favorable electrical condition of the atmosphere in these places.

At times the productions of paper mills becomes charged with static electricity and retain the charge for a long time like any other condenser. It is very difficult to use such paper in printing presses, because the paper will fly towards the conductors formed by the metal parts of the press, the loss by rumpled sheets reaching as high as 50 per cent.

In citing some of these elements in which electricity forms a part in relation to textile and paper mills, I do not perceive how this article could be made more useful than perhaps to stimulate some mind to a successful treatment of the difficulties arising from the generation of static electricity in mechanical processes, a problem, whose solution would be of more advantage to the textile industry in the United States than any invention since the days of Arkwright.

A COULOMB METER OR INSTRUMENT FOR MEASURING THE CONSUMPTION OF ELECTRICITY.[1]

BY PROFESSOR GEORGE FORBES.

You all remember that in England, at the time when electric lighting took a decided start, there was a regular rush for lighting-up towns by central station lighting. I looked into the matter at that time, and I could not see that a single scheme that was then proposed was capable of being worked. We were absolutely ignorant at that

1. A paper read before the American Institute of Electrical Engineers, Oct. 11, 1887.

Digitized by Google

time of the methods of distribution of electricity. In the first place we were absolutely ignorant of what amount of current we might pass through different-sized wires. One had to go all through that, and work out that programme, before one started upon anything. Then the different systems of distribution which had been proposed had to be discussed in each particular case, to see which was the most useful, and perhaps you will remember that I myself came to the conclusion, at that time, that a direct supply on a multiple arc system, which was that in most general vogue in those days, could not be carried out on economical lines to a distance of more than 220 yards; and when the three-wire system, the next decided advance, was introduced, it extended the distance of economical working to about a quarter of a mile. The greatest step, it seems to me, which has been taken in the distribution of electricity since the period when electric lighting took such a start, in 1878, is the use of alternating currents with induction apparatus, which was achieved by the most indefatigable industry and plucky perseverance, against the opinions of everybody who seemed to be capable of giving an opinion. I have never omitted, on every occasion when I have had to speak about the distribution of electricity, to express the profound admiration I have had for the energy and pluck which was shown by Messrs. Gaulard and Gibbs in working out that system, upon which so much ridicule was cast during the whole period of their experiments. At the present moment, the only difficulty which has seemed to exist in the way of a general system of distribution, lies in the want of a meter for the purpose. It is all very well to do as we are doing just now—to charge people for lighting their houses the same price that they used to pay for gas, or to charge them at so much a lamp and let them burn all night long, or just as much as they please; that is all very well as a makeshift. But every one of us knows perfectly well that that cannot go on forever; and therefore we must have a meter for measuring the consumption of electricity in houses. With a direct or continuous current, such as has been generally used in the ordinary multiple arc system, or in the three-wire system, the problem is not a very difficult one, and has been solved with greater or less simplicity, with greater or less accuracy, in a variety of ways. But even in that system it has always been felt that there was great room for improvement over anything which has been done. In using alternating currents, however, there has been until lately, at any rate, absolutely no meter in existence which was capable of giving, with even a fair degree of accuracy, the consumption of electricity in a house.

I believe that the meter which I present before you this evening is as simple in construction as any meter can be which requires wheel-work to indicate the amount of electricity which has been used. It has wheel-work, just as a gas meter has wheel-work, so as to indicate upon dials, by means of indexes, the exact number of units of electrical energy, just as a gas meter measures the exact number of feet of gas which have been consumed. But, in making this comparison between the gas meter and the electric meter, you must not imagine that they are to be put upon a par with each other. The gas meter has become a proverbial instrument, not for the great accuracy with which it performs its work, but for totally different qualities, from which I trust the meter before you is wholly free.

During all the time I have acted as an electrical engineer, my chief interest has been in the development of systems of electrical distribution from central stations. Until this plan is generally adopted we cannot hope to have the electric light supplied economically. The advances which have been made of late years have rendered the general distribution of electricity, even to great distances, an accomplished fact and a solved problem. Only one difficulty was encountered—the want of a meter for measuring the amount of electricity used by the consumers. In the old method of distribution (in parallel) the current always flows in one direction, and even here the want of a good and simple meter is felt. But in the modern system of distribution by alternate currents, no meter has hitherto supplied the want. Nearly a year ago an American in England spoke of the thing as impossible, and defied me to produce one. That same evening I went home and tried a simple experiment, which convinced me I had found a solution of the problem. Of all the effects of the electric current, I was sure that the only one which would suit alternate currents was the creation of heat in a conductor. The experiment I tried was to cut a circular disc of paper into a spiral, and to support this spiral at its centre on a needle-point. Holding this in an upward draught of air, the spiral rotates. I tested this, and found that a very feeble amount of heat sufficed to produce this effect. I then put some wire under the spiral and passed an electric current through it, and found that the spiral moved with an extremely small consumption of electric energy. From this beginning, after nine months' incessant work, I evolved the coulomb meter which I now exhibit. From this work has resulted the simplest and most accurate meter conceivable, which is equally suitable for continuous or alternate currents, which is read off by indexes and dials like a common gas meter, and which, when set in place, never needs to be touched, the readings being taken simply from the dials.

There are four dials in the latest instruments, reading units, tens, hundreds and thousands. The unit I adopt is the English Board of Trade unit, measuring the electric energy consumed in a hundred-volt lamp using one ampere of current for ten hours, the cost of which unit may be a little less than ten cents in a good system of distribution. When the inspector goes his rounds each quarter of a year he reads off the indexes, and subtracts the reading of the last quarter, and so he has directly the number of units consumed. If the lamps be not of 100 volts, he must multiply his result by the volts, and divide by 100 to get the number of units of electricity used up in the quarter year.

I would say that the board of trade unit is equal to a thousand revolutions of the mill-wheel. This instrument is made to work up to 20 amperes, and it might work twenty hours a day for four or five months before the readings of the instrument would be exhausted.

The instrument is ridiculously simple, and consists of four parts: (1) A mill-wheel (or smoke-jack as Sir Frederick Bramwell has called it); (2) a wire under the mill-wheel which creates an upward current of air when the electric current goes through it and heats it; (3) wheel-work for counting the number of revolutions of the mill-wheel; and (4) dials and indexes for reading off the number of revolutions.

The mill-wheel consists of eight mica vanes fixed by pieces of pith to the circumference of a circular disc of mica, at an angle of forty-five degrees to the horizon. This disc of mica has a circular hole in the middle, where it is supported by a thin paper cone, apex upward. At the top of the cone there is a jeweled cup, fixed inside a pinion. The jeweled cup rests on a point fixed to the base of the instrument.

The wire which is to be heated by the electric current is of iron, and forms a flat spiral of four turns just underneath the vanes of the mill-wheel. The ends of this wire are attached to one of the wires carrying electric currents to the lamps.

The pinion on the cone of the mill-wheel works in a train of wheels, so as to reduce the speed. One thousand revolutions of the mill-wheel indicate one unit on the dials.

Each of the dials has ten divisions. The entire instrument is placed under a cover, to keep off dust and irregular currents of air.

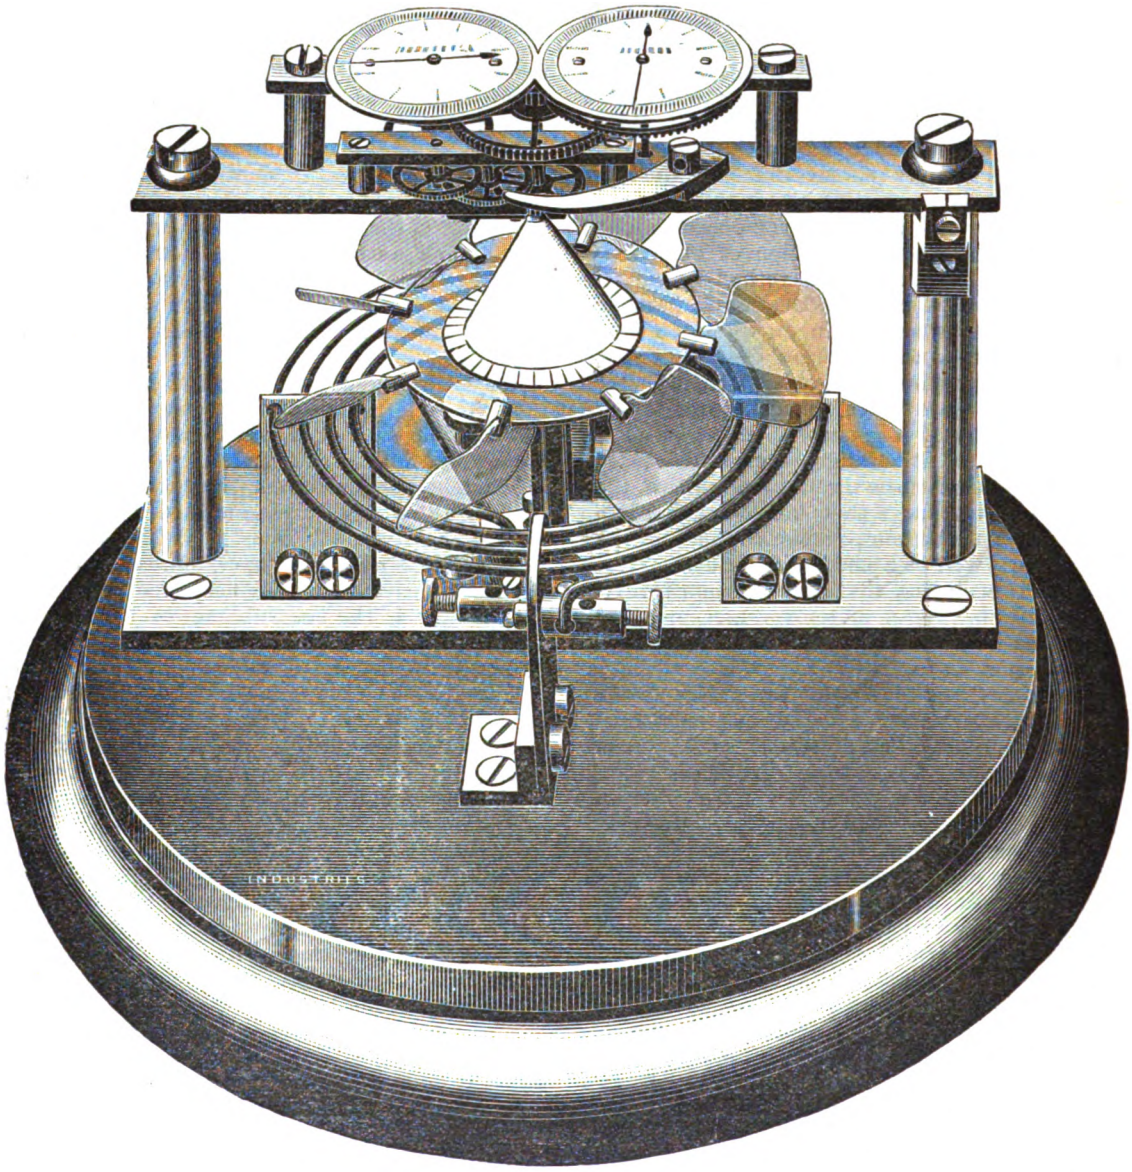
The instrument, as now made, starts with half an ampere, and is fairly accurate with three-quarters of an ampere (the amount of current generally used in an incandes-

Digitized by Google

cent lamp). From two lamps up to thirty lamps, the speed of revolution is exactly proportional to the current passing.

The same identical instrument will indicate from 20 to 600 lamps with the same accuracy. This is done by diverting part of the electric current from the meter by a shunt wire, so that only one-twentieth part of the whole current is measured.

If I want to measure from one lamp to 600 lamps, I use two meters, one with and the other without the shunt. With small currents only the meter for thirty lamps is connected. When the current for thirty lamps is passing, it is strong enough to act on an auxiliary apparatus which allows the greater part of the current to pass through the second meter. The two meters are then in parallel. This auxiliary apparatus is an electro-magnet, with a coil of twenty turns of wire going to the first meter and one turn going to the second. When the current is strong enough it pulls down a lever, which makes connection with the second meter, and holds it there as long as it is wanted.



The want for such a meter has long been felt. Neither consumers nor suppliers of electric light and motive power can be satisfied with a price determined solely by the number of lamps in a house, and not by the hours of consumption. The meter must be simple and cheap, and must be readable by the consumer, as well as by the supplier of electricity. These conditions are all fulfilled by the meter I am exhibiting to you.

In isolated plants, where storage batteries are used, this instrument enables us to see how much electricity is put into the batteries, and how much they give up.

In distributing motive power by electricity it is quite impossible to charge the consumer by the number of motors, because the time he is actually running the motors may be very variable. A meter is indispensable.

I may now refer you to the table on the black-board, showing the indications of the instrument, from which you will see that the ratio of speed to current is practically constant:

Current in amperes.....	.25	.35	.45	.6	.75	1	2	3	6	12
Ratio $\frac{\text{current}}{\text{speed}}$..	76	61.2	50.4	51	50.7	51	51	50.7	51	51.6

I cannot conclude this description without acknowledging the generous enthusiasm, free from all jealousy, with which this meter was received by English electricians when I showed it for the first time—namely, last month—at the meeting of the British Association at Manchester.

Digitized by Google

I must say that the kind sympathy of these eminent men went to my heart. May I be allowed to quote the remarks of one or two, from the London *Electrical Review*, Sept. 23?

Sir William Thomson said, "I have very great pleasure indeed in congratulating Professor Forbes. Every one who knows anything about electric lighting understands perfectly that the want of a meter is one of the greatest practical wants in connection with the introduction of central station lighting. I speak feelingly on the subject, for I have tried, year after year, to produce a meter. There is nothing to which I have given up so much time in endeavoring to make an instrument work as in endeavoring to produce an electric meter, and the patent office contains records of some of my attempts. Each one of them has been to some degree capable of giving a result, and the last of them, which I worked at a very great deal till four months ago, promised considerable accuracy, and was perfectly available for either direct or alternate currents. But the difficulty of seeing a way to bring this instrument out, and to make it a practical thing at a moderate cost, for general use, was so great that I do not feel that I intend to go on with it at all. It is just possible that I might make it succeed as a meter for a large station. But I am exceedingly glad to see the great success which Professor Forbes has obtained. I think I may say I am untinged with any feeling of regret at its having been done by another. On the contrary, it is with the most unmixed feelings that I say I am exceedingly glad, and that Professor Forbes is to be congratulated."

Professor Perry said, "One has no right to ask an inventor of such a beautiful instrument as this by what means he arrived at the idea embodied in it. I could not have imagined that he could have got this result. The figures certainly show that it is a beautifully simple instrument, and effects its purpose well. But how any one could arrive at such a method from any theoretical information passes my understanding. The whole action seems to be so complicated. I do not think I should have tried it if the idea had come into my head. I suppose one must miss a tremendous lot of valuable things in this way, because one does not see the theory. It is a marvelous thing. I certainly think it is one of the most beautiful things we have had before us for a long time. I speak now as an inventor of a meter which is in considerable practical use, not in this country, unfortunately, where it is patented, but in Germany. That is also a very simple one, but I think that this beats it."

I will not trouble you with further quotations. I can only say that I was deeply touched by the sympathy of other inventors, and that the reception I met with in England led me to take this opportunity of showing the instrument to you on this side of the Atlantic.

THE ELECTRIC CURRENT.

BY PROFESSOR F. C. VAN DYCK.

READERS of Prof. Ayrton's admirable book, "Practical Electricity," will see on page 2, a statement of that author's views as to what the electric current is *not* like.

It appears to me worth while to say something on the other side of the question, pointing out a basis of analogy between the electric current and what may be called a sound current. What follows refers to a single experimental fact, viz., that the energy developed (as heat, for instance) in an electric circuit varies as the *square* of the current in that circuit. Or, it may be put in this form, viz., the energy expended in maintaining difference of potential varies as the square of the quantity of electricity transferred from higher to lower potential.

How does this fact accord with the various hypotheses as to the nature of current? In the first place the electric current cannot be regarded as analogous to a current of *water*, for the energy of a water current varies as the cube not the square of the current. This is so important in this connection that I venture to give a brief statement of the reason for the fact, by way of reminder.

To say that the energy of a water current varies as the cube of the current, because one must maintain n-square-fold head to get n-fold flow does not *explain* the matter, but really states it from another standpoint. The real explanation is to be found in the character of the flowing substance. Water is practically incompressible, that is, its volume is independent of the pressure causing flow. Hence to get n-fold current from a given orifice or tube we must force n times as many volume-units (drops) out in a given time. Therefore each volume-unit must be made to travel n times as fast as it did when unit current flowed. Consequently, each volume-unit has n-square energy, and, as there are n times as many of them traversing the orifice or tube, the energy of the n-fold current must be n-cube-fold the energy of unit current.

Now, water acts as a vehicle of energy by virtue of its *mass*.

If, then, electricity is an "incompressible fluid," how does it come to pass that the energy of the electric current varies as the *square* instead of the *cube* of the current? Is there any way to explain it on the assumption that some other property than mass is efficient in the case?

In the second place, the electric current is plainly not a flow of "energy," for it cannot be that the energy of a current of energy varies as the square of the current.

In the third and last place, let us see how far an electric current is analogous to a sound current.

The idea can be given by making some suppositions and drawing inferences from them. Suppose, first, that the human ear were sensitive to sound of a given pitch only, and that sound had become a commercial quantity, transferred by conductors. A meter could easily be constructed to measure amplitude of vibration, and so "current." If the apparatus at the transmitting end of the line were worked by a spring suitably mounted, energy would have to be used to keep the spring at the requisite "potential." On these suppositions we should have—

(1) Current proportional to potential.
(2) Energy required to maintain potential proportional to the square of the current.

Just as we have in the case of electricity. It is established that static electrification is closely allied to elastic stress, and why may it not be that dynamic electricity is amplitude of vibration of some medium or media? Perhaps the difficulty of making detailed descriptions of the mechanism of the operation may be insurmountable, but it can only be profitable to insist that such a fundamental fact as the relation of current to energy must be taken into account in our theorizing.

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Continued from page 389.)

CHAPTER IX.—REGULATION OF MACHINES.

THE simplest and often the most convenient way of regulating or adjusting the current or potential which is generated by a machine, is to move the brushes toward or from the neutral line. It has been shown in chapter iv that the halves of the continuous winding of an armature are connected in multiple arc with each other, and that the total electromotive force generated in each half is equal to the sum of the electromotive forces of the separate coils in that half; if, therefore, the brushes are moved away from the neutral line, say a distance equal to the width of one commutator bar, it is evident that one coil on each side of the armature will thereby have been switched from one

Digitized by Google

side to the other of the line joining the brushes (see figures 6 or 8, chapters iv. and v). As the direction of the induced current will tend to remain the same in these two coils, it will evidently be opposed to the other coils as now connected, and will therefore diminish the available electromotive force at the two brushes. For instance, if there were 64 armature coils and if each coil generated three volts, there would be 32 coils in series in each half, giving $3 \times 32 = 96$ volts; if now the brush be moved the width of one commutator bar, there would be 31 coils left, generating 93 volts, but these would be opposed by the three volts of the coil which was added, thus leaving 90 volts. This will continue to decrease by continuing the displacement of the brushes until they have been moved through 90° when the coils will all oppose and neutralize each other. In actual practice the results would be modified somewhat, quantitatively, as the electromotive force induced in the coils near the neutral line is generally less than in the others, thus making the regulation more gradual at first; furthermore, the direction of magnetization of the armature by its own current, will, of course, follow the movement of the brushes, and therefore will tend to move the neutral line in the same direction; but in well built armatures with few windings, this effect will be small if at all appreciable, as the magnetization due to its own current will be small as compared to that due to the field.

This method of regulation is evidently equally well applicable for adjusting the current in the external circuit, as well as the electromotive force, for the former may always be regulated by proper adjustment of its electromotive force. It is furthermore evident that by thus diminishing the electromotive force or current, or both, a nearly proportionate amount of power will be saved, as the opposing electromotive force does not generate an opposing current, and therefore no energy is required by it. This can be shown by moving the brushes through about 90°, in which case no current will be generated and the dynamo will run light, that is, without consuming power.

An objection to this form of regulation, and one which makes it prohibitive in most cases, is that it generally causes very bad sparking when the brushes are too far from the neutral line. It is well known to all who have adjusted the brushes of a dynamo, that there is one definite position, and generally only one, in which there is least sparking, and that the sparking is increased by altering this position. This is partially due to the fact that at least one coil is continually short circuited by each brush, and when the brushes are moved too far from the neutral line this coil, instead of being "dead," that is, without an induced electromotive force in it, is "alive," that is, has electromotive force induced in it, and therefore on being short circuited, it will have a more or less great local current circulating in it, which, even if the electromotive force is small, may be very great, as the resistance is small; when this current is broken at the end of the brush, it evidently will spark more or less badly.

This method of regulation, when not accompanied by any regulation of the field, is therefore not to be recommended, except for small machines in which the sparking is not objectionable, or for machines with many armature windings and weak field in which the neutral line will shift with the brush line, or in such inferior machines in which the sparking is very bad in all position of the brushes, or in such machines as the Thomson-Houston in which the evil effects of the sparking are avoided to a great extent by a blast of air between the commutator bars.

It may be remarked here that the position of the brushes which gives least sparking, is not always coincident with the position for greatest electromotive force It is evident that they should always be adjusted to the former and not to the latter, which may always be accomplished by determining the winding of the magnets as described in the last chapter.

The second method of regulating the electromotive force, and therefore the current, is to vary the speed of the dynamo, but as this is in most cases impracticable, it need not be discussed here. What was said in previous chapters concerning the effect of the speed will enable one to determine the amount of the adjustment; for instance, the effect of a certain change of speed is much greater for a shunt than for a series machine, under certain conditions in the external circuit. A change of speed may in many cases be accompanied by a change of position of the line of least sparking, and should in those cases be accompanied by a change of position of the brushes.

A third method of regulation is to use a variable dead resistance in the external circuit, which will absorb a certain amount of energy, thus enabling the rest of the energy, that is the useful part, to be adjusted. As this method wastes energy, its general use is not to be recommended, but in certain special cases, belonging more particularly to the subject of systems of distribution rather than dynamos, there are advantages gained by this method which cannot be attained as readily by other methods, or in other words, the advantages gained are commensurate with the cost of the wasted power. To calculate the most economical form of such resistances, proceed as follows: determine by calculation, or preferably by trial under actual working conditions, what the difference of potential, V, is, which must be absorbed by each of the successive adjustments of the resistance; also the current C, which flows through the resistance in each case; the quotients $\frac{V}{C}$ will be the resistances. If german-silver wire or flat bands are to be used, their cross-section is next determined from the heating limit. If convenient and reliable formulæ are at hand this may be calculated directly, the necessary length being then readily determined from this cross-section, the resistances $\frac{V}{C}$, and the specific resistance of german silver. But in the absence of such formulæ, or if the specific resistance of the german silver (which varies greatly) is not known, the following experimental determination will be found reliable and simple: Take as long a piece as convenient of the wire or the bands of which the resistances are to be made, measure its length, and mount it as an open spiral or otherwise, as it is to be mounted in the finished resistance. Pass a current through it from a dynamo or battery, and increase this current slowly until the wire has been raised to as high a temperature as is permissible, allowing sufficient time for the temperature to attain its greatest value; then measure the current c, passing through it, and the difference of potential v, at the terminals of the wire. The length of the wire (of the same cross-section) for the required resistance which is to absorb V volts, will then evidently be, V divided by v, and multiplied by the length of this trial piece; the number of such wires which must be placed in multiple arc in the resistance for the current C, is evidently C divided by c.

By mounting this trial wire in different ways, and raising it in each case to the same temperature, the most economical method of mounting may readily be determined; the object is, of course, to present as much surface to the free access of air, as possible. Up to a certain limit, differing under different conditions, it will be found to be more economical to use a larger number of small wires in multiple arc, rather than a smaller number of larger wires.

This method of experimentally determining the resistance wires, applies only to those cases in which the wires are all of the same size as the test wire, their number in multiple arc being then made proportional to the current. If different sizes of wire or bands are to be used, they must be calculated by means of the well-known heating formulæ for wires. In many cases the following modification of the formula will be found convenient for round wires: Make the same test as before, with any convenient

Digitized by Google

wire, measuring merely its diameter, say in mils, and the maximum current. Cube this diameter, and divide it by the square of the current; this will give a number or constant, which can be used to calculate the diameter of any other wire of the same material, but for a different current which will not heat it to a higher temperature than that of the test wire. For instance, if C, be any other current, square it and multiply it by this constant, the cube root of this will then be the diameter in mils, which the wire must have, in order to carry this current and not to heat any more than the test wire. The required length of the wire is then determined from this cross-section and the resistance which it must have.

If bands of different width, but of the same thickness are used in place of wires, the width should be proportional to the current. If they are of the same width but of different thicknesses, the thickness should be proportional to the square of the current. This shows that it is much more economical to use bands as thin and as wide as possible.

The fourth and most common method of regulating the electromotive force or current of a dynamo, is to vary the strength of the magnetizing current or the ampere-turns of the field magnets. The method of effecting such adjustments of the magnetizing current will evidently be different according as the machine is shunt, series, or separately excited, and also whether the machine is to be regulated for constant potential or constant current. In all these cases, the electromotive force of the machine, but not necessarily its current, will be nearly proportional to the magnetizing current, provided the magnets are not oversaturated; in the latter case the strength of the magnetizing current must be varied through a greater range, to produce the same change in electromotive force. The current in the external circuit will, of course, depend on the resistance of the circuit, and on the electromotive force, and must therefore be adjusted for different resistances by varying the electromotive force.

Separately excited machines are regulated by adjusting the current strength of the exciter. This can be done by a variable resistance in this exciting circuit, or better, by regulating the field current of the exciter itself by any convenient method. The former does not waste much power as it consumes only a fraction of the energy for the field current, which latter is itself only a small fraction of the total power.

Shunt machines are regulated by an adjustable resistance in the magnet circuit. If the machine is to be regulated for constant potential, as when used for incandescent lamps in parallel, the amount of this regulation is dependent on the resistance of the armature, and will therefore be small for low resistance armatures. The amount of this resistance is most readily determined by an actual trial, that is, by running the machine first with full load and then with no load, and adjusting in each case any convenient resistance in the magnet circuit until the difference of potential at the poles of the machine is normal. Measure these two resistances, as well as the current which flows through them. The smallest allowable cross-section for the resistance wire is then determined from this current, as described above, and its total length is then calculated from this cross-section and the total resistance. The wire is then mounted so that successive parts of it may be switched into the magnet circuit, the number of such parts (usually from 10 to 20) depending on the desired nicety of the regulation. As the variation in the current through this resistance is comparatively small, one size of wire will usually suffice for the whole resistance; if, however, the current varies considerably, it will be more economical to use different sizes of wire for different parts; they may be calculated from the heating formula given above. Such machines are usually wound as described in the last chapter, so as to enable some resistance to be placed in the magnet circuit even at full load, for the purpose of adjusting for slight irregularities, such as the heating of the magnet coils, lowering of the speed of the engine, etc. The variation required between full and no load is of course due to the difference between the electromotive force and the difference of potential, as described before, and therefore depends on the armature resistance. The energy wasted in the resistance is insignificantly small.

If the shunt machine is to be regulated for constant current with consequent great variations in electromotive force, as for instance an arc light machine for a varying number of lamps, the determination of the required resistance is best done experimentally as described above, only that it must be determined for a large range of values, and not merely for the two extremes. The reason for this, is that this resistance does not vary in proportion to the electromotive force, as the latter will itself vary the current in the shunt magnet circuit. It may even be found that the resistance must be varied first in one direction and then in the other, for regular diminutions of the electromotive force. The current in the magnet circuit should also be measured, and if it varies considerably, the resistance wires may be made of different sizes for the sake of economy. The successive steps of the adjustable resistance may have relatively different values to effect a regular increase of electromotive force. As shunt machines for such high potential as would be required for many arc lights in series would necessitate the use of a very large amount of quite fine wire for their magnet coils, they become very expensive and are therefore not used very much. They possess no particular advantages over the ordinary series machines if the latter are, as is usually the case, automatically regulated, and therefore not subject to the destructive effects of the unavoidable short circuits in the external circuit.

Shunt machines may also be regulated by winding the magnet coils in independent sections; by means of a switch-board to which the terminals are attached, these sections may be successively cut out or switched into the circuit, thus varying the ampere-turns of the magnets. But as this complicates the construction greatly and has no particular advantage over the other method, it is not practiced to any great extent.

Series machines for constant current may be regulated by winding the magnet coils in sections as just described, but the same objections apply here as well. A modification of this, is to solder smaller branch wires to different parts of the coils and by means of a suitable switch-board, to which these wires are led, short circuit the successive sections. But though this is an improvement of the method, it possesses in general no particular advantages over the next method to be described. In some particular cases the advantages may be sufficiently important to justify its preference over other methods. In such cases, care should be taken to cut out the successive sections so as not to unbalance the field.

The simplest and most usual method of regulating series machines is to use an adjustable resistance as a shunt to the magnet circuit, that is, to connect an adjustable resistance between where the main circuit enters and where it leaves the magnets. The successive steps of such a resistance may be best determined by an actual trial with any convenient resistances, which are afterwards measured and serve to calculate the length of the resistance wire. If the magnets are not over-saturated the resistances may be calculated (knowing the resistance of the magnet coils), so as to shunt off such portions of the main current as will leave the magnet current proportional to the electromotive forces to be generated. But owing to the fact that the unknown self-induction of the magnet coils acts to increase their resistance, and also to the fact that the brushes will in many cases be required to be adjusted together with the field, owing to the shifting of the neutral line, such calculations will not be very reliable, and it is therefore best to eliminate all such inaccuracies by an experimental determina-

Digitized by Google

tion. In this test the current which is shunted around the magnets and through the resistance, should be measured for each successive step, and from this the cross-section of the resistance wire is determined by the heating limit, as described above. This current will vary from almost nothing for the maximum resistance, to almost the whole main current for the smallest resistance, thus requiring quite different sizes of resistance wires for different steps of the regulation. Machines regulated in this way may readily be adjusted to maintain a constant current even for a short circuit. The energy wasted in this resistance being a fraction of that used for the magnets is not significant.

Series machines might also be regulated in this way to maintain a constant potential for variable currents in the external circuit; but a simple calculation for an actual case will show that in order to maintain the constant potential for a small current in the external circuit, the field magnet coils would have to be wound with comparative small wire, and that, therefore, very much current would have to be shunted through the adjustable resistance when the current in the external circuit is a maximum. This would necessitate resistances of large size, and would waste considerable energy when the machine is doing its greatest work. Such a system should, therefore, if used at all, be limited to cases in which the range of adjustment is quite small, as for instance to machines which are used with a nearly constant load of lamps. The advantage of such machines over a shunt machine is evidently the saving in the cost of the wire and winding of the magnet coils. For a comparatively high resistance armature there will be less regulation required for constant potential; this method is, therefore, applicable best for small, cheap machines for nearly constant loads.

All the methods of regulation described may be made automatic by the addition of a proper mechanism which automatically alters the resistances, position of brushes, etc. Such regulators consist essentially of two parts, first, the detector, the object of which is to detect changes in the potential or current which is to be maintained constant, and second, the mechanism which is actuated by this detector and which effects the necessary changes in the resistances, sections of coils, brushes, or speed. Numerous more or less effective automatic regulators of this kind have been devised, some of which have proved to be very satisfactory. As they have been described in detail in text books and periodicals, it is not necessary to repeat the description here.

(*To be continued.*)

SKETCH OF THE PRINCIPAL ELECTRICAL PAPERS READ BEFORE SECTION A, DURING THE LATE MEETING OF THE BRITISH ASSOCIATION AT MANCHESTER, 1887.[1]

BY PROFESSOR OLIVER J. LODGE, D. SC., F. R. S.

It may serve a useful purpose, and be not uninteresting in itself, to pass rapidly under review some of the communications made to the physical section of the British Association at its recent sitting, to sketch what appear to be the main objects of each paper, and to indicate as far as one can its net result. In attempting this it must be apparent that such a sketchy account cannot avoid being meagre and in many respects unsatisfactory; but inasmuch as sooner or later the publication of each paper will take place, and the complete views and intentions of the author can then be appreciated, no harm will be done by a partial and crude preliminary abstract.

The simplest order in which to quote the papers will be that in which they were read.

Immediately after the president's address on Thursday, Prof. Schuster described his new experiments on the electric discharge in vacuum tubes. He finds that if a discharge be sent through air rarefied to a pressure of a millimetre of mercury or thereabouts, the whole of the air in the vessel becomes conducting; so that, for instance, a gold leaf electroscope inside the vessel is unable to retain the slightest charge while the discharge is passing, and a single cell battery is able to propel through several inches of air a steady current capable of deflecting a galvanometer perceptibly. And this happens whether the discharge be a continuous one as from a powerful battery, or an intermittent one as from a common induction coil. Moreover, it happens when the discharge region is partitioned off by a good electrostatic screen from the region of the gold leaves or weak battery circuit terminals. All that is necessary is that the partition shall not be a complete one in the mechanical sense, it must permit the passage of *air* round or under or through it, but it may be as complete in the electrical sense as a sphere of fine wire gauze or as a plate of sheet metal.

The meaning of the experiment is believed by Dr. Schuster to be that the air is dissociated by the discharge into atoms respectively oppositely charged, and that these charged atoms wandering about are able to convey a current of electricity between electrodes exactly as they are supposed to do in the case of an ordinary liquid electrolyte.

Anyone who is not familiar with the appearance of a continuous battery current through a vacuum would be much struck with the beauty of this form of the experiment.[1]

Later in the day Prof. Horace Lamb hastily gave the gist of a paper on a subject which has an electric as well as a hydrodynamic bearing. When water or other fluid flows through a tube, it is well-known that the stream is most rapid at the axis of the tube, where it is freest, and most retarded near the walls of the tube. This is a natural result of friction and fluid viscosity. But the question arises whether the layer of fluid which actually touches the wall of the tube moves at all, or whether it clings so tightly as to be actually and completely stationary. Certainly water adheres to glass with considerable force; the inside water is sheared along the outside water, but is the outside water sheared along the glass? is there, in fact, any "finite slip"? The simplest and ordinary procedure in hydrodynamics is to assume none: to treat the outermost layer of water as stationary. But now comes in the electrical contribution to the subject. Prof. Wiedemann and others have observed that an electric current sent through a tube of liquid tends to propel that liquid bodily along the tube. This is called electrical endosmose. Prof. Quincke, on the other hand, has observed the converse phenomenon, viz., the fact that if a current of water be driven mechanically along a tube, its two ends acquire different potentials and can deflect an electrometer. Both these effects have been explained by Prof. von Helmholtz as due to a contact electromotive force between the water, on the one hand, and the glass of the tube—or, at any rate, an outer skin of water *affected by* the glass of the tube—on the other: the water becoming, say positive, and the glass negative—like most other things when put into contact. If now the two ends of the tube be kept at different potentials, it is very natural that the water (being already slightly electrified by contact) should be driven along the tube, being propelled, in fact, by its own skin.

1. From the *Electrical Review* (London).

1. There is just one point on which the views of the author are not clear to the present writer, viz., where Dr. Schuster considers the fact that he can drive a current through air by means of an E. M. F. of one-fourth or one-tenth of a volt as being itself a proof that there is no important difference of potential between the metal of his electrodes and the air. Seeing that any step of potential up from metal to air at one electrode must be precisely counterbalanced by an equal step down at the other electrode, I do not see how the fact that you can easily drive a current from one to the other proves anything.

If the two electrodes were of different metals, say one zinc and the other platinum, and if it were found equally easy to propel a current either way between these, then something extraordinary could be deduced; but no doubt such an arrangement would act as a simple battery. So long as the two electrodes are identical, even though they be both zinc, I fail to see how their behavior can prove anything about difference of potential between metal and air; though at the same time, so long as platinum or oxidized aluminum is used, I am very willing to admit that the actual difference of potential is most likely minute.

Digitized by Google

The effect, however, is excessively small and can hardly be observed in a wide tube. A capillary tube, or better still, the interstices of a porous partition are the best for showing it and making it conspicuous.

The converse effect is likewise easily explicable, for when water is driven along a tube the finite slip occurring at the boundary acts like any other frictional machine and produces ordinary electrification. The only reason why the observable effects are so small is because water is a conductor, and the electricity leaks back along it almost as fast as it is produced. Fine tubes, therefore, do better than coarse, and alcohol or other bad conducting liquid would do better than water.

But Helmholtz, instead of thus simply and naturally assuming a considerable finite slip between water and glass, apparently felt impelled to try whether the effect could not be produced without such an hypothesis, to which many facts seemed contrary. He, therefore, assumes that the outer layer of water divides itself into two—an "electrical double layer" as he calls it—between the components of which a contact difference of potential exists; and he then supposes that the outermost skin of this double layer clings fixedly to the glass of the tube, by the contact of which its properties are modified, and that the inner skin slides over it. He thus calculates out the experimental laws of the phenomena, and finds numbers agreeing with observation. Probably he was driven to this seemingly forced hypothesis, of the modified and unmodified water layer, and the sliding of one over the other, by finding the amount of slip necessary to explain the effects greater than could reasonably be assumed between water and glass.

Now comes in Prof. Lamb's modification. He has gone over Helmholtz's work point by point, and sees reason for differing from him with regard to some of the molecular magnitudes involved. He introduces into the formula a new factor having 10^{-8} in its denominator. The result is, that although he also requires a finite slip to explain electric endosmose and its converse phenomenon, yet he makes a very much less slip sufficient; so that he is able to return to the simple and natural view that the outer layer of water actually slides on the glass, but that an almost infinitesimal slide is all that is wanted to explain electric endosmose. He thus to all intents and purposes confirms the old view of the scientific hydraulic engineer, that the outermost layer or skin of water is practically stationary. Prof. Lamb's paper is ordered to be printed *in extenso* among the reports, and it will be then easier to appreciate the exact modification introduced by his theory, which at present is, of course, *sub judice*.

Immediately after this paper occurred the event of the meeting, the thing for which in all future times the visit of the association to Manchester will probaby be famous. Not that it made any sensation at the time; it scarcely took up 10 minutes of the time of the section; the president made no remark upon it, and only by two or three individuals who happened to have been thinking in the same direction was its real significance understood. It was a short paper by Sir William Thomson, entitled, "On the Vortex-Theory of the Luminiferous Ether." To understand the meaning of it one must go back a little.

It is well-known that several years ago Sir William Thomson suggested a vortex theory of matter, based on the observed behavior of a vortex ring and on the properties of vortices in general, as investigated mathematically by Helmholtz. The "vortex-atom," as it is called, is a favorite subject of speculation, and Prof. J. J. Thomson is attacking the problems of chemical combination by its means. But although this remarkable theory of the nature of matter was before the world, and its consequences being traced, yet of the nature of the ether we had no such theory. It was perceived that many of the properties of the ether must be those of a perfect fluid, else how could planetary bodies move unresistedly through it? But, on the other hand, some of its properties must be those of a solid, else were it incapable of transmitting waves of light. It was likened, therefore, to a jelly, and to pitch, which in some respects are semi-fluid, in others semi-solid; it was pointed out that bullets could sink through apparently solid pitch if time enough were given them; and the difference between this slow creep and the rush of a planet was asserted to be only one of degree. Yet this was felt to be not quite satisfactory, and the contradictory properties possessed by the ether remained paradoxical.

Then Prof. FitzGerald, of Dublin, made a brilliant guess: the properties of the ether could only be explained, he conjectured, by an assemblage of minute vortices in a perfect fluid—a "vortex sponge," as Sir William Thomson had previously called such a structure. If the ether consisted of a perfect fluid, everywhere completely enwrapped in utterly minute vortices, much more minute than the comparatively gross vortex rings constituting the atoms of matter, then it would permit the passage of bodies through it with perfect ease. It would also act as an electric and magnetic medium in the way needed by the Faraday-Maxwell theory; and in all probability, so he surmised, it would be found capable of transmitting the transverse waves of light. But to prove this last property deductively from the theory of vortices seemed a task of supreme difficulty, from which he shrank.

Actuated possibly by this suggestion, perhaps quite independently of it, it must have occurred to Sir William Thomson to consider this problem as a mathematical exercitation during some hours of leisure. However it happened, he did consider it, and did solve it; apparently too, without very much difficulty, or much consciousness of the feat he had achieved. At Manchester he scribbled the proof in a few lines on the black-board; and it was thenceforth known that a vortex sponge of perfect fluid could do everything that the luminiferous ether was known to do. Among the audience was Prof. W. M. Hicks, who probably knows as much of vortex mathematics as any man living, and he expressed himself afterwards as fully satisfied with the proof, and conscious of the greatness of the discovery.

Prof. FitzGerald, in proposing afterwards at the committee meeting that the paper be printed *in extenso* among the reports, characterized it as the greatest step towards the comprehension of the intrinsic structure of the universe which had been made since the time of Newton; the only possible exception occurring to him being the vortex theory of matter itself.

It is, perhaps, rash to wax enthusiastic over the greatness of an infant at the moment of birth: a man must commonly live, and must die, before his right magnitude becomes really known; nevertheless, when a discovery has been watched and hoped for, it is surely not only natural but seemly to herald its advent in not too dull and prosaic a manner.

It is not to be supposed that the discovery is complete and finished; a great deal more remains to be done to get it into shape and work it out, but a splendid start has been given.

Thus much for the results of Thursday. Passing on now to the next day, we come first to the new electric measuring instruments of Sir William Thomson.

The idea of these is to do away with all alterable opposition forces, such as permanent magnets and torsion or other springs afford, and to balance the attracting power of a current by the dependable force of gravity itself. The attraction between two pairs of coils is in fact weighed, and hence all possibility of variation in the constant of the instrument is avoided. If once correct, it remains correct until it becomes damaged or broken. It is set right first by a voltametric silver determination, and ever afterwards it serves as a standard of current, and, with certain reservations, of E. M. F. also. A beautiful series of instruments for different purposes was shown; whether they are not

Digitized by Google

too delicate for workshop use remained doubtful; but as they are certain to be speedily depicted and described in every electro-technical journal,[1] it is needless to dwell on them further.

There is one point of special practical interest in their construction, viz., the means adopted for conveying a powerful current to the balance arm without friction or much rigidity. This is effected by means of a pair of thin flat bands or combs composed of a multitude of very thin copper wires suspending the balance arm.

Mr. Glazebrook's optical report, and other optical papers, followed, but though optics is at the present day becoming but a branch of electricity, yet this view of it is hardly yet fashionable, nor are electricians generally so interested in the nature of light as doubtless by next century they will become.

Towards the end of the sitting Prof. Ewing described his recent remarkable researches in magnetism.

It is perhaps known that the Ampere-Weber-Maxwell theory of magnetism requires that for some very high magnetizing forces the magnetization produced shall cease to increase and begin to diminish; in other words, that the susceptibility of a substance to magnetism shall decrease and even become negative for sufficiently high magnetizing force. Thus, then, iron, if enormously over-magnetized, might actually become diamagnetic like bismuth.

To verify this prediction, the writer of this article has himself made some attempts, and is able to show a body which is paramagnetic in a weak field and diamagnetic in a strong one; but then such a body is not simple, pure, and homogenous, it is purposely built up of a magnetic and a diamagnetic substance. Or even when not purposely built up, who is to say that some trace of impurity is not at the bottom of the phenomenon?

Prof. Ewing has proceeded in a different way. He has pushed the magnetism of iron far bevond hitherto recorded limits, and believes that he finds indications that the decrease of susceptibility has begun. Whether this be so or not, there is no doubt of the tremendous magnetic inductions he has obtained. On the same scale as that on which the earth's horizontal intensity is .18 units, Prof. Rowland, of Baltimore, had obtained a field in iron as high as 25,000 units; and had given reasons for believing that this was about the maximum possible. Afterwards, Prof. Ewing managed to get it up to 32,000; and now, with the great magnet of Edinburgh University excited by a storage battery, putting a sharply sloped double-coned piece of Lowmoor iron with very narrow neck between its large poles, he has succeeded in beating his own record and forcing the magnetic induction in iron up to 45,350. Cast-iron has gone up to 31,270; and even in air he has measured a field of 25,620 units.

Prof. Ewing and Mr. Low, and, on another day, Prof. Barrett also, described further experiments on the peculiar 12 per cent. manganese steel, which is scarcely more susceptible to magnetism than is zinc. They find indeed that its magnetic permeability is only half as great again as air, and that accordingly it may become very useful for ship's plates and for the bed-plates of dynamos.

On Saturday sections A and B sat together for the consideration of electrolytic and electro-chemical subjects. The papers read will most of them shortly appear in these pages, and a brief general review is all that seems necessary.

After a report had been read, Prof. FitzGerald and Mr. Trouton gave a further statement of their experiments as to the exactness with which electrolytic conduction obeys Ohm's law.

They have been greatly troubled by temperature difficulties, which in liquids are far more accentuated than in metals, for reasons which Prof. FitzGerald clearly explained.

They succeeded, however, in proving that if there were any deviation from Ohm's law in copper sulphate solution it must be less than 1 part in a hundred thousand; a very satisfactory and valuable result. But whether this statement will apply equally well to very pure water or other bad conductor is still, strictly speaking, an open question.

Dr. S. P. Thompson communicated a paper by Prof. von Helmholtz on the effect of pressure on the electrolysis of water. Helmholtz gives a formula whereby the change of E. M. F. needed to decompose water under any pressure, produced by any gas or mixture of gases, could be calculated, so long as those gases reasonably obeyed Boyle's law. By experiment this formula was verified for very low pressures, with at any rate fair accuracy; and the result was that whereas 1.7 volts were necessary to the decomposition of water with platinum electrodes at atmospheric pressure .17 volt more would be required at 1,000 atmospheres, and .17 volt less would be sufficient at the one thousandth of an atmosphere. Pressure of the liquid's own vapor need not be reckoned. Whether the solubility of gases was taken into account or not I am not sure; I incline to think not; and if so the calculated results for high pressures are less likely to be accurate than those for low. Moreover, at very high pressures the mixed gases are apt to explode spontaneously.

Prof. Roberts-Austen then described his experiments on the passage of a current of several hundred amperes through a fused alloy of gold and lead, and of silver and lead, to see if any decomposition whatever could be detected. Assaying to within one part in 10,000 he could detect no difference; thus proving that, for these alloys at least, the conduction is wholly and simply metallic.

Prof. Lodge made an interim report on the experiments which he and Mr. E. E. Robinson are carrying on with regard to the rate at which the ions travel in electrolysis. He experimentally proves that in such a solution as salt and water containing one-tenth of a gramme equivalent, or 5.8 grammes of common salt per litre, the hydrogen atoms move at the rate of .0029 centimeters a second; that is 10½ centimeters, or about 4 inches an hour; when urged by a slope of potential of 1 volt per centimeter, that is 30 volts applied to the ends of a tube 1 foot long.

Prof. Rowland then described some remarkable experiments made partly by himself partly by others, on chemical action in a magnetic field. It is found that if a piece of intensely magnetized iron is being dissolved, say in nitric acid, the parts most strongly magnetized are half protected and are consumed less rapidly than other portions. Points and edges, for instance, are in this protected condition; hollows and flat places go first. It may be expected, therefore, that highly magnetized iron shall be somewhat electro-negative to ordinary iron, so that if the two be immersed in any corrosive fluid and joined to a galvanometer they shall act as a feeble battery and give a current. This also is found true.

It is plain that in dissolving and removing iron from a highly magnetized pole a little more work has to be done than if it were not magnetized; and, therefore, the protective tendency of magnetization is to be expected. The only question was whether iron *in solution* would be sufficently attracted to cause a perceptible effect. Some time back the writer of this article made somewhat similar experiments on magnetized and unmagnetized iron immersed in ferrous sulphate, using an arrangement very like that described by Prof. Rowland, though without so clearly perceiving the efficacy of points; the idea was to get a current by pulling iron out of solution with a magnetic pole. But oxidation of the ferrous sulphate by air caused a lot of trouble from spurious currents, and with insufficient perseverance the attempt was abandoned. It does not follow that it would have been successful, because this idea of the protection of iron from corrosion, though based on the same principle, is different in detail.

1. Sir William Thomson's instruments were fully described and illustrated in the *Review* for May 27th and June 10th, 1887.

Dr. Gladstone gave an account of some experiments on the effect of passing an electric current through solutions in which a chemical precipitate is slowly forming. It is well known that the formation of a lagging precipitate can be hastened either by heat or by shaking. Dr. Gladstone now finds that the passage of an electric current has a similar and marked effect. This also is an interesting result; showing that electrolytic conduction assists the interchanges or double decompositions occurring between mixed compounds.

Messrs. Gee, Holden, and Lees, brought forward some laborious experiments on the effect of pressure on the electrolysis of water and on the electromotive force of polarization. They worked at very high pressures, and were met with the difficulty of spontaneous combustion of the mixed gases. It must be remembered that this recombination need not necessarily occur in free space. It is known to occur easily in the presence of platinum, and there is no reason to suppose other solids incapable of bringing it about in the films condensed on their surfaces, especially at pressures of 300 atmospheres or so.

Prof. Silvanus Thompson explained the conditions under which *brass* can be electro-deposited, and showed how any desired proportion of copper and zinc can be obtained. The important points to keep sight of, in understanding how an electro-positive metal like zinc comes to be deposited at all in presence of copper, are the enfeeblement of the solution near the cathode plate, and the effect of this on the E. M. F. necessary for deposition of any particular metal. He also exhibited results of the commercial electro-deposition of good metallic *platinum*, which if non-porous is likely to be extremely useful.

Mr. W. N. Shaw gave the gist of a long and elaborate paper by Mr. FitzPatrick on the effect of the solvent in electrolytic conduction. It appears that whereas methyl alcohol by itself conducts better than does pure water, yet a solution of salt in methyl alcohol conducts distinctly worse than the corresponding aqueous solution—a singular and interesting result.

Monday was divided between meteorology and pure mathematics, but on Tuesday some more electrical papers were taken up.

Prof. Quincke described his observations on the behavior of gases immersed in a strong magnetic field. He takes a glass tube, closed by a sensitive pressure gauge, and fills it with the gas to be examined, sometimes at high pressure. He then immerses it in a very powerful magnetic field, and reads the gauge with a microscope. He thus finds that the magnetic stress in the gas is accompanied by a slight increase of pressure, amounting in some cases to as much as five millimeters of water. He gives, as the formula for the increase of pressure,

$$p' - p = \frac{\mu H^2}{8\pi};$$

where H is the strength of the field, and μ the magnetic permeability of the gas; and so makes it analagous to the effect caused by an electrostatic stress. The measurements of μ thus obtained by Quincke agree very fairly with those of Faraday—"Exp. Res.," iii., p. 502.

Mr. Glazebrook reported on the construction of standards of electrical units, and stated that the B. A. unit coils had not varied perceptibly among themselves since Mr. Hockin examined them 15 years ago; and since they are made of several different materials, the probability is very great that they have not varied at all.

Prof. Rowland gave the final result of the elaborate series of determinations of the value of the ohm standards which he has been carrying out for the past few years under the auspices of the American government. His value in ohms of the old B. A. unit agrees almost precisely with that found by Lord Rayleigh; but his determination of the column of mercury representing one ohm shows a discrepancy which, though small, is nevertheless large considering the care taken and the comparative simplicity of the operation.

Mr. Glazebrook adduced evidence showing that M. Mascart's mercury standards had varied from the time they were made to the time they were tested at Cambridge and retested again in France; and the feeling of the meeting plainly was that some explanation of the outstanding discrepancy between Prof. Rowland's and Lord Rayleigh's mercury determinations would probably be forthcoming after Prof. Rowland had returned to America and overhauled his tubes.

The correspondence between the ohm determinations at Cambridge and at Baltimore was so close as to be matter for congratulation, considering the extreme difficulty of the measurements and the difference of methods employed.

Prof. Ewing and Mr. Low described some interesting observations on the effect of a cut across a bar of iron on the magnetism developed in it by a given magnetizing force. The bar was made part of a complete magnetic circuit and wrapped with a certain number of ampere-turns; and then measurements were taken of the number of lines of force passing through it, first when entire, next when cut once through, then with two, three, and ultimately seven cuts, so that the bar became a column of eight pieces piled on one another. Not only was the bar tried thus but pressure was brought to bear upon it so as to cause better contact over the cut faces, and to show the effect of this. The cuts were first made carefully in the lathe: later they were also highly polished and made true Whitworth planes. Briefly it may be said that whereas each cut very distinctly weakens the magnetic induction, diminishing the permeability of the bar, pressure assists to restore some of it again; although it acts in a double fashion: squeezed *iron* being less permeable, while a squeezed *joint* is more permeable than an unsqueezed.

The Whitworth plane faces, however, enabled pressure to bring the bars so well into contact that they practically became whole again, and the cut had then no effect—at least so long as the pressure lasted.

On the whole, Prof. Ewing believed the effects of the cut to be completely accounted for by the presence of air films some thirtieth of a millimeter thick between the faces; nothing more occult being needed to explain the defect of permeability. But as Sir William Thomson urged, it would be well to repeat with a film of gold leaf before being absolutely sure of this result.

The remaining papers were not of high scientific importance, though doubtless of some general and technical interest. There was a curiously rudimentary, not to say trivial paper by Sir William Thomson on Poggendorff's method of measuring electromotive force, as given in any text-book, except that one of his current weighers is used instead of a tangent galvanometer. Mr. Preece related the continuation of his large scale experiments on induction between wires, which the resources at his command render possible. Prof. Forbes exhibited his ingenious smoke-jack coulombmeter, which acts both as a tell-tale of how much current is being used and as a record of how much has been used, whether said current be alternating or steady. Mr. Swinburne explained how he proposed to eliminate temperature errors from galvanometer and other such coils by winding them with two opposition coils of unequal strength and different temperature co-efficients, so proportional as to produce compensation, on the gridiron-pendulum principle; and Dr. Edward Hopkinson summarized in a complete and comprehensive form the general theory of dynamos, up to which he has been working for the past few years, both in conjunction with his brother and by his own practical experience. This paper is in type and does not lend itself to further abbreviation. Suffice it to say that it marks a distant stage of progress in the history of the science to be able to treat the phenomena of magneto-electric induction in this general and satisfactory manner.

LIGHTING TRAINS BY ELECTRICITY.

ON THE AUTOMATIC ELECTRICAL LIGHTING OF TRAINS.[1]

BY MR. THOMAS P. CARSWELL.

THERE are three methods of train lighting in use, namely, by oil, gas and electricity. As this paper is only intended to deal with the latter, the first two systems will be passed over. The amount of light from each is in favor of gas against oil, and of electricity against gas. Incandescent lamps only are used in train lighting by electricity, the arc light not being suitable. In using the incandescent lamps they are placed in each compartment, and generally take the place of the oil or roof lamp. There have been three practical applications of train lighting by electricity. In the first two the roof lamps are replaced by incandescent lamps, while in the third case they have not been interfered with. The first two methods are those which have been more or less used, while the third has just been tried.

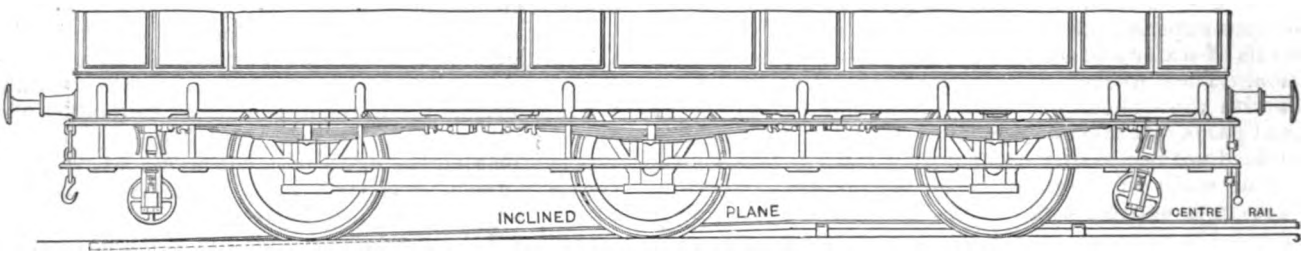

Fig. 1

What I propose to speak of as the third method (patented May 17, 1886) is that which is now being tried for the first time, I believe, on the Glasgow City and District Railway. On the City and District Railway the circumstances under which the light is required are entirely different from almost all others, as it is specially required during the day, and while the trains are in the tunnels only. These trains run in the open air the greater part of their journey, but have to pass through the tunnels from three to fifteen times daily; or in other words, they are on an average somewhat over an hour in darkness. The arrangement for lighting each train as it enters the tunnel is as follows:

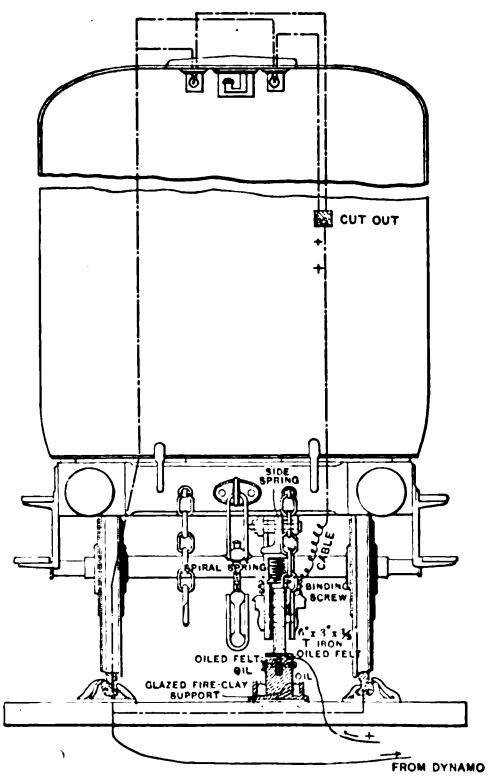

Fig. 2.

A centre or third rail has been laid down from one end of the tunnel to the other, but is omitted in the open air. This is shown in several of the accompanying illustrations. It is formed of ordinary T iron, and is inverted and laid on insulators or supports, so that it stands 4 in. or 5 in. higher than the ordinary rail, as shown in figures 2 and 6. It is jointed together by small angle irons with four bolts, there being a small strip of sheet copper between the two, so as to help the contact, figure 3. The holes in the rail are oval, to admit of expansion and contraction, and it is held in position by iron cotter pins, which pass through the sides of the jaws or supports. At each end of the tunnel, this centre rail or inverted T iron is bent down to the level of the ordinary rails so as to form an inclined plane (see figures 6 and 7).

The insulators or supports which are used are made of glazed fire-clay, and have the central part or stem isolated from the base. The stem has two slots in it, one to receive the T iron and the other for the cotter, or split pin to pass through. A small piece of roofing felt, soaked in oil, is laid in the slot on which the T iron rests. The lower part or base is made in the form of a trough, which is filled with oil to help the insulation, and is fastened to the sleepers by means of two coach screws.

By this method of fixing the centre rail, it is always kept at the same height above the ordinary rails, and if the latter are raised the former is raised also as it rises with the sleeper. These supports are fixed about 5 ft. apart, and as far as can be seen they stand very well.

Two contact makers or pulleys, figures 1, 2 and 4 are fixed to the framing of each carriage, at a height to correspond with that of the centre rail. Only one is actually required, but it is found that two give a steadier light, and where there are junctions to pass over, both are required to maintain the connection. These pulleys are made of crucible cast steel, and are 15 in. in diameter. They are hung on a centre so as to move in horizontal direction and have a spiral spring on the top of the axle-box, which allows it to rise vertically 3 in. or 4 in. Two side flat springs are fixed on the hanger or jaw in which the pulley works so as to keep it in a vertical position.

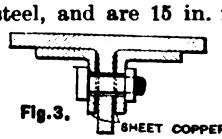

Fig. 3.

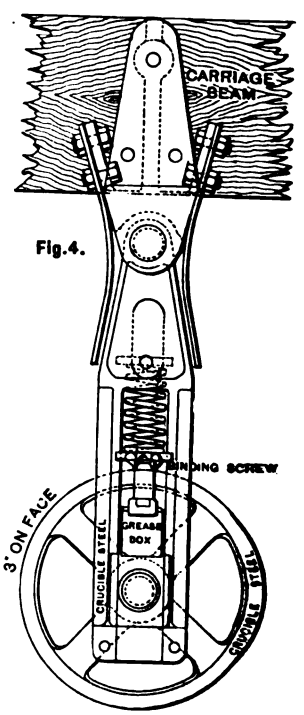

Fig. 4.

The current of electricity for lighting the lamps is derived from a large Crompton compound-wound self-regulating dynamo, having a potential at the terminals of 110 volts. This dynamo is always kept running, the positive lead being connected to the centre rail, and the negative lead to the ordinary rails. It is driven by the same engine as is used for lighting Queen street high level station. The leads are not connected directly with the center rail, but to three Hedges' safety fuses in the engine room, designed to give way in case of a short circuit (see figure 7).

The tunnel is divided into three circuits, namely, College to Queen street station (low level), and Queen street to Charing Cross and to Finnieston, as shown in the last-mentioned figure. By this means, in the event of there being a breakdown in either tunnel it can be switched off so as not to interfere with the other two. The lengths of the circuitare 748, 484 and 2196 linear yards respectively. The area of the central rail increases as it leaves the dynamo, while the resistance of each circuit is the same. The estimated loss or fall in potential at the end of each circuit, with a train in it, was 10 volts, and it is found that at Finnieston station, which is 2196 yards away, such is the case. It is possible to have two trains in two of the circuits, and four in the other, or eight in all; and the cables leading to each have been arranged accordingly. Insulated cables laid in creosoted troughing and filled with pitch have been laid from the dynamo to the center and ordinary rails.

The wires from the contact pulley are connected to two 16 candle power lamps, which have been placed in each compartment, fixed on either side of the ordinary roof lamp, so as not to interfere with it and in order that the latter can be used when required (see figure 2). These lamps, which are of the Swan type, are 25, 50 and 100 volt lamps, but only one is lit at a time, the second being a reserve which automatically lights itself in the event of the first one failing.

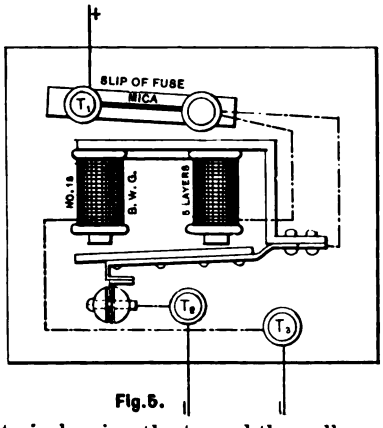

Fig.5.

Each circuit is formed in the following way: The positive lead to the lamps is connected to the two contact pulleys, while the negative is connected to the spring of the carriage. It will thus be seen that as soon as the train enters the tunnel the pulleys make contact with the center rail, the current flowing from the dynamo through the center rail and pulleys to the lamps, and returning through the springs and wheels of the carriage to the ordinary rail, and through it back to the dynamo again. On the train leaving the tunnel the pulleys run down the inclined plane of the center rail, breaking the connection and so putting the lamps out.

between the carriages, so that the train can be broken up or shunted as usual, while the light is maintained whether the train is in motion or at a stand.

During the new year holidays some of the trains were running with only one carriage fitted, while others had six or eight fitted and the remainder not.

During the passage of these trains through the tunnel the speed of the dynamo was nearly constant, and their presence in the circuit could only be detected by a slight hissing noise at the commutator brushes, and faint sparking, if any. This system has now been in use four months, and two trains have been running all this time, only being off one day weekly to be cleaned. The number of lamps in the two trains was on an average 60; and, in the four months' lighting, three of them have had to be renewed. Two of the three were broken maliciously, the outside globes having been broken also, while in the other the carbon filament gave way, having burned 100 hours.

Since this paper was read, eight trains—or, in all, 74 carriages—have been fitted and are running daily. Taking the running of these trains for six months, the total number of lamp hours is 39,642. During this time it has been necessary to replace 44 lamps, so that the average life of the lamps has been 900 hours each; but as eleven of these lamps were broken maliciously by passengers in the trains, their actual life is 1210 hours.

In this system the electric light is not used at night, the gas or oil lamps being still made use of, which are there to fall back on should a breakdown take place. In the other systems the electric light was used alone, and could be made use of any time, whereas in this it can only be had in the tunnels. Of course, it has the advantage of allowing the trains to be broken up (which is done sometimes twice a day), without having any extra coupl-

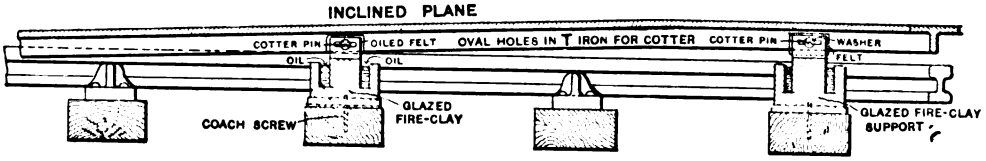

Fig.6.

As regards the power required for each train, it may be said to be about 2000 watts, or from two to three horse-power.

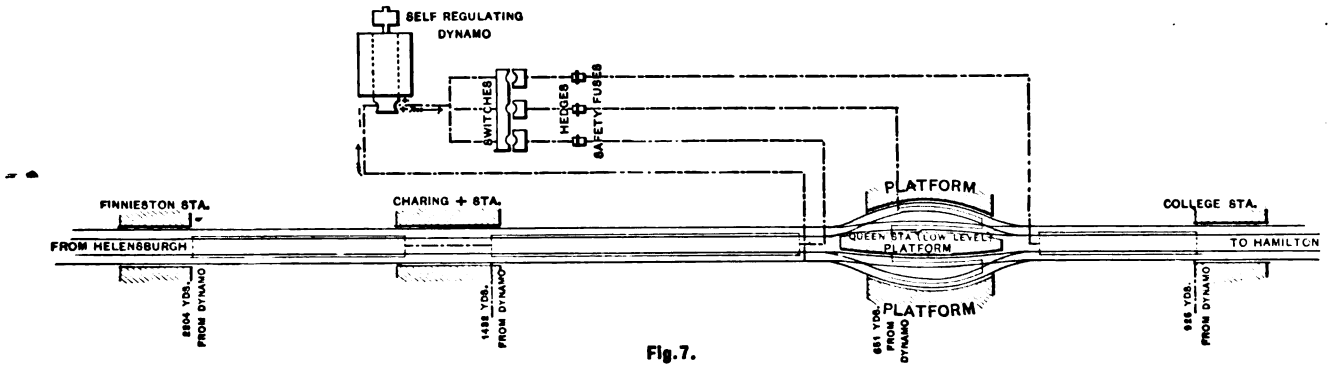

Fig.7.

In order to prevent the rusting of the centre rail, and to keep it clean so as to make good contact, a steel wire brush is fixed on one carriage in each train. It is found that the brush makes better contact and gives a steadier light than the pulley, but, owing to the friction, the tear and wear would be too great to adopt it entirely.

It is found that the "cut-outs" work best either with the 25 or 50 volt lamps, as they take more current, but even regulated and connected to a single 100 volt lamp they act well.

As already mentioned, the end of the center rail at Finnieston station, which is furthest away from the dynamo, is distant about 1¼ miles (2196 yards); and at this point, with one train in circuit or 36 lamps, the potential is 100 volts, or that required to light the lamps.

The insulation of the center rail is not quite perfect there being a slight leakage, but it cannot be traced to any particular part and it is practically inappreciable, being only about 3 amperes. This leakage may arise by the steam conveying the current to "earth," as on a dull day the center rail is quite wet; and in the distance from the dynamo to Finnieston the area exposed is no less than 840 square yards on one line alone, so that the leakage is not to be wondered at.

It will be seen that by this system the train, or rather each carriage, is lighted and extinguished on entering or leaving the tunnel—automatically, as it were. There are no connections

that of either of the other two, and fully a third less than that of gas, while the working expenses are much the same as the first two systems, but a third less than gas lighting.

ON INDUCTION BETWEEN WIRES AND WIRES.[1]

BY WILLIAM HENRY PREECE, F. R. S.

LAST year at Birmingham I pointed out that the electro-magnetic induction between wire and wire upon lines of telegraph extended to distances much greater than was anticipated, and that effects were observed even when the wires were separated by the breadth of England. I was not satisfied with the last experiments made in the north of England. I had reason to believe that they were vitiated by induction and conduction through the network of cross circuits and railway wires in that part of the country, so in October of last year I took the district between Gloucester and Bristol along the banks of the Severn, where it was possible to completely isolate two systems of wire separated by the river Severn for a length of 14 miles at an average distance apart of 4.5 miles, and where any disturbing cross-inductive or conduc-

1. Read before the British Association for the Advancement of Science (Section A.—Mathematical and Physical Science), Manchester, September 6th, 1887

Digitized by Google

tive connection was impossible. The circuits on each side of the river could be completed by the earth or by metallic returns passing far inland, in the one case through Monmouth, and in the other cases through Stroud. The experiments made were very numerous, but the results were almost negative. No measurable effect whatever could be detected when primary currents of .449 ampere strength were intermittently sent by a rapid vibrator or buzzer on each side, though it was just possible to distinguish faint Morse signals. It was quite clear from subsequent experiments that we were on the extreme verge of audibility, and had we been able at the time to increase the strength of our primary current we should have heard louder effects. In fact, I have taken this experiment as a measure of the limit of audibility—a conclusion fully confirmed by subsequent results. The experiments fully justified my conviction that those reported last year as occurring between Newcastle and Carlisle were wrong.

In all the following experiments the primary currents were always of rapid frequency, producing a buzzing sound, which could be easily read when audible, if sent in the Morse code, and received on a Bell telephone.

Two squares of 1,200 yards of gutta-percha covered copper wire, or 300 yards each side, and of a resistance of 15 ohms were placed 300 yards apart in the Porthcawl Sands in South Wales, and conversation by the Morse code was readily maintained with primary currents of .226 ampere. Conversation by telephone was impossible. Two other similar squares were subsequently (December) suspended on scaffold poles 15 feet above corresponding squares lying on the sands, which latter were covered with water when the tide was up.

No difference whatever could be detected in the strength of the signals received by induction, whether the space were air or water, or a combination of air and water. The Irish wires on the railway were 150 yards distant from the squares, and the usual disturbance was evident on all the squares, whether under water or not.

The principal object of this experiment was an endeavor to differentiate any electro-static from the electro-magnetic inductive effect, and the conclusion drawn was that the whole phenomenon was electro-magnetic, for no electro-static effect could be obtained. No doubt with parallel wires on a line of poles, where the distance between wire and wire is far less than that between wire and earth, electro-static induction comes into play, but its effect in the cases investigated was absolutely inappreciable.

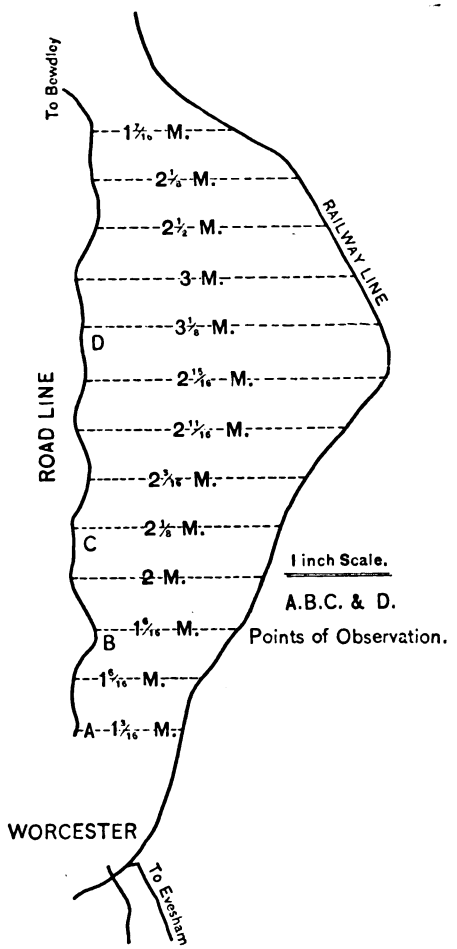
This was confirmed by further experiments made with squares of 33 feet sides, fixed three feet apart.

Moreover, it tends to the conclusion that the magnetic field extends uninterruptedly through the earth as it does through the air, and that if the secondary circuit had been in a coal pit it would have been equally evident.

It also accounts for the peculiar disturbance observed in submarine cables when lying near each other as described in my previous paper. I hope to have the opportunity some day of testing the limit of audibility in water. Cables, as a rule, lie too far apart for the purpose. I have made several efforts to get results on our Irish cables; but they lie apart far beyond the limit. Mr. Ash, the superintendent of the Eastern Telegraph Co. at Porthcurnow, in Cornwall, joined a telephone to the ends of two cables, one terminating at Lisbon 820 miles away, the other terminating at Vigo, 620 miles away. Signals could be distinctly heard on the telephone from the Brest cable landing about half a mile away, and terminating at Penzance.

We happened during the autumn to be constructing a new trunk line carrying four copper wires from London to the coast of North Wales, and for many miles of its length in different places it ran parallel at various distances to the Great Western Railway. On November 11th, 1886, between Shrewsbury and Much Wenlock, a wire on the railway, 10¾ miles in length, was made the primary wire, along which a periodic current of .08 ampere was sent. Strong signals were received on the copper wires, although they were completely isolated from any possible interference. The frizzling sound due to the ordinary induction from the mixed signals used in ordinary working were also evident, but the separating distance for eight miles was only one quarter of a mile. Between Much Wenlock and Bewdley for a length of 12½ miles, where the separating distance averaged one mile 1,046 yards, the ordinary induction sounds entirely disappeared. On November 28th, 1886, similar experiments were repeated on a system of wires separated and isolated by the River Mersey for a distance of 11 miles. The primary circuit completed by the earth was on the Lancashire side. On the Cheshire side the secondary circuit was completed by a well-insulated metallic loop running inland, and measuring 38½ miles in length. Morse signals were distinctly received. The separating distance was 1¼ mile. In February, 1887, the section between Worcester and Bewdley was divided into lengths, as shown in the following sketch:—

A wire on the railway was made the primary, the periodic current being .12 ampere, but the results were *nil*.[1] In no case could induction be heard between any of the points A, B, C, or D or upon the whole length. Resort was again made to squares in a field near Cardiff, removed from all possible interference, and the standard of comparison made was the limit of audibility. This is not an absolute or a scientific standard to use, but it is practical. It depends on the variation of the human ear and the sensibility of the telephone receiver, but as the results recorded were always the conclusions of several persons, and the same telephone receiver was used in all cases, the normal ear may be assumed to have been used, and telephones do not differ much



from each other when the same pattern is used. But they are much dependent on surrounding circumstances and extraneous sounds, on slight noises arising from the wind, from the rustling of the trees, from showers of rain, from passing persons or vehicles. The results of these experiments are given in the following table:—

TABLE A.

Experiments on Induction at Lisvane, February 2d, 3d, and 4th, 1887.

Experiment.	Current in primary. C_1.	Working face of primary.	Working face of secondary. (l)	Resistance of secondary. r_2.	Limit of audibility. x.	Calculated results.
	Amperes.	Feet.	Feet.	Ohms.	Feet.	Feet
1	.69	600	30	700	179	179
2	1.3	600	30	700	257	246
4	.69	600	60	700	585	
5	.69	600	30	700	182	
6	.69	600	30	200	641	641
7	.69	600	60	50	915	926
8	.69	600	90	75	1100	1134
9	.5	600	90	70	1373	1280

The extreme limit of audibility is derived from the Severn experiments, and is taken at 1.9016 miles which would be the case were we operating with one mile of line and one ampere. Other conditions remaining the same.

$$x = 1.9016 \sqrt{\frac{C_1 \, l}{r_2}}$$

from which the sixth column is calculated.

On April 10th, when the system along the banks of the Severn

1. The limit of audibility in this case was .66 mile.

Digitized by Google

was again resorted to, as a primary five wires running on the Midland Railway between Gloucester and Stonehouse were bunched at each extremity, and the secondary was one of the road wires which was parallel with the railway, and at an average distance of one mile, over a length of two miles. This secondary could be joined up at will into sections of one and two miles long, the observations being made in the middle. Under these circumstances the following observations were taken.

TABLE B.

Experiments on Induction, Gloucester and Berkeley, 10th April, 1887.

Experiment.	Current in primary.	Length of secondary.	Resistance of secondary including telephone.	Results.
	Ampere.	Miles.	Ohms.	
1	1	1	85	Good.
2	.73	1	85	Somewhat lower than in No. 1.
3	.53	1	85	Slightly lower, but above limit.
4	.33	1	85	Not much distinguishable from No. 3.
5	.22	1	85	Just audible. Taken as limit.
6	.11	1	85	Not a sound.
7	.11	2	112	Faintly heard, but below limit in experiment No. 5.
8	.148	2	112	Somewhat better than No. 7, but still low.
9	.22	2	170	In these experiments the two-mile length was made equal in resistance to twice the mile length, the audible sounds being under these circumstances alike in both wires.
10	.22	1	85	
11	1.0	1	425	Current in primary increased five times, and resistance in secondary in like proportion. Audible limit reached.
12	.44	1	165	Current in primary, and resistance in secondary doubled, and audible limit again reached.
13	.85	1	335	Current in primary, and resistance of secondary increased four times. Limit of audibility again reached.

Having thus obtained the conditions that determine the limit of distance across which induction is perceptible by the telephone, it became necessary to make some careful measurements so as to formulate the law that regulates the observed effects.

Let there be two wires placed parallel to each other for a length, l, and at a distance, d, then whenever the circuit is made in one wire a secondary current, C_2, due to electro-magnetic induction, and in the reverse direction will be produced in the other wire, and when the primary circuit is broken a current in the same direction will appear in the secondary. The relation between the primary C_1 and induced currents is given by the formula

$$C_2 = M\, C_1$$

M being a co-efficient of induction depending on—

1. The length, l.
2. The distance, d.
3. The resistance of the secondary circuit, r_2.
4. The rate at which the primary current rises or falls.
5. The condition that determines the rate at which the current rises or falls in the secondary circuit.

The following experiments were made to determine these different functions of M. The new general post office at St. Martin's-le-Grand is an oblong building, with four convenient corridors or galleries all round the building, along each of which perfectly insulated gutta-percha covered copper wires .050 inch in diameter were suspended along the wall. The wires were 20 feet apart, and each formed a complete metallic circuit, 250 yards in length, in which any apparatus could be inserted. The building itself is a huge magnetic field in a constant state of perturbation owing to the concentration there of a thousand circuits conveying messages. The consequence was that each experimental circuit was always in a state of disturbance, rendering accurate measurements during working hours impossible, and speech out of the question. Nevertheless, it was quite possible to differentiate the sound of the voice from the rest of the noises though 80 feet of space intervened. It being quite evident that no other instrument than the telephone could indicate these effects, and my object being to measure them in absolute measure two wires were suspended around one corridor at a uniform distance of six inches apart. After obtaining reading at this distance the space was increased to 12 inches, and, finally, reduced to a distance of one-fourth inch.

The primary current .21624 ampere was obtained from a Daniell battery, and was made uniform in strength in all cases. The secondary currents were read by the throws of a Thomson galvanometer. These deflections were reproduced and measured as is done in measuring condensers. The average results of many experiments come out as follows :—

Inches.	Observed.		Calculated.
.25	.004	amperes	.004
6.	.000007	"	.000007
12.	.000002	"	.0000018

It will be seen that the law follows the inverse square of the distance, and this is fully confirmed by previous and subsequent experiments. Moreover, it is easy to show that it must be so when we can neglect the influence of the earth. It is well known, and has been fully verified in all these experiments, that the strength of the secondary current will increase directly with the strength of the primary current, and directly as the length of wire under influence within the limits of these experiments. We can thus calculate a useful standard for use.

Two hundred and fifty yards of .21614 ampere, at 12 inches, induced a secondary current of .000002 ampere in a circuit of 13.27 ohms, or one mile of one ampere, at one mile distance, would induce a secondary current of .0000000000013, or 13×10^{-13} ampere ; and at 2 miles 3×10^{-13} ampere in wires such as were experimented with.

We can write the law thus—

$$C_2 = \frac{C_1\, l}{d^2 r_2} \times M.$$

I intend to repeat these experiments with care to obtain the value of the constant, M, in C. G. S. units.

The disturbances due to the mixed working currents on our telegraphs cannot be appreciable beyond 450 feet, but those employed in distributing electric light by means of secondary generators must extend to miles unless they are neutralized by the two conductors being fixed parallel and close to each other.

I have not yet been able to make any experiments to determine satisfactorily the influence of retardation and electro-magnetic inertia on this limiting distance.

I erected two wires of iron for a mile alongside the copper wires, but was not able to get any conclusive results. It is, however, quite certain that there is a difference in the effect when the wires are of iron or of copper, and that the distance across which induction is perceptible must reach a limit of length when the resistance and capacity reduce the rate at which the currents rise and fall, and the effects must begin to diminish. Hence the disturbing effects due to short lines are more pronounced than those due to long lines.

This limit of audibility enables us to calculate the current required by a Bell telephone, like that used in these experiments, to become just audible. It is roughly the sixth ten thousand-millionth of a milliampere, or in figures, .0000000000006 ampere, or 6×10^{-13} ampere.

Hence the air telegraphs used in America by Edison, Phelps, and others for communication with passing trains are readily comprehended, and the distances to which disturbances are propagated between telegraphic, electric lighting, tramway circuits easily calculated. The distance through which communication can be maintained between ship and ship, between lightship and shore, between islands and the mainland, between the defenders inside and those outside a beleaguered city, becomes simply a calculation. I have been assisted in carrying out these experiments by Mr. J. B. Chapman, of my own office ; by Mr. J. Gavey, of Cardiff, and Mr. J. R. Edwards, of Liverpool, both members of the Society of Telegraph Engineers, and the post office engineers in charge of the districts affected, all of them careful and reliable experimenters.

NEW ELECTRIC BALANCES.[1]

BY SIR WILLIAM THOMSON, F. R. S.

THE balances are founded on the mutual forces, discovered by Ampère, between the fixed and movable portions of an electric circuit. The mutually influencing portions are usually circular rings. Circular coils or rings are fixed with their planes horizontal to the ends of the beam of a balance and are each acted on by two horizontal fixed rings placed one above and the other below the movable ring. Six grades of instruments are made, named centi-ampere, deci-ampere, ampere, deca-ampere, hecto-ampere, and kilo-ampere balance. The range of each balance is about 25. Thus, the centi-ampere balance will measure currents of from 2 to 50 centi-amperes, while the kilo-ampere balance will measure currents of from 100 to 2,500 amperes. Since the indications of the instrument depend on the mutual forces between two parts of an electric circuit of permanent form and on their relative position, they are not subject to the changes with time

1. Read before the British Association for the Advancement of Science (Section A.—Mathematical and Physical Science), Manchester, September 2, 1887.

Digitized by Google

which are so troublesome in instruments the constants of which depend on the strength of permanent magnets.

The most important novelty in these balances is the connection between the movable and the fixed part of the circuit. The beam of the balance is suspended by two flat ligaments made up of fine copper wires placed side by side. These ligaments serve instead of knife edges for the balance, and at the same time allow the current to pass into and out from the movable coils. The number of wires in each ligament varies from 20 in the centi-ampere to 900 in the kilo-ampere balance. The diameter of the wire is about $\frac{1}{10}$th of a millimeter, and each centimeter breadth of the ligament contains about 100 wires.

The electric forces produced by the current are balanced by means of weights which can be moved along a graduated scale by means of a self relieving pendant. Two scales are provided, one a scale of equal divisions, the other a scale the numbers on which are double the square roots of the numbers on the scale of equal divisions. The square root scale allows the current to be read off directly to a sufficient degree of accuracy for most purposes. When high accuracy is required the fine scale of equal divisions may be used and the exact value of the current obtained from a table of doubled square roots supplied with the instrument.

An engine room voltmeter on a similar plan was described. It consists of a coil fixed to the end of a balance arm, suspended in the manner above described, and acted on by one fixed coil placed below it. The distance of the two coils apart is indicated on a vertical scale by means of a magnifying lever and serves to indicate the difference of potential between the leads to which the instrument is connected. The coils of the instrument are of copper wire, and an external platinoid resistance of considerably greater amount is joined in circuit with it. The electrical forces are balanced by means of a weight placed in a trough fixed to the front of the movable coil, and weights suited to the temperatures 15°, 20°, 25°, 30°, C., as indicated by a thermometer with its bulb in the centre of the coil are provided.

Two other instruments were described, namely, a marine voltmeter suitable for measuring the potential of an electric light circuit on board ship at sea, and a magneto-static current meter suitable for a lamp counter.

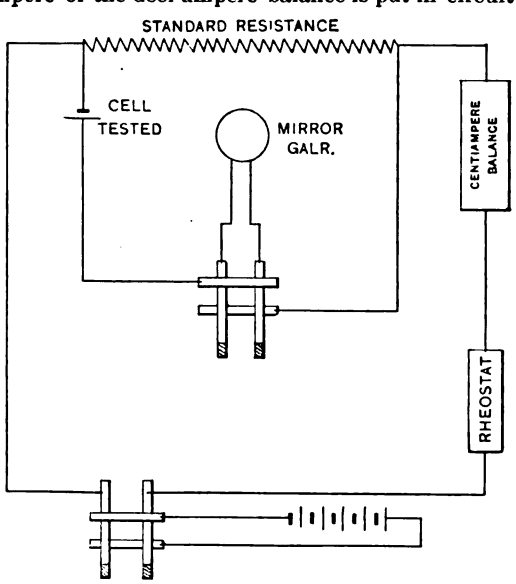
In the marine voltmeter an oblate spheroid of soft iron is suspended in the centre of, and with its equatorial plane inclined at about 40° to, the axis of a coil of fine copper wire by means of a stretched platinoid wire. When a current is passed through the coil the oblate of soft iron tends to set its equatorial plane parallel to the axis of the coil and this tendency is resisted by the rigidity of the suspension wire.

The lamp counter is a tangent galvanometer with special provision for preventing damage to its silk fibre suspension, and for allowing the constant to be readily varied by the user to suit the lamps in his circuit.

ON THE APPLICATION OF THE CENTI-AMPERE OR THE DECI-AMPERE BALANCE FOR THE MEASUREMENT OF THE E. M. F. OF A SINGLE CELL.[1]

BY SIR WILLIAM THOMSON, F. R. S.

FOR the purpose of measuring the E. M. F. of a single cell the centi-ampere or the deci-ampere balance is put in circuit with a



battery of a sufficient number of cells, a rheostat, and a standard resistance in the manner shown in the diagram. The current measured by the balance is then varied by means of the rheostat until the difference of potential between the ends of the standard resistance is exactly equal to the potential of the cell. This equality is tested by placing the cell in series with a mirror galvanometer or a quadrant electrometer in a derived circuit, the ends of which are connected with the ends of the standard resistance, and observing whether any deflection is obtained by closing this circuit. Suppose, for example, the standard resistance to be 10 ohms, and the current as indicated by the balance 0.108 amperes, when no deflection is obtained on the mirror galvanometer by closing its circuit, the potential of the cell is $10 \times .108$ or 1.08 volts. Proper precautions must, of course, be taken to eliminate thermo-electric or other disturbances in the circuit.

The quadrant electrometer may be used with advantage in the derived circuit, when it is important that no current should flow through the cell; but the mirror galvanometer has the advantage of much greater sensibility.

1. Read before the British Association for the Advancement of Science (Section A.—Mathematical and Physical Science), Manchester, September 6, 1887.

UNDERGROUND AND AERIAL CABLES.[1]

BY B. E. SUNNY.

A MILE of Patterson cables has been put down in West Madison street in Chicago, made up of one 150 wire cable and cables of from 25 to 125 conductors, containing in all about 200 miles of wire. Number 18 American gauge was used, and the insulation and capacity tests are very satisfactory.

These cables were put down to abandon a pole line of 90 wires built about six years ago. Nothwithstanding the fact that the wires on the route were badly decayed and contained many defective connections, and that the cables were of the best manufacture, the wires on the pole route talked about 25 per cent. better than those in the cables.

The cross-talk is only noticeable at times, and is not heavy. These cables are laid in a box of creosoted wood and covered with one-quarter inched tarred sheet iron. The box is just big enough to take the cable and no filling of any kind is used. A gang of twenty men put this cable down at a rate of 500 feet per day, finishing up everything excepting the permanent restoration of the pavement. Eleven hundred feet of conduit has been built to carry the cables from the present central office to the new building. The construction includes the use of wrought-iron pipe two and one-half inches inside diameter, free from burs and presenting a smooth surface to the cables. The pipes, sixteen of them in all, are spread apart and the interstices filled with concrete. We are putting No. 18 gauge 200 conductor cables into the pipes, and find that they work smoothly, and that a gang of six men can put in four pieces of cable 400 feet each per day. The underground cables put down two years ago are giving satisfaction. Recent tests on some of them show an insulation ranging from five to fifteen megohms. One cable put down by the Standard company two years ago indicated a very low insulation on the regular test. We opened the street in two or three places and finally located the fault in a splice. No abrasion of the lead pipe could be noticed nor was there any superficial evidences of a fault. A piece including the splice was cut out and another piece of cable put in. The piece cut out was laid on a board, and shortly it was noticed that water was coming out of the splice through a blow hole the size of a pin in the solder. There was perhaps half a pint of water in the sleeve. It took two years for the fault to develop. In another instance a Standard cable was cut into by plumbers some time last November. In June the insulation was found to be low, and when the fault was located it was discovered that the water had gone into the core through a bad cut in the lead and had worked back forty feet, requiring new cable to that extent. We have several cables chiefly aerial, that are defective and are being looked up. It requires the constant attention of a galvanometer corps to keep them in good shape. By means of semi-annual tests defects have been discovered and removed before they had time to affect the service. The trouble from low insulation at the terminals is being overcome by filling the terminals with paraffine wax or some other insulator, and keeping the terminals well protected from moisture. The trouble outside of the terminals on air cables is made up of cuts in the lead by hooks cutting through, bullet holes, and careless workmen.

The following tests recently made may be of interest: Two wires were selected which ran together through nine cables of seven different styles, a distance of 4.4 miles. The cables are Patterson aerial and underground and Standard aerial and underground, and contain from 50 to 150 wires, each ranging from eighteen to twenty-six gauge. The resistance measures 444 ohms. The first test was made on a day of alternate sunshine and rain, when everything was damp. There was absolutely no cross-talk from one wire to the other, and conversation could be carried on freely and without any more effort than on an air line. The introduction of an annunciator drop into the circuit made no dif-

1. Read before the National Telephone Exchange Association, Pittsburgh, September 27, 1887.

Digitized by Google

ference. A test for insulation showed 400,000 ohms for the distance and a static capacity of 1.4 microfarads. A week later the same wires were used in the same manner with less satisfactory results. The weather was dry and warm. It was found that counting on one could be distinctly followed on the other, and vice versa.

The cross-talk from the other wires was very noticeable, but not of sufficient volume to disturb the user. Conversation at a distance of eight inches from a fairly adjusted transmitter was indistinct and muffled. With the lips close to the transmitter, and by speaking in the usual tone of voice, the results were fairly satisfactory. This was particularly true when an air line of one and one-half miles was added. The measurements made after the test showed the insulation to be 4 megohms for the distance against .4 of a megohm on the previous test, and 1.15 microfarad capacity against 1.4. By opening one of the wires at both ends, so that all connection with the earth was removed, conversation could be freely carried on between three parties who were looped in. The first one was 5,000 feet from the open end of the cable, and the other 12,000 feet. The only difference noted by the intermediate parties in the working of the wires with the ends open was that the cross-talk was much heavier than with the grounds on. The second test indicates conclusively that we have used up all our margin, and that a slight addition to the length of the cables will make the connection of no commercial value. In fact, in ordinary dry, clear weather, conversation is only carried on by frequent repetitions and considerable discomfort. The nine cables included in this test are all in good condition, and with the exception of a few pieces of air cable, are new. On the above circuit there are sixteen terminals in use, but in all cases, except in exchange offices, the cable wires of one cable were connected with those of another at the terminals with kerite or okonite wire, so that the insulation was good at these points. The experience of four years has proven the fallacy of the practice of requiring the manufacturers to furnish a cable showing an insulation of from 300 to 800 megohms per mile. While this insulation can be secured immediately upon the completion of a cable, it is utterly impossible to maintain it. Nor is it desirable to maintain it, for the reason that cross-talk is greater on a cable with a "fancy" insulation than in one of a megohm. Subscribers always complain of cross-talk when their wires are put into a new cable, but after a few months we hear no more about it. This is not so much because they have become accustomed to the cross-talk as it is that with the lowering of the insulation the cross-talk is decreased. A better specification would be one megohm per mile and not more than five, and a guarantee from the manufacturer that this insulation will hold up for ten years. Such an insulation exceeds anything that we are able to get on air lines. In a recent test nine wires showed each an insulation of 5.3 megohms. Rain began to fall, and in ten minutes the insulation had fallen off to 3.2, and no doubt went lower. This illustrates the extreme sensitiveness of a high insulation to moisture, and indicates clearly that where there is a large number of cables in use the conditions are constantly varying, and nothing like uniformity in the working of the wires can be expected or secured.

ELECTRICITY AS A MOTIVE POWER.[1]

BY WILLIAM WHARTON, JR.

SINCE the last annual meeting of this association the subject of using electricity as a substitute for horse-power on street railways has received much attention, and great advances have been made in the practical application of it to that purpose, so that it may now be stated broadly there is no longer any doubt or uncertainty that electricity can be successfully and economically employed in a great many places, if not most places, as a substitute for animal power. Quite a number of electric railways are in operation in the United States running satisfactorily under all the requirements of public service, so that there is much greater familiarity with and a more general knowledge of electricity among railroad men and the public than ever before. There is so much confidence in the practicability of electrical propulsion of cars being well established, that the subject is no longer treated with doubt or disdain; on the contrary great interest and respectful attention are at once manifested whenever the subject is brought up. Although some parties, interested perhaps in pushing forward their own special inventions, may claim too much, the actual facts as presented daily in the regular work of the cars are good enough to warrant this belief and confidence. Electricity in its manifestations, applications and capabilities, has been hitherto a subject, the knowledge of which has been confined mainly to scientific circles, but it is evident that the time has come when it will be put in harness in place of the horse to draw cars and to perform many other duties, which a few years ago would have been considered entirely chimerical and visionary. So long as the oxidation of metals or other chemical action was the only available method by which electricity could be produced, the expense attendant upon such means limited its use to a very narrow sphere. Since, however, steam power and water power have been so successfully employed to generate electricity, and to do it so cheaply, the range of its usefulness and application has been wonderfully enlarged from year to year. It is not intended in this paper to make use of scientific terms, or to discuss the question from any standpoint but that of practical observation and experience; nor is it intended that any comparisons shall be drawn between electric motors and steam locomotives, but there is a wide field for work in which neither the locomotive nor the horse is able to satisfactorily accomplish the duty called for.

The systems at present in use for electrical propulsion of cars are divided into two classes.

First, that in which the electricity is conducted from one or more active generating sources along a suitable conductor or conductors to be used in the cars with proper return connections; and secondly, that system in which the electrical power is obtained from accumulators or secondary batteries carried along with or within the body of the car. Of the first there are several methods, namely, that in which the electricity is carried along a conductor above the ground, considerably above the car, either directly over it or toward one side.

That in which the electrical conductor is situated at the side of the railroad and elevated a few feet only above the ground.

That in which the electricity is carried upon the surface, either by a third rail or other conductor, running on the level of the ground or pavement.

That in which the electricity is carried beneath the surface by a conductor placed within a suitable conduit for its protection, access being had to said conductor through a slot in the top of the conduit, so as to allow of electrical connection with the motor on the car.

The plans of having the conductor along the surface or at the side of the railroad not much above the surface have so many evident and practical disadvantages that they need not be taken into consideration in this paper; therefore the question is reduced to the three methods of overhead conduction, underground conduction and storage batteries.

It is evident that better service must be furnished at the same cost, the same service furnished at a cheaper rate, or that both objects combined shall be attained by the use of electricity before it takes the place claimed for it. The writer believes fully that the last proposition of both better and cheaper service has already been proved by actual service and daily use, but in the nature of things, improvements upon the present methods will be discovered, and "the survival of the fittest," which applies as well to mechanical appliances as to animated life, will by its inexorable laws weed out and discard those which are deficient or incompetent. There are so many intelligent persevering and scientific minds engaged in active experiments and researches into the mysteries of Nature's powers, and more especially those relating to electricity, that discoveries are constantly being made, human knowledge in this age extending more rapidly than at any previous time. The subject is fascinating, and the prizes sought after are brilliant and valuable. The increased cheapness in production of electricity which may fairly be assumed for the future, will of course add to the advantages, and enlarge the scope, of its use. At present there are many places where electricity can be generated at a nominal cost by the use of water power, and this energy can be carried a number of miles without any loss or leakage of practical consequence. Where this can be done of course the parties have special advantages. So also there are many towns and cities in coal regions, or natural gas regions, where the same result of cheapness in production can be obtained, although by different means. As a case in point, it may be mentioned that the electrical railway in Scranton, Pa., has its power station located about midway of the route, and immediately at the foot of a large hill or great mass of hundreds of thousands of tons of culm, which is principally composed of the small fine particles of coal produced in mining, or left after the screening and preparation of the commercial sizes of coal for the market. This has been accumulating for many years, is still accumulating, and has hitherto been considered only an inevitable nuisance, which the mining proprietors would gladly have given away for nothing to get rid of it, and not have it occupy their land. The price which the railroad company pays for this culm is but ten cents per ton, and as it only has to be wheeled through the door of the engine house, the whole distance from the culm hill to the furnace under the boilers not being over fifty feet, and as the whole consumption per day is on the average but five tons, or in money value but fifty cents per day, it is evident that the cost of electricity in this case is exceedingly small indeed, that sum being sufficient for the fuel to produce the steam power which generates electricity enough to run four and sometimes five cars, carrying at times seventy-five passengers each over a railroad track about four and

1. Read before the American Street Railway Association, Philadelphia, October 19, 1887.

Digitized by Google

a half miles in length, having long grades, a number of which are five or six feet to the hundred, and the steepest of which is seven and a quarter feet per hundred. The tractive power required upon some of these grades is still further increased by curves or switches occurring on them. It may be well to mention some other points about this railroad in Scranton, which has been running about a year, with great success, and exhibits in many respects a favorable example of an electrical railway with overhead conductors. The cars have four wheels; two of them are open cars, each carrying one motor of 20 h. p. The motor is placed in the body of the car midway of its length, and all four of the wheels are driving wheels, the connections between the motor and the wheel axles being made by means of chains and sprocket wheels. Three of the cars are closed cars, each with one motor of 15 h. p., which is placed on a closed platform at the forward end of the car. In these the forward wheels only are driving wheels, and their connection with the motor is made in the same way as on the open cars, with chains and sprocket wheels. The company will shortly place four more cars upon the line, each with a motor of 25 h. p. These larger cars are intended not only to propel themselves, but to be able each to haul in addition two other cars loaded with passengers up all the grades. The running time of the round trip on the main line, being in all eight miles, is one hour, which includes all stoppages and the waiting at each end of the route, so that the average speed attained is more than eight miles per hour. There is no difficulty in going much faster; in fact, the men in control of the cars have to be watched to prevent their running at excessively high speed, particularly on the return trip to the city, where the grades allow the car to be run for most of the distance by gravity alone. At the generating station there are two stationary engines of 180 h. p. each, two dynamos of 100 h. p. each, and four boilers of 100 h. p. each. Only one engine and dynamo, however, and two of the boilers are in use at any one time. The railway company expects also to furnish in the future electricity for the lighting of the town of Dunmore, situated at one end of the line, by which the income of the company will be materially increased. The duplicate engine and dynamo and the duplicate set of two boilers are for the purpose of providing against contingencies of accident to those in use, and also to allow of alternations in service, thus giving opportunities of frequent examination and inspection. Upon this railway, as before stated, the overhead system of conduction is employed, having flexible connection between the motor on the car and the carrier traversing the conductor, which is a solid copper wire of five-sixteenths inch diameter, suspended on a part of the route from transverse wires attached to wooden poles placed on both sides of the street about one hundred feet apart lineally, about twenty feet high and about six inches in diameter at the surface of the ground, and on the rest of the line suspended from arms projecting sideways from wooden poles at the side of the railway about twenty feet above the ground. The line is a single track railroad with several turnouts or passing places, at which points the electric overhead conductor branches off over the side track also, and an ingenious system is in use by which the carrier, running upon the overhead wire, with two grooved wheels of about two and a half inches diameter automatically shifts the connections at the points of divergence from the main line, so that the carrier always follows that one of the overhead conductors which is above the track upon which the car is traveling. It is contemplated, however, to use two separate and independent overhead conducting wires throughout the whole length of the route, so as to avoid the possibility of any difficulty with the carriers at the points of intersection at the turnouts, although this has not happened often. The return current of electricity is taken by the rails. The electrical current has a tension of about six hundred volts, which while sufficient to give a shock, could not produce any dangerous effect on man in case the current should by any means be diverted. Part of the road is laid with tram rails and the rest with T-rails, and a part is paved and the rest unpaved, so that these different conditions, in connection with the many grades and the curves and turnouts give ample opportunity to thoroughly test the working of the system. Although the overhead wires in this case do not present any more unsightly appearance than the numerous telegraph cables and wires to which we are so accustomed, it is, however, evident that the use of the overhead system will be prohibited in most cities and towns, especially since the general determination to place all electrical wires through cities underground. The noise of the carriers running on the conductors is not much, although it can be readily noticed, but the noise produced by the motors and the chain and sprocket connections is quite considerable. This latter could be entirely avoided by the use of a noiseless motor and a better method of connection, of which motors and connections there are several kinds easily obtainable. Noiseless, efficient and durable electric motors suitable for use on cars can be had in which the weight per horse-power does not exceed sixty pounds.

In a paper of the length to which this must necessarily be limited, it will be impossible to do much more than treat of the subject in a general manner, but it can be stated specifically and certainly that electric railways with overhead conductors have demonstrated beyond a doubt their capability to propel a few cars, even if heavily loaded, at less cost and much greater speed than could be obtainable on railways operated by horse-power. This is true in places where the coal required must be bought at usual rates and the exceptional advantage of fuel at merely nominal cost does not exist as at Scranton, and likewise at Wilkesbarre, where an electrical railway is under construction, upon which the cost of coal used will not exceed sixty or seventy cents per day for five cars.

In the case of electrical railways with underground conduction the effort has been made to give all the advantages of the overhead system, and at the same time remove the objection which, in most places, is absolutely prohibitive, of having the conductors and poles, or other supports, obstructing the streets. In doing this, however, great difficulties arise, some of them of a very serious character. The costly conduit, with the needful arrangements for drainage and for cleaning out, together with the increased care necessary to provide against the considerable loss or leakage of electricity, which, nevertheless, generally takes place in spite of all precautions, detract greatly from the apparent advantages of the plan. Many inventions have been patented, and numberless devices contrived, to overcome the many objections of this method, but there is great room for doubt whether practical success has yet been obtained.

Neither by overhead nor underground conduction have more than a few cars, as yet, been moved simultaneously upon railways, although many ingenious arrangements are offered by various parties, who confidently assert they can run any required number of cars. This, however, yet remains to be proved. Both plans, also, are open to another serious objection in the entire stoppage of travel on the whole line in case of breakage or derangement of any part of the conducting apparatus or the generating machinery. In this respect they are under the same disability that the cable system of car traction is hampered with. Possibly, by suitable arrangements of duplicate engines, boilers and dynamos, duplicate conductors, and auxiliary, sectional, or relay systems of conduction, this disability, threatening as it appears to be, may be so reduced as to be of no great detriment. This, however, also remains to be demonstrated. Taken altogether, underground conduction does not compare favorably with overhead conduction up to this time. One great trouble with the latter plan, however, is that although it can be used to great advantage and economy on lines running a few cars in towns, or in suburban districts outlying large cities, it will probably never be allowed by the municipal authorities in large cities, which, of course, are the very places where the advantages of electrical propulsion are needed the most. To move a large number of cars, as for instance upon the Third avenue or Broadway lines in New York city, the electrical conductor, whether overhead or underground, must be of great size if the current is of low tension; while on the other hand, if a small or moderate-sized conductor be used, the current must then be of dangerously high tension, and of course it would then be very difficult to avoid great loss of electricity from leakage.

There remains to be considered the accumulator, or secondary battery system. In this each car carries its own supply of energy, and is entirely independent of any method of continuous electrical conduction. No change of track or roadway is required, nor any costly conduit or unsightly poles, or other supports, while the cars can run anywhere that a car can be taken by horses. These points are of immense advantage, and are the chief merits advanced by its advocates, independent of its economy over horse-power.

In practice, cars of the size of the usual two-horse cars are provided with about eighty accumulators, weighing, when filled with fluid and ready for use, about 40 pounds each. These cells are placed under the seats, one-half being on each side of the car. Their combined weight is 3,200 pounds, and the weight of two motors, each of 5 h. p., should not, together with their connections to the car axles, exceed 800 pounds, so that the additional weight imposed upon the car is, say 4,200 pounds, which allows 200 pounds for the apparatus to control the current and for other electrical appliances. This added weight, if placed upon a four-wheel car, may be of disadvantage to the car or to the track. If this should be the case, the difficulty is removed by the use of eight wheels on two swinging trucks, which support the car much better, and distribute the weight upon the track. Both these kinds of storage battery cars are in service with entire success. The charging of the cells is done by a dynamo driven by steam power, or any other desirable means, and it takes four hours to charge cells which are able to perform four hours' work. To remove from the car the cells which have done their work, and to replace them by freshly-charged cells, takes no more time than the time required to change horses. It requires 10 h. p., exerted for four hours, to charge the batteries or cells of each car, so that 40 h. p. hours are needed to accomplish it.

The cost of running large stationary steam engines, of say 200 to 400 h. p., constructed with the modern improved cut-off appliances and other economical devices, has been found, after extensive investigations, not to exceed two-thirds of one cent per horse-power hour.

Digitized by Google

The allowance is a liberal one, and is above, rather than below, the actual average cost, including fuel at average market prices, attendance, repairs to engine and boilers, oil, etc. We will, however, take it at one cent per horse-power hour: Forty h. p. hours at one cent costs 40 cents, which is the cost of four hours' car service, and as the day's work of a car should be taken at 16 hours, we have as the whole cost of a day's supply of electricity four times 40 cents, or $1.60. Since four teams of two horses are required to draw a car for 16 hours, and as one additional horse per car is the usual allowance for sick or disabled horses, nine horses per car are needed for a day's work, which, at 50 cents per horse for feed, bedding, attendance, shoeing, etc., is $4.50, against $1.60 for the storage battery electricity. Making extraordinary allowance for possible errors in this comparison, the difference is still astonishing to those who have not looked into the matter critically. With motors properly constructed a speed of eight or nine miles per hour is readily accomplished—in fact, eight miles per hour may be taken as the speed at which such motors will work to the best advantage, and return the greatest percentage of mechanical efficiency. The requirements of street-car service demand variable rates of speed, as for instance, in crowded streets, behind other vehicles, or in turning curves and entering switches it is necessary to go slowly and cautiously; and the weight of the load carried at different times will vary from an almost empty car to one overloaded. These conditions, together with increased power needed to ascend grades and to start loaded cars, especially on up grades, call for electric motors which will under such greatly varying circumstances respond at all times almost equally well.

There are motors which, while engaged in performing an equable work and running at an equable speed, for both of which purposes the motor was specially made, will return 90 or possibly 95 per cent. of efficiency, while the same motor when run at some different speed or under some different load may return but 30 or 35 per cent. So that the average performance of such motors in street car service would probably give only 50 per cent. return of efficiency. Motors can, however, be obtained which will under all the variations of street car work constantly return 75 per cent. of efficiency.

The durability of storage batteries is a point which those interested in other systems are very prone to doubt, but it has been proved in actual use in cars that they will continue in good serviceable condition for 18 months or two years. Makers of these batteries offer to guarantee them good for two years of street car service. The lead-lined wooden containing boxes will last for many years, the negative plates are good for more than two years, while the positive plates are certainly good for 18 months, if not more.

The plates being of lead and lead oxide are still of value when they become unserviceable, for the metal can be recast into new plates, and the lead can be recovered from the oxide. The first cost of storage battery cars and the engine and dynamos is at present prices considerably more than the first cost of cars provided with suitable complement of horses and harness, but when the saving in first cost obtained by dispensing with the ground and the stables required for horses is taken into account, the balance will, in many cases be in favor of storage battery cars. This is, of course, applicable more particularly to large cities where ground is very valuable. By methods now being introduced into the manufacture of storage batteries, their production will shortly be made at a reduced cost, and their durability increased at the same time.

It should be remembered that the increased speed at which electric cars can travel is so much greater than horses could draw them, that two cars can readily do the work of three horse cars, especially as the electric cars require no time for resting at the ends of the route; but although they can easily do this, so much increase of speed would not be allowed or be practicable through the streets of most cities or towns. It could be done with safety and advantage through wide streets or avenues and in suburban districts. It will, however, be perfectly safe to say that three electric cars can do the work of four horse cars, and, if desired, they can at the same time be of greater capacity than horse cars, for while the horses can do no more, no such difficulty exists with electricity. Without referring to the excessive first cost required for the expensive cable traction system, and comparing the first cost of the entire plant and equipment needed for a storage battery electric railway on which three cars will perform the service of four horse cars, with the first cost of the entire plant and equipment of a railway using horse-power, it will be found that the advantage will in most cases be in favor of storage electricity. Let us now compare the operating expenses.

Running expenses of four two-horse cars for one year, to wit:

Conductors, 365 days, at $3.00 each car per day of 16 hours.....	$4,380
Drivers, " " 2.50 " " "	3,650
36 horses, " " .50 each per day.....	6,570
	$14,600
One year's deterioration and repair of 4 cars at $200 each.....	800
" " of 36 horses, at $40 each.....	1,440
	$16,840

Running expenses of three storage battery cars for one year, to wit:

Conductors, 365 days, at $3.00 each car per day of 16 hours...	$3,285.00
Drivers, " " 2.50 " " " ...	2,737.50
Electricity, " " 2.00 " " " ...	2,190.00
	$8,212.50
One year's deterioration and repair of 3 cars, including dynamos, storage batteries and motors, $1,600 each.....	4,800.00
	$13,012.50

This leaves a balance to the credit of the storage battery cars of $3,827.50.

The fact of each storage battery car carrying within itself its own energy gives to the individual cars an independence of action which neither the cable traction plan nor the overhead or underground system of electrical propulsion possesses, for all of these depend upon central sources of power, which may at any time be interrupted, so that breakage or accident to any part involves the stoppage of the whole line.

In a sanitary and cleanly point of view the withdrawal of the car horses from our streets would be of great benefit, and this would be accomplished without having, as in the case of the cable railway, an open drain, which, although supposed to be kept clean, in fact nearly always contains a deposit of street refuse to a greater or less extent.

The leakage of electricity in storage batteries, charged but not in use need not be taken into account for any length of time that cars would probably stand idle. In fact, the leakage from batteries in good condition would not exceed 10 per cent. in three months.

The percentage of mechanical energy given by the steam engine which is recovered in actual work under the variable conditions of street car service on the driving axles, with storage battery cars properly equipped, is at least 40 per cent., and with electricity by direct conduction at least 50 per cent. In cable traction, after deducting the power needed to move the cable and to revolve the wheels guiding and carrying the cable, not over 25 per cent. is left for drawing the cars, and on some cable railways even less.

The increased speed so easily and advantageously obtained on electric railways as a class, not only enables three cars to do the work of at least four horse cars, and effects the great annual saving shown above, but it has a tendency to invite travel and thereby increase receipts, also to give street railways the opportunity to extend their lines advantageously further into outlying districts and to compete on better terms with elevated roads and steam railroads than would be possible with horse-power.

The rapid deterioration and destruction of street car horses shows the exacting and terrible nature of their work, although it is for only four hours per day. Their powers are already overtaxed, and they can do nothing more either in speed or in load carried.

Electric cars, by dispensing with horses, allow more room in the streets for other vehicles, and this advantage in crowded streets is of moment. Take, for instance, Washington street, Boston, or Broadway, New York, and it will be readily seen that this relief to the clogged traffic would be great.

Electric cars can go backward or forward with equal facility, they are under perfect control, can stop and start more quickly than horse cars, and in case of delay can make up lost time. They never get sick with epizooty or other disease, and during strikes or other periods of enforced idleness do not require to be fed. On down grades they will run by gravity without the expenditure of other force, and on level or nearly level stretches a very little electric energy continues their motion when once they are started.

The electricity, beside running the motors, will supply the car with incandescent electric lights, actuate an electric signal going, and operate electric bells for the use of the conductor and passengers in stopping or starting the car. It is usual to have the regular hand brake for stopping the cars, but the motors can be instantly reversed by electricity if desired. This method, however, should only be employed when it is necessary to stop the car very quickly to avoid accident, or for some other imperative reason. By this means the car can be stopped in much less distance than is possible by the hand brake, which, of course, operates with the same efficency whether upon electric cars or horse cars.

It has been questioned whether in winter, when the tracks are liable to be obstructed with snow or ice, the electric cars will be able to propel themselves, owing to the fact that they obtain their power of propulsion from the adhesion of the wheels upon the rails, so that if the wheels are prevented from reaching the track there would be a great liability of their slipping and turning around without giving any forward motion to the car itself. In answer to this, it may be stated that during last winter, on the electric railway in Scranton, having the overhead conduction system, and from experiments made in Philadelphia with a storage battery car, it was found that there was no unusual difficulty presented in snow storms, the wheels, owing to the added weight, settling more readily through the snow, and thus reaching the rails. Upon roads properly equipped with snow plows, or snow sweepers with revolving brushes, propelled by powerful

Digitized by Google

electric motors, the clearing of snow from the tracks would no doubt be much more efficient than horse-power could effect. Street car electric motors of 50 h. p.—or more, if required—can be as easily made, and are as easily controlled, as motors of 5 or 10 h. p., so that electricity has ample ability to keep the tracks clear from accumulations of snow. As with locomotives, sand-boxes should be placed upon electric cars, so that if any slipping of the wheels should be observed, either from the greasy, slippery condition of the track—sometimes seen in damp weather when the streets are not properly cleaned—or from snow or ice upon the track, the driver, by opening a suitable valve, can let out a little sand upon the rail, and at once overcome the difficulty.

It is sometimes asked why two motors of 5 h. p. each should be needed upon a car usually drawn by two horses. In explanation of this it may be stated that a car horse can, and very often does, exert for a short time, in starting a car or upon steep grades, a force of 5 or even more h. p. A mechanical horse-power is the measure of the moderate duty which a horse can constantly and regularly exert day after day, in a regular day's work, without injury; but car horses are constantly temporarily called upon to exert unusual and unreasonable power, which is the reason they are so rapidly destroyed in street car service. It is evident therefore that the electric motors must be able, when called upon, to exert the same power that the horses, under pressure, can be made to perform temporarily, so that a maximum of 5 h. p. in each of the two motors will develop only such force as the requirements of street car service are constantly demanding during short periods of time.

It is not intended in this report to indicate that cable railways for use on steep hills or high grades will be superseded by electric railways, for the latter are limited to such grades as the adhesion of their wheels upon the rails will enable them to surmount, just as in the case of the steam locomotive, so that there is a suitable and proper sphere of usefulness for cable railways in the many places for which they are particularly adapted.

It has been proposed to increase the tractive power of electric cars upon inclines by causing magnetic attraction to be developed between the wheels and the rails, and also by the use of other devices. All these methods present complications which probably will more than outweigh the advantages sought to be attained.

In developing the best construction and management of electric cars and railways, careful attention to details, some of which at first sight may appear trivial, should be exercised, in order to obtain the best results, no matter which of the three plans be adopted. It should, however, be said that in practice at the present time the running of electric cars requires no more intelligence or skill than the running of horse cars, and also that the electric current, with continuous conduction, on lines using a few cars, need not be of such tension as to endanger human life, 500 volts being sufficient. With the storage battery system the tension of the current is so low, 160 volts being sufficient, that no shock whatever could be experienced by a man taking through his body the whole current required to propel the car. This has been repeatedly done, some of the people stating they felt nothing at all, and the others no more than a slight tingling sensation.

The term "storage batteries" so generally in use, is apt to give a wrong impression, no electricity whatever being stored or contained within them, for in charging the batteries a chemical action is forced to take place, and, when this chemical action is allowed to reverse itself, electricity is generated thereby. The car motor immediately uses this, and when the motor is stopped the chemical action and, therefore, the generation, of electricity ceases.

In this report care has been taken not to refer by name to any patented inventions, or to recommend any particular make of electrical appliances. As to these matters, those proposing to use electricity, whether by overhead or underground conduction or by storage batteries, should, of course, be careful to select such methods as are the most reliable, efficient and durable, and to deal with parties not only responsible as to the validity of their patents, but capable of doing what they undertake to perform.

Any one who peruses the railway journals, and notices the number of electric railways now in operation, and the still greater number of those in course of actual construction, or projected, has cause for suprise, if he has not been closely following the course of events.

That electricity, by some of the present methods of its use, or by better ones yet to be invented, will entirely supersede the use of horses and cable traction upon all street railways, excepting under the special conditions for which cable traction is occasionally applicable, is a question that admits of very little doubt.

NOTES ON LONG-DISTANCE TELEPHONE WORK.[1]

BY E. J. HALL, JR.

To talk between points hundreds or thousands of miles apart as though standing face to face is a feat, the accomplishment of which may well call for our best efforts. Apart from all commercial considerations, it presents the fascination of an unsolved problem. No sooner had the telephone exchange been an established fact than inventors and "promoters" began to suggest all sorts of visionary schemes for long-distance telephone work.

Of the early experiments, none were more successful than the trials between New York and Chicago, speech being transmitted between those points by a number of people with fair results. These trials showed that, under certain conditions, it was possible to talk for a distance of over a thousand miles. We all know, however, that commercial business could not be carried on under these conditions, as all successful tests were made when the wires were free from outside disturbances. As they were clear only on Sundays, and even then only when there were no storms or heavy earth currents, the effect of early experiments was rather to discourage work in this direction.

In Canada, and in the western states, some long lines have been operated with success, the distances covered being far in excess of any practical working lines in the eastern states. The reasons for this have often been discussed in our conventions, and I will not go into them now; it is enough to say that, giving all due credit for what has been accomplished, no large business can ever be worked up on the basis of using grounded circuits, owing to the inevitable "cross-talk" between parallel wires. The first really practical success in talking over long distances was over the copper metallic circuit constructed between New York and Boston, by Mr. T. B. Doolittle, for the American Bell Telephone Co., in 1883. The distance was about 300 miles, and I call it the first practical success because it was the first circuit that worked at all times regardless of outside electrical disturbances.

Early in 1885 I was appointed by that company to take charge of the development of this branch of telephone service, and the American Telephone and Telegraph Co. was organized to carry on the work. At the outset, it was decided that only copper wire in metallic circuits should be used, and that nothing should be spared to make the plant, in every respect, as perfect as we knew how to build. A builder whose work is known to you all (Mr. W. H Fairbank) was appointed general superintendent of construction, and the first line was constructed between New York and Philadelphia. The specifications for this line required the use of poles not less than seven inches in diameter at the top and from forty-five feet upward in length; to be set six feet in the ground on straight lines, and seven feet on corners or sharp curves. The poles had gains for seven ten-pin arms, and three arms were at once put on, carrying twenty-four copper wires. In addition to the copper wires, one No. 8 iron wire was strung on a top pin to strengthen the line (especially during construction). The utmost pains were taken in guying and bracing, and the good results of this care in building have been fully demonstrated by the nominal expense of maintaining the line since it was finished.

There are nearly three miles of submarine cable in this line, and all crossings are made with four seven-conductor kerite cables. In three of these cables the conductors are each composed of three No. 18½ B. W. G. copper wires, twisted together and insulated to $\frac{3}{64}$ of an inch, and the cables are armored with eighteen No. 4 galvanized iron wires. The fourth cable has conductors of three No. 16 wires, twisted together and insulated to $\frac{3}{64}$ of an inch, and is armored with eighteen No. 2 galvanized iron wires. The cable houses are large, dry and well lighted, and special care was taken to guard against lightning, and against bad connections and leaks in the terminals. All underground and aerial cables are of large conductors, heavily insulated, and the general result has been a line which, for nearly two years, has worked with uninterrupted success. Wind, sleet, lightning and electrical storms have, so far, passed over it without causing more than the most trifling damage, and we have secured one of the most essential elements in commercial business—reliable service.

That this line would "talk well" no one questioned, as the distance (about 100 miles) is far within the limit which previous experiments had shown to be entirely practicable. I will say here that we have not yet reached the limit of distance, but having worked over 400 miles, we know it exceeds that. It is probable that the progress of electrical development will keep the possible limit up to the distance over which it will be commercially profitable to supply this service.

Since the completion of the Philadelphia line, we have started lines of a similar character between New York and Boston (250 miles), and New York and Albany (160 miles). The Boston line will be ready for service in a couple of months, and the Albany line by the end of this year.

Having completed our first line, we were at last in a position, not to commence business, unfortunately, but to work out patiently and thoroughly the problem of making these lines serviceable. Many of you will remember that at our Providence meeting, two years ago, we discussed the question as to whether there would be any serious "cross-talk" between metallic circuits when we had a large number of them working on the same line of poles. Opinions then varied, but the Philadelphia line showed at once that the interference between metallic circuits was, practically, about as bad as between grounded circuits. We determined not

1. Read before the National Telephone Association, Pittsburgh, Sept. 26, 1887.

Digitized by Google

to offer an imperfect service to the public, and months of hard work resulted in perfecting a simple and practical method of absolutely removing all trouble from this cause. Meantime, the matter of providing suitable apparatus and methods for working metallic circuits quickly and reliably with each other, and with grounded circuits at the terminal stations, was receiving constant attention, and we are now able to do this work satisfactorily, although this part of our service will always be one in which we may expect continued improvement.

As an illustration of the difficulties encountered: The repeating coil, which gave excellent results when used between New York and Philadelphia, was a complete failure when used between New York and New Haven, and a long course of investigation and experiment was necessary before we discovered the cause and provided a remedy. We have completely reversed the old idea that "Anything is good enough for a telephone line;" now I would say "Nothing is good enough." But a friend suggests that, strictly construed, my statement makes the matter worse. At any rate, the best is not too good, and I am confident that the future experience of all of us will convince us, if we still doubt, that the best is emphatically the cheapest in the long run.

The telephone business has now been established long enough to bring us fully into the reconstruction period—the haste of early construction is over, and the problems of underground construction in our larger cities, the general use of cables in all exchanges, the necessity of providing improved switching facilities for the masses of wires which centre in our large offices, and the complicated work of providing quick and certain means of communication between our scattered exchanges, are matters which call for the expenditure of much brain-force and money before the "second construction" gives us a perfected system.

When we look over the history of the development of the telegraph, and see the slow and painful progress made by the pioneers of that enterprise, it may well be a matter of surprise and congratulation that the telephone has so quickly found a profitable place in the business world. To a great extent that place had been prepared by the changes in business methods wrought by the railroad and telegraph. The use of local private telegraph lines (and especially the District Telegraph service) was of especial value to us in preparing the way, by educating people in using electrical appliances for securing quick local communication.

Undoubtedly, the use of the telephone has made far easier the work of introducing the electric light. This process of education is going on at a rapid rate, and the use of private wires between distant cities, which is now so common as to be almost a necessity in certain lines of business, and the extension of our "extra-territorial" telephone lines, is preparing the way for the long-distance telephone.

I am often asked the question, "How can you expect people to use the telephone on your long lines, with rates five or ten times as high as the telegraph charges?" The answer is simply this: The telephone has a field of usefulness entirely separate and distinct from that occupied by the telegraph. Of course no one will pay a dollar for a telephone message, when he can accomplish the same result by sending a telegram for ten cents; neither will he pay ten cents for sending a telegram, when he can accomplish the same result by sending a postal card for one cent. If the long-distance telephone competes with anything, it is with the railroad, and it does that in the same way and about to the same extent as the local telephone competes with livery stables and street cars.

As a matter of fact, the service offered by the telephone is something which is entirely new, and when people learn its uses, its place will be just as securely fixed, as a most important factor in the transaction of business between distant points, as it is now in local service, and the railroads and the telegraph companies will not suffer any more than the livery stables and street cars do now from the telephone exchange. When people ship freight for which they are in no hurry, they send it by a sailing vessel or by rail as ordinary freight; when time is of some importance it goes by steamer, or by a fast freight line; when goods are perishable, or time is important, shippers send by express or by special messenger.

So when in communications time is not important, people write letters; when greater haste is necessary, they send telegrams; but when time presses, and there is urgent need for haste, they telephone. When the nature of the business requires personal communication, question and answer, the railroad or the telephone line must be used, and this is our field; quick communication, with instantaneous replies, and prolonged personal interviews. I might give scores of illustrations, but two will suffice: A New York lawyer recently called up by telephone a lawyer in a city nearly a hundred miles away, engaged him for an important case, dictated a lot of legal papers, and, inside of an hour, was able to file attachments securing for his clients their interest in a large amount of property which would otherwise have been lost. This illustrates one class of service; the other is the case of the Pennsylvania Railroad, which has ample telegraphic facilities between New York and Philadalphia, but, in addition, leases a private telephone circuit, so that the officers of the road can, without the intervention of operators and the delay of writing messages, carry on conversation between the two cities.

The contracts for service which we are daily making, and the emphatic commendation of business men who are using our lines, prove beyond question that the long-distance telephone is wanted, and that good service will be paid for at rates which will make it profitable to supply the demand. It is just as certain that there is no demand for, and no profit in attempting to furnish poor service, either in trunk lines or exchanges. Just what constitutes "poor service" is a question upon which we may not all agree. I think Mr. Jacques defined good commercial service well in a discussion of this question recently, when he said in substance that he considered a good commercial line to be one over which non-experts could converse about subjects with which they were not both familiar, without repetitions. Judged by this standard, how many exchange and toll lines would stand the test?

NEW YORK AND VICINITY.

Subway Matters.—The State Assembly Telephone Investigation Committee.—Abolishment of the Ten Cent Telegrams.—Asbury Park will have no more Wooden Poles.—End of the Electric Light Contest at Elizabeth, N. J.—The Baxter Electric Motor Company to have its new Headquarters in New York.—Mayor Cleveland, of Jersey City, on Corporation Privileges—Joint Meeting of the Institute of Electrical Engineers and the New York Electrical Society at the Exhibition Building.—An Interesting Program for the Season laid out by the Institute of Electrical Engineers.

THOSE gentlemen who labored so arduously to secure the passage of an "underground" law, probably had a very misty idea of the state of affairs it would bring about. Contracts for electric lighting have been awarded by the city authorities, and no conduits have been provided in which to place the necessary wires. Permits are sought to place the wires overhead, and the Board of Electrical Control is divided in itself as to the policy to be pursued. The mayor loses no opportunity to growl about the streets being torn up, and altogether no one appears to be satisfied. The conduits which are being laid down-town are primarily for the accommodation of the telephone wires, and it is believed that their occupation will lead to much needed improvements in the telephone service.

The state assembly telephone investigating committee has been continuing its researches by an examination into the finances of the Bell Telephone Company of Buffalo. Only two complaints were made by citizens, both of which were directed at the toll system. The secretary of the company, Mr. H. C. Palmer, described the process of watering the stock. It was organized in 1879, with a capital of $30,000, which was all subscribed by citizens of Buffalo. During the same year the capital stock was increased ten-fold, $140,000 being paid for in cash, and the remainder distributed *pro rata* among the stockholders. In June 1883, the stock was doubled to $600,000, out of which $210,000 went to the parent company to pay for the franchise, $56,840 retained as treasury stock, and the remainder distributed as a stock dividend to the shareholders. The treasury stock was subsequently sold to provide money for extending the business. The American Bell company now owns only five shares less than half the capital stock of the company. A table was submitted to the committee showing the earnings of the company since 1880, to have been $1,210,487, the expenses during the same time being $919,017. The cost of the Rochester plant was $100,000, and that of Buffalo $200,000, while it was estimated that the proposed underground work would cost about $200,000 more. The committee will meet in New York, November 10.

The abolition of the ten cent rate of telegraphing since the sale of the Baltimore and Ohio company is arousing the usual amount of newspaper indignation. The people who complain, could easily economize in other directions, say by patronizing Bowery lodging houses, and dime restaurants. They might not get any more for their money than they actually pay for, but that is not expected in a strictly legitimate business. Perhaps a slight boom will now be given to uncle Sam's special delivery system, which has languished since the novelty of the scheme has worn off.

The Asbury Park, N. J., commissioners have ordered that no more wooden poles shall be erected along the line of the sea-shore electric railway, and that those already in position shall be removed. The officers of the road appealed in vain to have the resolution rescinded. Owing to the peculiar form of personal government existing in the borough of Asbury Park, the ideas of the commissioners will be carried out, and the wooden poles will have to go.

The electric light war in Elizabeth, N. J., has finally been settled by an amalgamation of the interests of the Schuyler and the newly formed Westinghouse company. By this movement

Digitized by Google

it will be possible for the work to go forward more rapidly, and it is possible that a considerable number of incandescent lamps may be introduced during the coming season.

The Baxter Motor Company, of Baltimore, is about making arrangements for the establishment of their headquarters in this city. The various companies engaged in the motor business appear to be thoroughly satisfied with the outlook, and the very instructive exhibit of its possibilities as practically demonstrated at the electrical exhibition of the American Institute will, no doubt, give it fresh impetus. The exhibit of the Baxter company at the electric light meeting in Boston, was in itself a revelation to many of the people in that city, who then realized for the first time the actual progress which was being made in that line.

Mayor Cleveland, of Jersey City, has sat down with a very forcible veto upon an ordinance passed by the Board of Aldermen granting unusual privileges in the streets to the Jersey City Electric Light Company. In the course of his veto message after calling attention to the "enormous and unrestrained power" which they propose to grant the company, he goes on to show how the city is already corporation-ridden, in the following language:

> The corporations have been ingenious in seizing upon pretty much everything tangible within the city limits. They have taken rights and privileges from citizens without even the form of law. They have taken whole streets to the extent of more than a million dollars of value within my recollection without a dollar of compensation. They have spread their dust and cinders upon our roofs and set fire to our buildings. They shriek through the towns nights till they destroy all comfort of persons and reduce the value of property, but it would seem to me that they might leave us the shade trees that are none too plenty now. They are the pride of the well-to-do and the comfort of the poor, and I am sure your honorable body did not intend to grant the right to destroy them.

He closes his message by saying:

> A simple and fair and honest ordinance could easily be prepared, giving this company all it needs for its own purposes, embodying the suggestions above made, and one that no fair mind could fail to approve. But the present ordinance is not honest. It is unique. It is the most ingenious piece of crazy patchwork of surprises I have ever seen in so few words, and I do not see how any member of your honorable body can vote for it after attention has been called to its powers and omissions.

The mayor did not forget to intersperse the stereotyped remarks regarding overhead wires, and the probability of their being placed underground in all large cities at an early day.

A joint meeting of the American Institute of Electrical Engineers and the New York Electrical Society, is to be held in the manager's room at the Exhibition building of the American Institute, on November 9th. A paper will be read by Mr. Charles Cuttriss, electrician of the Commercial Cable Company, upon the subject of "Recent Improvements in Apparatus for Ocean Telegraphy." This is a branch of electrical work which has been very imperfectly understood by a large portion of our American electricians, and as this paper is to be accompanied by an exhibition of the siphon recorder, the proceedings will be exceedingly instructive. The officers of the Institute intend to make the present season a most interesting one, by bringing forward most important topics for discussion and publishing them fully and promptly for the benefit of the members in all parts of the world.

New York, Oct. 24th, 1887.

PHILADELPHIA.

How the Westinghouse-Thomson-Houston Combination is regarded in Philadelphia.—The Morse Underground Co.—The Mitkiewicz Chinese Syndicate.—Recognition of Superintendent Wm. B. Gill's Services at the celebration of September 15th.—Restraining orders against Infringers obtained by the American Bell Telephone Co.—Cape May, N. J., to have an Electric Railway.

THE announcement of the combination of the Westinghouse and the Thomson-Houston Electric Light companies, has undoubtedly caused something of a flurry in electric light circles. It is believed that other combinations will follow, and that the most important developments are yet to come. The Electrical Trust, through which the majority of the stock of all the electric lighting companies which have franchises in Philadelphia, except one, is controlled, does not itself operate the corporations, and none of them have lost their separate existence or corporate individuality. The trustees hold, under certain conditions, a majority of the stock of each company (except the Keystone), which they have the power to use under the provisions of the trust. In fact, the trust is a pool under another name, with such legal protection to those who are in the deal as the trusteeship can give them. The trust does not protect any of the combinations which are not protected already by the patent recently granted to Mr. Edison for the multiple arc system of distribution. It is a combination simply of the local companies; and if Mr. Edison's parent company should bring a suit against the Maxim company, for instance, which is represented in the trust, and if the courts should sustain the patent and decide that the system of distribution used by the Maxim or United States Electric Light Co. is an infringement of the Edison patent this corporation would be compelled to do one of three things—compromise with Edison, find a new system of distribution, or go out of business. A thoroughly well-informed electrician of this city says of the combination between the Westinghouse and the Thomson-Houston companies: "In addition to the better position in which it places the Westinghouse company in any fight over the use of the multiple arc system of distribution, the two companies can work much better in combination than as separate organizations for this reason—they can supply power from a common centre to the arc lights and to incandescent lamps, thus cheapening the cost. It is possible, of course in Philadelphia under the Electrical Trust, that some arrangement can be made which will enable the companies here, incandescent and arc, to accomplish the same thing, by a harmonious working together of all the interests in the trust." Capitalists interested in the electric lighting business are anxious to know how and when Mr. Edison will attempt to enforce the patent granted to him, and the present situation is likely to stimulate electricians to invent a new system of distribution which can be adopted in case Edison's suits shall be successful. In any event it looks as though there is to be a good deal of tedious litigation before the matter shall have been disposed of.

At a meeting of the Electrical Committee of Councils, held a few days ago, an ordinance granting permission to the Morse Underground Co. to lay its conduits along Delaware avenue from Walnut to Arch streets, was taken up for consideration. It was explained that the company desired the privilege for the purpose of making a test of the system. It was contended that the company had received similar privileges from councils before but had never taken advantage of them. Mr. A. Ellwood Jones stated that he understood the company was in the hands of speculators. He was not opposed to the company if it was legitimate, but if it was run for speculators the committee should know it. President Mershon, of the company, said that much that had been said by Mr. Jones was true in the past, but things have changed. "The company is in different hands since. I was opposed to the methods of the directors, but I was only one amongst 12, and my counsel was not listened to. I have not sold a share of stock, and as I am interested in my patents, I am anxious to see them succeed, and will be personally responsible." He explained in answer to inquiries from the members of the committee that the capital of the company was $2,500,000. After some further discussion the matter was referred to a subcommittee of five.

The doubts which have recently been thrown upon the permanency of the telephone, telegraph, railroad and other concessions made by the Chinese government to an American syndicate, represented by Barker & Bro's. of this city, have apparently been strengthened by the receipt of the following despatch from London, through the Associated Press:

> The *Standard's* Shanghai correspondent gives further particulars regarding the American banking syndicate. Mitkiewicz, while trying to obtain the concession, used the name of Mr. Vanderbilt, which was mentioned in the agreement signed by Li Hung Chang. Mr. Vanderbilt was warned, but not in time to prevent the use of his name. Then Mitkiewicz mentioned the names of Messrs. Gould and Mackay. On Mr. Gould's son denying his father's connection with the syndicate, Mitkiewicz engaged the Barker Bros., of London, who, after consulting a large banking firm of London, pronounced the scheme untenable. It transpires, moreover, that whatever railways and other works should be undertaken with money raised in America were to be mortgaged to the syndicate.

This was shown to Mr. Wharton Barker, and after reflection, Mr. Barker said: "This is pure fabrication. I have it directly from the Chinese envoy, who was present at all of the conferences with the Viceroy, that the name of no firm was mentioned except that of our own, and that the whole story as telegraphed from London is false." Mr. Barker added: "All of the details have been arranged, and I propose to go to China in two months. These stories are absurd. I have assurance, from the Chinese minister that our concessions are all right, and we have no difficulty."

The following letter explains itself:—

Philadelphia, Sept. 28th, 1887.

To Wm. B. Gill, Esq., Superintendent Western Union Telegraph Co.

My Dear Sir: Before closing the work assigned me in connection with the civic and industrial demonstration of the 15th inst., I avail myself of the opportunity to return to you, and through you to the company you represent, an expression of my high appreciation of your generous and cordial support in connection with the work committed to me.

The public spirit that granted the free use of your wires and, in addition, the services of 16 operators, with messengers, along the improvised line of telegraph erected along Broad street, is worthy commendation of the public, as it certainly has received the appreciation of all those who understood the generous action that gave these facilities without any cost to the commission.

I beg leave to convey to your company, on behalf of the commission as well as on my own behalf, an expression of my cordial appreciation of the liberal and hearty support given to the branch of the work assigned me. If anything could add to the liberality of your action, it was the kindly spirit in which it was tendered. I am very truly yours,

A. LOUDON SNOWDEN,
Chairman Committee and Marshal Civic and Industrial Display.

Counsel for the Bell Telephone company obtained a restraining order on the third of the present month from Judges McKennan and Butler, prohibiting the Electrical Supply and Telephone Co. of this city, from selling the "Long telephone," which is said to be an infringement of the Bell patents, until the question can be

Digitized by Google

heard on a motion for a preliminary injunction. Similar action has been brought in the courts of West Virginia, Maryland, Texas and New Jersey,

The city council of Cape May, N. J., has passed an ordinance to its second reading authorizing an electric railway company to lay its tracks on certain streets and avenues. The new road will connect the Gentleman's Driving Park with Ocean Pier.

PHILADELPHIA, Oct. 19th, 1887.

BOSTON.

The Gamewell Police-Signal Boxes.—Privilege to run Electric Cars granted to the Cambridge Railroad Co.—The new Electric Car of the West End Street Railway Co successfully tried.—Electric Lighting Notes.—The Consolidated Electric Light Co. of Portland, Me.—Output of The American Bell Telephone Co.—The Erie Telephone Co.'s reports.—House Warming of the Boston Electric Club in its new rooms.

THE Gamewell police signal system, referred to last month, has excited considerable attention from the public in more ways than one. An opinion has gained some credence, to the effect that the small octagonal structures were for the purpose of confining an intractable prisoner within, pending the arrival of the police wagon. The committee of the board of aldermen on electric wires have received many complaints on account of the location of the Gamewell police-signal boxes in various sections of the city, and will soon give a hearing to the complainants and to the police commissioners on this subject. An impression prevails, that the boxes occupy too much space on the sidewalks, and that they are unsightly. The agent of the company says they are in use in nearly 30 of the largest cities in the country, over 500 being in use in Chicago; in Pittsburg the citizens are making requests to the authorities to place the sentry boxes on their sidewalks. The boxes now being erected in Boston are similar to those in use in Brooklyn, Chicago, Cincinnati, and other places. The system, it is expected, will be in working order in about a month, and not until that time can the citizens of Boston have practical proof of their efficiency.

At a meeting of the board of aldermen on the 27th ult., Mr. Prentiss Cummings, president of the Cambridge Railroad Co., presented a petition for leave to run one or more cars between Cambridge and Boston by means of electricity and storage batteries; stating that it appears that such motive power can be used successfully to operate its road, and that leave so to do had been granted by the city of Cambridge.

The following order was passed:

Ordered, That the Cambridge Railroad Co. be authorized, until otherwise ordered by this board, to use electricity in propelling one or more of its cars within the limits of the city of Boston, provided that such use shall be by means of storage batteries. Considerable interest is felt in the new electric car which has been on trial on the Fourth and Madison avenue tracks in New York recently, and intended for use in Boston. On its sides are the words "West End Street Railway Co." It is of the ordinary size, neatly finished, and only differing from our street cars in its higher elevation from the street. It is furnished with Sprague motors, and the Julien storage batteries, placed under the seats. It is fitted with a centre four-light electric chandelier, besides the customary end lights. There is an electric signal bell for the conductor's use in stopping and starting, an electric alarm bell to take the place of the bells ordinarily used on the horses to give notice of the car's approach. Mr. H. M. Whitney, the president of the West End Street Railway Co., was present, and witnessed the trials in New York, and ordered the car to be sent to Boston, being satisfied that improvements which are sure to be suggested will sooner be perfected by practical tests on our streets than by short experimental trials. The car has run as high as 10 miles an hour, and is capable of being run 40 miles with one changing of its storage cells. The car arrived Oct. 4th; and very successful trial trips have been made.

It may interest electric light people to know how the case of Matthew Burns *vs.* Newton Electric Light & Power Co., a bill in equity to restrain a nuisance, mentioned in last month's letter came out. The judge visited the premises to find out the extent of the noise and other disturbance complained of, and in his decision stated that he thought as matter of law an injunction might be granted, but from the circumstances and nature of the defendant's business, he did not deem it advisable. The noise and tremor, he stated, were of too slight a nature to be the subject of restraint, but the exhaust pipe, as it existed at the time of the bringing of the bill, was clearly a nuisance. As the defendants had, however, changed its position, and it had ceased to disturb the plaintiff, he did not think it necessary, formally, to issue an injunction against it. The bill was dismissed without prejudice, and plaintiff's costs were taxed to the defendant.

Lewiston, Maine, is to have its streets lighted by electricity instead of gas. At the meeting of the board of aldermen and common council on the 29th ult., bids from 10 different electric light companies were considered, and resulted in the contract being awarded to the American Electric Manufacturing Co. of New York. Great care has been exercised by Mayor McGillicuddy and the committee in investigating the merits of the various systems, which resulted in the choice of the American, as being in every way satisfactory. Mr. Samuel Elder, the agent of the American company, was present, and closed the contract. One hundred arc lights of 2,000 c. p. each are to be placed on the streets immediately. It is thought this number will be doubled within the coming year.

The Ware Electric Light Co. has filed papers for incorporation in the office of the secretary of state. The president is H. C. Davis, and the treasurer H. M. Clark. Capital $15,000.

The annual meeting of the stockholders in the Consolidated Electric Light Co. of Portland, Me., was held at the company's office in that city Sept. 21st. The annual report shows the business to be in a flourishing condition with a growth that must be gratifying to the stockholders. The company's property is located in the heart of the city, and including the new block just completed, covers about 16,000 square feet of land. The arc light apparatus was put in by the American company, who own a controlling interest in the plant, and the incandescent apparatus is from the Edison company. The company light the entire city of Portland, and it is claimed that it is the best lighted city in America. It is understood that its capacity for arc and incandescent lights is soon to be largely increased and extended. Up to the present time the American company of New York has been pretty much the sole owners, but there are indications that a combination has been formed between the American company and what is known as the New Haven syndicate. This syndicate is composed of bankers and capitalists of New Haven, Conn., who it is said have capital invested in electric lighting plants in different parts of the country, amounting to several millions of dollars. Its operations, so far as we can learn, in New England cover the electric lighting business in Boston, New Haven, Springfield, Bridgeport, Newport and Waterbury, besides several smaller cities. The syndicate is under the management of Messrs. F. A. Gilbert, president of the Boston Consolidated company; James English, treasurer of the New Haven, Bridgeport and Newport companies, and H. P. Frost, general manager of the Southern New England Telephone Co. These gentlemen were elected on the board of directors of the Consolidated company. If this means combination with the American company it will help to strengthen the general business of electric lighting wonderfully, from the fact that the American company are about to move their entire factories to New Haven and double their facilities. It looks as though a combination had been made upon a large scale. The board of directors elected to-day is as follows: Weston F. Milliken, William R. Wood, Frank J. Robbins, Chas. R. Milliken, Frank A. Sawyer, Portland; F. A. Gilbert, James English, H. P. Frost, New Haven, Conn.; Silas Gurney, Boston; E. H. Goff, New York.

The gas commissioners have issued an order authorizing the Brookline Gaslight Co. to furnish electricity for lighting purposes and power in Brighton wherever the company has authority to furnish gas, and in Brookline, and also in so much of Boston as was formerly in the town of Brookline. It requires that the company shall construct and equip within six months from date, a plant with a minimum capacity of 180 arc lamps of nominally 1,200 c. p.; 100 arc lamps of nominally 2,000 c. p., and 300 incandescent lamps of nominally 16 c. p.

One by one, as the leaves fall, the early telephone promoters disappear from the telephone arena, and merge themselves with common clay. The last one of the much advertised Lowell syndicate to assume a new *role*, is Mr. Charles J. Glidden, who has resigned the treasurership of the Erie Telephone Co., and will become a member of the banking and brokerage house of Cordley, Young & Fuller.

The output of telephones by the American Bell company for the month ended Sept. 20th, and the fiscal year to date, is given as follows:

September—	1887.	1886.	Increase.
Gross output	4,110	3,800	310
Instruments returned	2,152	1,261	*891
Net output	1,958	2,539	581
Dec. 21 to Sep. 20—			
Gross output	40,651	31,761	8,890
Instruments returned	19,815	14,668	*5,147
Net output	20,836	17,093	2,743

* Decrease.

The Erie Telephone Co. reports earnings for August and the first five months of the current fiscal year as follows:

August—	1887.	1886.	Increase.
Gross earnings	$52,135.72	$43,937.29	$8,199.43
Gross expenses	35,142.79	28,841.70	6,301.09
Net earnings	$16,993.93	$15,095.59	$1,898.34
Construction	5,029.74	3,179.85	1,849.89
Surplus	$11,964.19	$11,915.74	$48.45
April 1 to August 31—			
Gross earnings	$248,127.31	$218,278.07	$29,849.24
Gross expenses	166,663.15	145,232.61	21,373.54
Net earnings	$81,521.16	$73,045.46	$8,475.70
Construction	17,157.16	11,070.39	6,086.77
Surplus	$64,364.00	$61,975.07	$2,388.93
Number of subscribers.			
Added in August	87	96	*9
Added five months	372	223	149
Connected Sept. 1	10,094	9,147	947

* Decrease.

The assessment of railroad, telegraph and telephone lines of the state for 1887 has been completed by the New Hampshire board of equalization. It was determined that the taxable property of the state for the present year has been reduced for taxation 15 per cent. less than its actual value, and the valuation of railroads, telegraphs and telephones was reduced in like proportion, deducting the amounts taxed and paid to towns. The amount thus obtained is assessed at an average of other property throughout the state, to wit, $1.38 upon each $100 of valuation.

The house warming of the Boston Electric Club, held on the evening of the 5th inst, at the spacious rooms of that body, No. 66 Boylston street, proved a highly enjoyable as well as a noteworthy occasion. It drew together about 200 members and their friends, and while celebrating the formal opening of the club with a night of pleasant intercourse and social relaxation, illustrated the remarkable vitality of a society which, though only formed in June of the present year, has already the prestige of growing numbers and assured success. The house committee of the club had scattered their invitations far and wide, and such was the response given that at 8 o'clock the rooms were thronged with guests. When the guests had all gathered in the reception room, President Ridlon took the chair for the transaction of preliminary business. Having first extended a hearty welcome to those present, he introduced Mr. P. H. Alexander as toastmaster for the evening, and then called upon the secretary. Mr. Allan V. Garratt announced that it was his unpleasant duty to communicate the resignation of Mr. W. J. Hammer, one of the vice-presidents. The secretary read a letter from Mr. Hammer, who explained that he was about to remove from Boston, regretted the step he was forced to take, and expressed his confidence in the future prosperity of the club. A committee of three, with Col. C. M. Ransom as its chairman, subsequently brought in a resolution on the subject. They accepted the resignation with regret, and, in doing so, expressed the high admiration felt by the members of the club for Mr. Hammer as a gentleman and as an authority on electric matters. The resolution gave expression to these feelings, and was adopted by acclamation. Supper was served about half-past nine o'clock, and then Mr. P. H. Alexander, chairman of the house committee, called the company to order and speeches were made by several members and guests, as follows: "The Boston Electric Club," Colonel C. S. Ransom; "The New York Electric Club," Mr. Callender; "The National Electric Light Association," Frank Ridlon; "The Boston Press Club," Irving S. Meredith; "The Electric Telegraph," Mr. Suel Smith: "The Telephone," A. H. Chapman; "The Electric Light," Professor Thomson; "The Electric Motor," W. J. Hammer and Lieutenant Green; "Storage Batteries," Morgan Brooks. An amusing incident occurred early in the evening. The electric light suddenly went out and for a while one kerosene lamp furnished all the light there was. But with such a host of experts it did not take long to remedy the difficulty.

CHICAGO.

Difficulties in the Gas Trust.—Prof. Barrett's Estimates on Lighting the Business Portion of the City by Electricity.—A New Move of the City Council to Mulct the Telephone Company.—Sentence of the Central Union Telephone Company's Book-keeper for Forgery.—The Chicago Electric Club Installed in its New Rooms; Its Current Proceedings.—Mr. W. J. Armstrong leaves the Chicago Office of the Western Electric Company and becomes the Representative of the "Western Electrician" in New York.—Resignation of Mr. W. A. Leary, general manager Iowa Union Telephone Company.—Marriage of Mr. J. J. S. Wilson, Jr.—The Contract for Electric Light Plant for the Union Depot awarded to the Thomson-Houston Company; the Yard Contract not yet awarded.—The Western Electric Company's Electric Light Business.—A Telephone Employe Killed by an Electric Light Current at New Orleans.—The Bell Telephone Company of Missouri; Mr. Durant advocates the use of Col. Flads' Tower System of Overhead Wires in St. Louis.—Electric Lighting in St. Louis.—The American Bell Telephone Company prosecuting Western Infringers.—Pan-Electric attacked in Little Rock, the Home of Attorney-General Garland.—The Texas Promoters of a Rival Telephone Company in Chicago go Home.

OF most interest in municipal affairs is the attack led by alderman Manierre on the gas trust. The franchise under which the Consumers' Gas Co. has been operating has been revoked because it is claimed the conditions under which the franchise was granted have been violated.

These conditions were that the company should not sell its plant to, or combine in any way with any other company. As is well known the gas trust includes the Consumers' company, and besides this three other gas companies which have separate franchises in Chicago, and as two of these franchises are in the shape of special charter from the state legislature, over which the city council of Chicago will hardly claim jurisdiction, there seems to be strength in the position of the gas trust. The agitation over this question, and the advance in the price of gas from $1.00 to $1.25 per thousand feet, leads inevitably to the discussion of the advantages of public lighting by electricity.

Prof. Barrett is ready with figures which convince those who give the matter attention, that it is only a question of time when gas will be displaced by electricity as a means of lighting our streets.

For the territory bounded by the river, the lake and 12th street, which comprises the principal business portion of the city, a careful estimate shows that the entire plant, including engines, boilers, electric light apparatus and underground circuits would cost not much more than $100,000. The cost of operating would be about $12,000 annually, and as the expense of lighting this district with gas is now $28,000 per year, there is a saving of $16,000 per year as interest on the investment, and a vastly superior illumination.

The city council recently passed an ordinance which provides that the Department of Public Works be instructed not to grant the Chicago Telephone Co. any permits for tearing up the streets to lay cables without first producing a receipt signed by the city collector for the payment of $10 for every telephone in use.

It will be remembered that an ordinance taxing the telephone company $25 per year, on every telephone, was authoritatively declared illegal and invalid only a few weeks ago. That the city council has not given up the hope of being able to mulct the telephone company is shown by this latest move. The new ordinance has not yet received the approval of the mayor, but has been referred to the City Law Department.

Wittman, the book-keeper of the Central Union Telephone Company, who stole $18,000 by means of forged checks, has received a sentence of four years in the penitentiary. It is probable that his sentence would have been more severe had he not made a full confession and assisted the officers of the company in ascertaining the extent of his stealings. It is said that his work was so cleverly executed that it is doubtful whether he could have been convicted had he not confessed. The telephone company recovers from the bank more than one-third of the amount stolen.

The Chicago Electric Club has taken possession of its new quarters The rooms are commodious, and for the tasteful manner in which they are furnished much credit is due to the committee which has had the matter in charge, Messrs. Buckley, Shaw and W. A. Stiles. At the last meeting of the club, which occurred on the evening of October 17th, Mr. E. P. Warner read a paper on "Automatic Current Regulation." At the next meeting Mr. Sunny will read a paper on the relations of electric light and telephone circuits.

Mr. W. J. Armstrong has accepted the position of eastern representative of the *Western Electrician*, and has severed his connection with the Western Electric Company with which he has been identified for nearly eight years.

Mr. W. A. Leary, who has been engaged in telephone business for the last six years as general manager of the Iowa Union Telephone Co., has resigned. Mr. A. F. Cutter, the secretary of the company, takes up the duties dropped by Mr. Leary.

Mr. J. J. S. Wilson, Jr., the auditor of the Central Union Telephone Co., was married recently in Bloomington, Ills., to the daughter of Dr. J. L. White, of that city.

The contract for the electric light plant for the Union Depot has been awarded to the Thomson-Houston Electric Co. The contract for the plant for yard lighting has not yet been awarded.

The Western Electric Co. has secured a contract for a 60-arc light plant for Independence, Mo., and one for a 30-arc light plant for Keyport, N. J. This company is also doing a good business in furnishing dynamos and lamps for plants already in operation, having orders on hand now for more than 200 lamps with the necessary dynamo capacity for this purpose.

The death of Henry Boscher, an employé of the Great Southern Telephone and Telegraph Co. in New Orleans, is announced as having been caused by the current from a Westinghouse alternating dynamo.

Mr. Geo. F. Durant, says the Bell Telephone Co., of Mo., has had a prosperous year. The number of subscribers in the St. Louis exchange has increased this year nearly 500. Mr. Durant is still advocating the Flad system with good prospects of having at least a part of the city provided at an early day with this ingenious and carefully planned arrangement for suspending wires and cables. One would think that St. Louis, with five electric lighting companies competing for business, would have plenty of light at low prices. But lights are no cheaper there than they are in Chicago, where the business is all in the hands of one company, and where the circuits have to be run underground: and the St. Louis city authorities have not made as much headway as those of Chicago toward introducing electric light for street lighting.

A restraining order was issued by Judge Thayer, of the United States District Court at St. Louis, directed against Messrs. Rose and Rein, "The Franklin Electrical Works," who have been doing

Digitized by Google

quite an extensive business with their small factory in the manufacture of infringing telephones.

At Little Rock, Ark., suit has been brought by the Bell company against the Southern Telephone company, users of the Pan-Electric telephone. This suit will be watched with interest, because it is brought in the state which is the home of Attorney-General Garland, and because it is based on the Edison patents.

The gentlemen who spent some months in Chicago trying to organize a company to rival the American Bell Telephone Co., have gone back to Houston, Texas.

CHICAGO, Oct. 22d, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, *115 Nassau Street, New York city.*

THE REIS TELEPHONE.

[78.]—I have read with much interest in your issues of July and October, the open letters between Dr. Stein, of Frankfort, a. M., and Prof. E. J. Houston, of Philadelphia, concerning the telephone controversy; and, if you will allow space in your valuable paper, will show, I think, that each is in a measure right and also wrong, in the stand he has taken, with the preponderance of right on the part of Dr. Stein.

The controversy is based upon the question—"Can the original Reis telephone transmit intelligible articulate speech?" Dr. Stein implies that it cannot, and that the art of transmitting speech became known only through the discovery of the undulatory or wave theory; that after having been advised of the true method, it is an easy matter for one to so adjust or use the Reis transmitting apparatus with a Bell receiver as to practice the undulatory method.

No one, so far as I am aware, has ever been able to transmit intelligible speech between two distant points with the Reis apparatus as a whole; at least we have no such conclusive proofs of such performance as would be accepted in a court of equity in this country.

If the apparatus taken as we find it, or as Reis left it, with his instructions for using it, is not capable of practicing Prof. Bell's method, then, in the language of our patent law, which must govern here, Reis is not the first inventor of the method, nor any part of such method, nor can his apparatus stand against Prof. Bell's claim.

The trouble with Prof. Houston's argument lies in his assuming a part of that which takes place in the transmission of speech to be the whole, viz.: he assumes that if the transmitting apparatus as Reis made it can be used with any improved receiving apparatus which will repeat the speech to the hearer, then Reis must have been the inventor of the art of transmitting articulate speech electrically.

The method so practiced falls short of all that actually takes place between the speaker and the hearer, in that it only sets up electrical waves or impulses, similar to the sound waves, and it ends there. But, it may be said, that is all that the famous Bell method in the 5th claim of U. S. Patent No. 174,465 covers.

I admit that this is true, and just here permit me to disclose a line of defense against this claim, which none of the learned lawyers seem to have noticed in the many cases heretofore tried, viz: that the claim is not to a method, but to a single step in a method, which is only complete when the whole series of steps or acts have been followed.

A correct and complete method claim would, in my opinion, be substantially as follows:

"The method of transmitting vocal and other sounds telephonically, which consists in creating electrical waves similar in form to the sound waves accompanying such vocal and other sounds, and then converting such electrical waves into secondary sound waves, identical in form with the primary sound waves, substantially as described."

The courts in this country have defined a patentable method to consist in a step or series of steps, an act or series of acts to be performed, whereby the result sought is attained. They have also held that a combination of elements to be patentable must co-act as a whole to perform a single or unitary result. A claim to a method is under our law, a claim to an art or improvement in an art of doing something and it is as essential to the clearness and the completeness of such a claim that all of the steps or acts be enumerated, as it is that all of the parts of a mechanism which go to make a combination claim should be named; see the decision of Hoffman *vs.* Young, 18 Official Gazette U. S. Patent Office.

I am willing to concede that the Reis transmitting apparatus may be, and doubtless has been, used to produce the first step of the method embraced in the claim which I have drawn above. So far then Prof. Houston is correct. But that it was so intended to be used is not apparent, in fact the weight of proof is to the contrary.

Under our law, it matters not that an old device can be put to a new use, after some one else has disclosed such new use in the nature of a new art which was unknown to the prior inventor. Such an apparatus cannot stand in the way of a meritorious inventor who opens up a new field, and in this our law has been shown to be abundantly wise.

I am satisfied from experiments which I have made, that Dr. Stein is wrong in asserting that speech cannot be transmitted by current impulses, in fact, the use of the Reis transmitter with hard metallic contacts, is in my opinion, a proof of his error. Do not understand me, however, as disapproving Prof. Bell's undulatory theory, for I am convinced he is correct in that view, but wrong in his impression that it is impossible to transmit speech by current impulses.

In a future article I will take this problem up, and discuss it with diagrams showing the conclusions I have reached.

C. J. KINTER,
Late Principal Examiner of the Class of Electricity, U. S. Patent Office

DISTRIBUTION BY TRANSFORMERS.

[79.]—While the subject of the invention of the system of distribution by transformers is under discussion, and while there appears to be a good many claimants for the honors due to those who have really made substantial advances in the art, I may be allowed to give here a few of the leading dates of what appears to me to be the most important advances made:

1835.—Faraday invented the induction coil open and closed magnetic circuit.

1856.—Cromwell Fleetwood Varley perfected the closed magnetic circuit transformer, making the iron enclose the conductors, and thoroughly laminating the iron, patent No. 3,059.

1857.—C. W. Harrison proposed to use induction coils; in a patent granted to him he proposes to use a primary circuit to supply the coils, and to work lamps from the secondary circuit.

1877.—M. P. Jablochkoff patented the use of induction coils, in a primary circuit containing the coils in series order, and working lamps from the secondary circuit.

1883.—Mr. Rankin Kennedy, of Glasgow, in the *Electrical Review* of London, pointed out the cause of the failures with coils in series order, and stated that, if placed in parallel order, they become self-regulating.

1885.—Messrs. Zipernowski & Deri patented the use of coils in parallel order.

These dates have been mentioned by Kennedy in his pamphlet, and others, as the leading ones, and, if correct, would seem to support his view that no "master patent" exists on the subject.

Yours truly,
ROBERT MITCHELL,
115 South Woodside Road,
GLASGOW, October 6, 1887. Kelvinbridge.

THE GUTMANN TRANSFORMERS—A CORRECTION.

[80.]—I find on reading my article on "Subdivided Transformers" in your October number, that it contains a printer's error. On page 414, instead of "Figs. 5 and 5*a*, top views of some spirals or layers," and "Fig. 5*b*, a side view of the two last spirals," read "Figs. 5 and 5*b*, top views of some spirals or layers," and "Fig. 5*a*, a side view of the two last spirals." Also, instead of "Fig. 5*a* shows a new form of an iron core," etc., etc., read "Fig. 5*b* shows a new form of an iron core," etc., etc.

Kindly insert this correction in your next issue, and oblige

Yours faithfully,
NEW YORK, October 11, 1887. L. GUTMANN.

PACIFIC COAST TELEGRAPH NOTES.

[81.]—Matters telegraphic are decidedly on the boom in San Francisco, and preparations are being made on every hand for the increased business that is looked for, and improved facilities required for the traffic that is now crowding every wire.

Colonel Clowry, with his staff, Messrs. Bristol and Summers, are "doing" the coast in their special car, and laying out the programme for additional wires. The operating force in the Western Union office now numbers about 45 persons, and it is rumored that John McRobie, of Chicago, will shortly appear on the scene as manager of the San Francisco office.

The Postal company are said to be doing a good business to all points covered by their lines, but have left the cream of the territory on the west coast (Southern California) to the old company, notwithstanding the inducements that this field offers to an opposition company.

Mr. B. S. Robeson, who came to California a few months ago

Digitized by Google

for the purpose of getting the Postal under headway, has fulfilled his mission, and will soon return to Chicago. He made many warm friends while here, and his energetic management won the admiration of all with whom he came in contact. It was something new here to have a "live" man in the field, and the Postal has a reputation for good service that is very flattering to his administration. He carries with him as a memento of his sojourn a handsome watch presented by the employés of the Postal company. Mr. Robeson's successor is Mr. M. C. Laven, who has been manager of the Postal office here since the opening of the line.

Mr. E. A. Beardslee has resigned from the management of the Postal office at Sacramento, to take charge of the Western Union office at Los Angeles, vice Mr. R. R. Haines, resigned. It will be gratifying to the many friends of "Commodore" Haines to know that the real estate boom struck him, and that the telegraph service will know him no more.

I. N. SULATOR.

San Francisco, Oct. 1st., 1887.

ELECTRICAL NEWS AND NOTES.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

MEETING OF OCT. 11, 1887.

THE meeting was called to order at 8 P.M. in the rooms of the American Society of Civil Engineers, 127 E. 23d street, New York, by the president of the institute, Mr. T. Commerford Martin, who introduced Prof. George Forbes, of London, in the following remarks:

The President: I need hardly say, gentlemen, that we all of us have great pleasure in welcoming here this evening so distinguished a scientist and so well known an electrician as Prof. Forbes of England. Some of us have already had the pleasure of listening to Prof. Forbes in this country, and remember the occasion of his visit here in 1884 at the time of the National Conference of Electricians and the International Electrical Exhibition in Philadelphia. Prof. Forbes is also known to us through his work in England, and as the author of a number of highly ingenious inventions, and I think by the close of the evening you will all agree with me that none of his inventions, evinces greater ingenuity or firmer grasp of electrical principles than the apparatus which he brings before us this evening. This instrument is one for which there has been a decided want, and it brings before us questions of the utmost importance and pre-eminence at the present time. I have no doubt that both the paper and the discussion upon which we shall enter this evening will do much to start us far along a new road of original investigation. Nothing for me remains, therefore, but to introduce to you Prof. Forbes, who will now read to you his paper on the Coulomb meter.

(Prof. Forbes then read his paper, see p 428.) Upon concluding the reading of the paper, Prof. Forbes proceeded to exhibit the operation of the meter before the meeting, and made further descriptive and illustrative remarks, as follows :—

I would like to show you one or two points about the instrument. In this instrument there is one part which I have not described to you. Perhaps before I describe it I ought to let you see it working. I will put on some battery current, and we will just make it go round and see what happens (turning on the current). I am starting it with a current of 11 amperes.

A Member—When you cut off the current how soon does the meter stop?

Prof. Forbes—It takes a little time to get up its full speed and a little time to lose its full speed. I have shown this lighter form of wheel work and I am making it even lighter than this in the instrument which is being manufactured now. This instrument has a good deal of metal work—much more than in any of the instruments which I have been using before, and the mass of metal absorbs so much heat that it goes on for a considerable time after the current is broken. Now this might suit the suppliers of electricity very well, but it would not, of course, suit the consumers, and one must defer to both sides. I do not want the meter to act in that way and I find that by reducing the metal work as much as possible that difficulty is taken away. There is another point about this instrument which I have not shown you or spoken to you about. It is an arrangement which is attached to it for lifting up the mica vanes (the mill-wheel) against a fixed stop above. I have moved the stop away, you see, at present. That lifts the mill-wheel up against the stop and enables us to carry the meter about with safety.

I must make one reservation; there is fear of danger if it passes through the New York Custom House. (Laughter.)

I brought in a lot of instruments, and after I saw a little of what the Custom House people were doing it sickened my heart so much that I let them lock the instruments up and put them in the public stores. I had worked six hours that morning like a slave doing their bidding; and by the time they came to my parcels I am sorry to say that many of the things were in a sad state. You will notice something hanging to that (exhibiting some ruins); that was an extremely delicate spiral spring which was attached to one of these mill-wheels, acting simply as an ampere metre, not acting for registering the consumption, but measuring the rate at which the current is passing through the conductor. That instrument is quite disabled and others too.

I have also some diagrams here. Here are actual examples of some of the readings of these ampere metres, and I have sometimes taken them under different conditions. I have, for example, got results from the instrument with the clock work in, and without the clock work, showing the amount of friction; and I may tell you this, that it looks as if the wheel work there would cause a considerable amount of friction which has to be got over. That friction is a mere nothing compared with the friction of the air which is circulating in these convection currents which are created. There are three frictions coming in—first, there is the air friction in the currents of air, which is the chief source of friction; secondly, there is the friction of the jeweled cup on the point, and lastly, there is the friction of the wheel work which is far less than the friction of the jeweled cup upon the point. That is what one of these diagrams shows (exhibiting a series of diagrams with curves of the ratio of speed to current varying but little in tests of the instrument in different states). Another one happens to show the effect when the apparatus for fixing the mill-wheel is taken out. Another one may be of some interest to you. It was from this instrument when it was an experimental instrument, I varied the distance of the vanes from the conductors, and I used it at $\frac{1}{16}$, $\frac{3}{16}$, $\frac{5}{16}$ and $\frac{7}{16}$th of an inch. You might expect that the nearer it was to the conductor the greater the velocity would be with a given current. That is not so. It then creates friction by pulling the air from the surface of the wire when it is too near. $\frac{3}{16}$th of an inch was found to be the most suitable distance.

There is a peculiarity of this instrument which I believe no other metre possesses, and that is I have not only my own tests of it, but I have got some independent tests. I have never been able to get any independent tests of any metre in the world; but I left word before leaving England a fortnight ago, to have one of these metres finished and sent to Sir William Thomson, who was kind enough to say that he would test the instrument. The sister metre to this one was sent. This metre has an adjustment to it—which no manufactured article ought to have and no manufactured metre will have—but this being in the experimental stage it had an adjustment which regulates the depth at which the first wheel works into the principal pinion. Now it appears that a screw had become loosened in transit when Sir William got it, and it was not found out until after the experiments were made. But the tests are being repeated. I have received the test made under the conditions of that instrument, which I will write down on the board. He applied different currents and he got the ratio of current to speed at these different velocities. He did not try to see what was the feeblest current he could start with. He began with one ampere, and the ratio of current to speed was 66.5; with 1.5 amperes the ratio was 45.5. I will leave out the decimal place if you please. He then used two amperes and the ratio of current to speed was 44. He then used three amperes, and the ratio was 39. He then used five amperes and the ratio was 39. He then used ten amperes and the ratio was 42½. He then used 52 amperes and the ratio was 42. Although I look at that as very bad indeed I think you will agree with me that that gives you a very good result under the defective condition of the instrument. I would have been very well satisfied with that six or eight months ago; but I confess I am not satisfied with it at present, when we are able to get so much more accurate results; however, I thought it would be worth while to give you these results of Sir William Thomson's. After the instrument had been going (it was one of these instruments with a large mass of metal in it) Sir William Thomson found what I have spoken to you about, that putting on the lower currents, after it had been running for a long time with 15 amperes, it was too favorable to the supplier of electricity and not favorable enough to the consumer. After that he put it on to 10 amperes, and he got only 37 as the ratio of speed to current instead of 42½ as it was originally.

I think that is all I have to say about the meter. I have no doubt that in the progress of discussion there may be points of interest raised which may give me an opportunity of saying something more about it, but I think I have really touched upon all the chief points of interest connected with it. (Applause.)

Prof. Forbes then turned a current through the instrument, and a recess of ten minutes was taken to enable those present to examine it. When the session was resumed, the president said:—

As we have now had an opportunity to examine the instrument the discussion will be in order, and the better ventilation the subject has the more profitable will be the evening. We have with us this evening some few gentlemen who are not members of the institute, and I beg to assure them that any question they may desire to ask and any information that they can afford us will be heartily welcomed.

DISCUSSION.

Doctor P. H. Van der Weyde—Is it the intention to have that apparatus under that glass shade while in operation continuously?

Prof. Forbes—At the present moment I intend to use that glass shade although I have no great preference for it. If any one has any objection to it a metal one is just as good, only one would need a glass window to read it by.

Dr. Van der Weyde—The objection would be that when the apparatus is in operation a little while the air will be heated, and the ascensive force would diminish and become very small at last when the air was considerably heated in the glass shade. To correct that nothing would be easier than to make an opening in the top of the glass shade to let the hot air out and keep the surrounding atmosphere more uniform. The apparatus would give an indication of less velocity if the air is made warm than if it is cooler. When the apparatus has been in operation for some time so that the air which surrounds it becomes heated, the indications would become a great deal less. I wish to do justice to Prof. Forbes for the ingenuity of the apparatus, and the remark I make is only for the purpose of suggesting something which may make the apparatus more perfect.

Prof. Forbes—These are very suggestive remarks that come from Dr. Van der Weyde, and, of course, the point occurred to me during the progress of the experiments. There is one lesson that I have learned from this instrument, which is that you cannot calculate on what is going to happen with a convection current. I have been as sure as possible, over and over again, when I was making a minute change in the instrument, that I knew as well as possible what it was going to do—and it never did it. Dr. Van der Weyde suggests that when the air at the top of the shade gets heated the instrument will be slower. The only answer I can give to it is that it does not do so in fact. It goes perfectly continuously however many hours I have it at work. He suggests that a hole should be made at the top to keep it cool. Nothing in the world will ever induce me to let a hole get into that mechanism any more than I would let the works of my watch be exposed to the open air to get dust into them. But it is quite unnecessary, for it goes any number of hours at a perfectly constant rate even when the top gets hot. It is remarkable that the first person who has spoken at this discussion has raised the first objection which every person who has ever spoken to me about it has raised, and that is that its indications will depend upon the external temperature: that when the external temperature is high it will go slower. This is the only one thing, however, in which practice does agree with theory in regard to convection currents. The theory of the thing is perfectly simple. The moving force is the difference of temperature between the conductor and the external air. It does not depend in the least on the absolute temperature of the place; it is only on the heat that is being generated in the conductor, and it is the difference of temperature created there from that of the external air which gives you the moving force. It is a matter of indifference whether you start with a temperature of 30 or 100. As a matter of fact the indications in a warm atmosphere and a cold atmosphere are identical. I may forestall the question that is going to be asked immediately—whether the barometer has any effect. I may say that I have not had the instrument under an air pump to test it, but I have tested it day after day and I have seen no perceptible variation,

Dr. Van der Weyde—No person of any information would talk about a barometer in connection with it; but what becomes of the heat which is continually generated?

Prof. Forbes—It is radiated from the surface of the glass. A great deal collects at the top. A fixed temperature is arrived at, of course, and afterwards the heat which is being created is all radiated from the surface of the glass.

Dr. Van der Weyde—It must be confessed, however, that heat is generated continually. Now if experience proves that that does not affect the instrument, that is all right; that settles the matter: but the suggestion is very natural, because we all know that the ascending force of air depends upon the difference of temperature between the air which is passing under the vanes and the air at the sides, and that the heat accumulated in the top must gradually descend and cause an influence I cannot help believing.

Prof. Forbes—You are able to test it when you are passing a high current through it; you are able to test it by holding the hand on it.

Dr. Van der Weyde—Putting the hand on it is not a good test. We have thermometers which can determine it correctly, and I cannot see why a small hole in the top would do harm. Prof. Forbes said he would as soon expose the works of his watch to the air as to have a hole in the top of that shade. But I would like to be informed what injury a small opening in the top would be, to let out the hot air which must come up from below.

Mr. Frank L. Pope—The amount of heat which is generated by the action of the current is not very great at the most, and as it gradually collects in the top of the glass it is probable that before the hot air extends down far enough to affect the operation of the instrument, the radiation has become great enough to carry away an equal amount of heat with that which is being generated, and the temperature, from that on, is stationary, and that the balance is brought about before the currents of air are affected sufficiently to influence the operation of the instrument.

Dr. Van der Weyde—But I suggest that the radiation through glass to the exterior air is very small.

Mr. C. O. Mailloux—There are some points which I would like to bring forward. One point is in respect to the friction of the apparatus. I would like to know whether the calibration of the apparatus does not depend for its constancy on the friction of the apparatus remaining constant as nearly as possible; and it also occurs to me to suggest that the friction of the apparatus may have a great deal to do with its sensitiveness as an integrating instrument. In other words, if there is very little friction, it is quite likely that the inertia would be greater, and its momentum once obtained would tend to carry it over, so that if there were any abrupt changes in the current it would not so readily respond to them. So that if we were to draw a curve of variations of current it would in reality not follow that curve closely but only partially, introducing a quantity in the result which would be the analogue of self-induction with an ordinary apparatus. There is another point. We all know that in order to obtain heat from a conductor we must have a certain amount of resistance, and I would like to know whether the amount of resistance that has to be introduced, in the wire, (which I presume is iron from its appearance) is of material consequence—whether it would figure at all as an element of resistance of the whole circuit, and also whether by virtue of its resistance or of its position it would introduce any such variation as has been called impedence in the circuit in consequence of self-induction or anything like that.

Prof. Forbes—The first question is as to the effect of the constancy of the friction—whether the speed of the instrument depends upon the constancy of the friction of the solid parts, and the second question I had better take in connection with it, which is whether that friction of the solid moving parts renders it less sensitive. First, we have to consider whether after the lapse of months or years, when the mechanical parts of the instrument are not in such good order as when it was started, whether its readings will be as accurate as they were at the beginning; and in the second place will it be so ready to start with a feeble current, with the friction of the wheel work as without it. I have already said that the most important part of the friction in that apparatus is the air friction; but that is especially so in the case of a larger current. When the currents come to the average size, or greater, the air friction is out of all comparison the greatest friction that we have in the instrument. At any time the friction of the steel work, incredible as it seems to most people, at first sight, who are not accustomed to thinking much of the subject—the friction of the wheel work is but a fraction of the friction of the jeweled cup upon the pivot. You must remember that the first wheel of the wheel work is rotated at only one-tenth of the speed of the mill-wheel, and its weight is extremely light compared with the weight of the mill-wheel, and the friction of the first wheel is therefore very slight indeed, and when you come to the second wheel, its speed of rotation is diminished ten-fold, and its lightness is small compared with the mill-wheel. I was told to expect this by a great friend of mine whose name I ought always to mention in connection with this instrument—Mr. Stroh, who assisted Sir Charles Wheatstone in all of his celebrated inventions, and who has assisted me in all this work, and there is no man capable of giving such assistance in the mechanical details of an instrument like this. (Applause.) I had intended to make a German pun, a thing I never did in my life before, and should have done so if it were not for the earnest objections of Mr. Stroh, and call this a Strohmeter. That is the way that the friction of the apparatus comes in. It is very slight indeed compared with the air friction except with very feeble currents indeed. The result then has always been that what I call the ratio of speed to current was constant whether the friction were a little more or a little less, but that it did not start quite so easily with extra friction, and I have no doubt that if the wheel work were to get seriously out of order and we were to have very much more friction, it would not be so sensitive to a single lamp, but at higher speeds there would not be the slightest difference in the indications. For example, to show you how that works I passed around two diagrams, I think, give you the ratio of current to speed when different currents were passing through with the clock work attached and without the clock work attached. You would notice in those that with the clock work attached it did not start with so small a current, but when the instrument was once in working order from one-and-a-half amperes or so, or upwards, the two lines of ratio of speed to current were identical. As to the resistance of the instrument, I am asked whether it would afford a sensible amount compared with the resistance of the lamps. As soon as it does that we must, of course, stop using it. I have never been able to raise this wire to such a temperature that it did not indicate proportionately. I have had my wires red hot, and up to that point it was still indicating proportionately. You must simply stop using

Digitized by Google

it when the resistance here compared with the lamps is something you do not like. There is another question asked which raises a subject that I ought to have spoken more fully of in my opening remarks. Mr. Mailloux has spoken about Mr. Oliver Heavyside's impedence (Mr. Mailloux had pronounced the word *impedence*). I beg Mr. Oliver Heavyside's pardon. He has distinctly asked us not to speak of it in that way but to call it *impedence*. He asks me whether the effects of self-induction are perceptible in the instrument. Now there are two effects of self-induction in a coil like that: one is the effect of induction of one turn of a spiral upon another, and the other is concentration of the current in all parts of the wire, not allowing the current all to pass through the whole section of the wire equally. These are the results of using an interrupted current or any variable current. Both these effects come into play. In this case I have only four turns of the spiral and their mutual influence is, of course, quite insensible. Many of you, I presume, read with interest, equal to my own, the delightful researches of Prof. Hughes, on self-induction a year-and-a-half ago, which he gave to the Society of Telegraph Engineers and Electricians in London. You will there find recognized the fact that a variable current passing through a conductor does not pass equally through the different sections, and it has been more generally recognized since that time than previously, that there was a greater resistance in a given wire to a variable current than to a steady current. Prof. Hughes undoubtedly showed that this change of resistance is far greater in iron than in other metals. The metal I use for my conductor is iron. I confess that having these experiments in mind, and having followed out Prof. Hughes' experiment myself in the laboratory, I did expect to find a change in the resistance when I used an alternating current, and I expected that to use the same instrument for continuous and alternating currents would necessitate the employment of a constant by which the readings should be multiplied in order to suit it for the alternating current. I confess with the utmost gratification that on testing it by means of the Siemens dynamometer on the alternating current and using the same Siemens dynamometer in testing it for continuous current, there was absolutely no difference in the readings of the instrument so long as the current remained constant, whether the currents were alternating or continuous: and then I remembered that all Prof. Hughes' experiments and all those I had made in continuation of them, were done with a made and broken current in which the rapidity of change from no current to the maximum of current is terrific, and that the very rapidity of change is what produces the spurious resistance, that apparent greater resistance when the broken current is being used, and that when we are using an alternating current—which alternates, it is true, very rapidly, but in a variable manner, the variations are not commensurate with the rapidity of the variations in the interrupted or broken current. In that case these effects which were so startling in Prof. Hughes' experiments do not appear sensibly. At any rate, as a matter of fact, with alternating currents and continuous currents, the instrument reads identically. No constant requires to be introduced.

Mr. S. S. Wheeler—I would like to ask what the resistance of the coil used is?

Prof. Forbes—Nearly a tenth of an ohm.

Mr. Wheeler—And I would also like to ask if you cannot overcome the effect of induction by making one coil reverse upon another?

Prof. Forbes—Perfectly; but there is no effect of induction.

Mr. G. D'Infreville—The instrument being so sensitive, is it not desirable to take some special precaution to prevent it from registering when no current passes through it: for instance, put it in some place where it will not be subjected to a current of air, or the radiation from the sun or other source of heat.

Prof. Forbes—No; I cannot say that it is. When it is under a shade, as far as I remember, I have no recollection of ever seeing the thing moving when there was no electric current passing through it. I am pretty sure it never does move; but you must remember it requires to go round a thousand times before it registers a sixpence worth; so even if there were a few turns it would not matter a bit.

Mr. Mailloux—I want to say that there is one point in the questions which I asked, that Prof. Forbes did not fully answer, though he has since nearly answered it in reply to my friend Mr. D'Infreville. It is in reference to the sensitiveness of the machine as an integrating instrument. In other words, if you take the rates of variation of a current that is not varying at too rapid a rate and then a current, which we will say is comparatively steady, but which is suffering some periodical variations, somewhat like this (illustrating on the blackboard—if we draw another curve in which the rate of speed of the mill-wheel is used to represent corresponding rates of current, then evidently, when we come here (indicating) if that has more or less inertia, then we will find that the increase of speed of the mill-wheel will be a little more, and then we will find that it will dally a little behind, and that here also (indicating) it will be a little slower. In other words, we would find that perhaps these waves would not be followed so closely. That is what I meant by impedence, and the factor which would be the analogue, though not the exact equivalent, of self-induction.

Prof. Forbes—The momentum of the apparatus has no effect. The momentum is extremely trifling. As soon as the momentum tries to carry it around at a different speed from that which is determined by the velocity of convection currents, these vanes are pulling every way through the air and act as a drag on it, and it immediately suits itself to the velocity of the air currents. Since that question has been raised I would like to say this, that you must not expect the instrument to go jumping about at every rapid rate of changes of lamps. With a small current it takes about five minutes to settle down to its readings. With the large currents it takes about a minute. So that really, if these were the variations in the current (illustrating) in all probability the reading you would get would perhaps not reach its maximum quite so soon, and here again it would have a curve whose variations would not be quite so great. That is not due in the least to any momentum in the instrument. That is due to its taking a sensible time to accumulate heat in the wire, and a sensible time to get rid of the heat accumulated in the wire.

Mr. S. F. Shelbourne—Prof. Forbes said it took about five minutes to get its rate of motion in the mill-wheel with a feeble current. Now, in regard to the first question that was asked by Dr. Van der Weyde in respect to making a hole in the top, does it not appear that the apparent inaccuracy of the instrument in registering light currents and in getting its rate may be due to the generation of heat at the commencement, and that heat accumulating in the top of the instrument and heating the glass before it arrives at a point where there is an equation between the generation of heat by the wire and the radiation from the outside of the glass. I simply suggest this, and I ask Prof. Forbes whether he ever has tried in making instruments, instead of making the whole of the cover of glass, to put a dome of copper or some other conducting metal upon it, so that the air which rises and accumulates at the top may sooner reach that equation of radiation from the outside of the instrument with the generation of the heat in the mill-wheel—which operates the mill-wheel.

Prof. Forbes—I am asked as to the inaccuracies of the instrument with a feeble current and the cause of it. I confess that as a user of the meter I have not the slightest objection to its not indicating at its full speed for the first five minutes when you are using very feeble currents. The monetary value of such a thing is imperceptible. If we were wanting to use the instrument to determine the true value of the ohm, or in any such profound research, it would be right to go to very great accuracy. But I do not think it is necessary to go to any greater accuracy than we have at present on that point, nor to make the feeble currents begin their accurate reading a little sooner. I really do not think that practically it is very important. Otherwise, I think the suggestion that was made might very likely be good—using a metal shade. Of course, I have made numerous changes in shades. I have tried a shade which was nearly all metal. But I found this shade before you the best one I have used up to the present time. However, I think it is quite likely that the suggestion just made might be a good one—that a metal shade would be fully as good as the other—might be better—might make it a little more sensitive perhaps. I think there may be a good deal in what Mr. Shelbourne says:

Mr. J. Wetzler—I have no doubt that the instrument in its present shape has gone through sufficient experimentation as to make any suggestions regarding its history a little out of place. But I am a little interested in knowing whether any experiments have been made to determine the best angle of those vanes and the best shape of them, and if the shape determined on there has been found to be the best.

Prof. Forbes—As to the angle I have committed the grossest folly that a man with the experience I have had with this meter could commit—I have trusted theory, I have been positively certain that an angle of 45 degrees must be the best. I am sorry Mr. Wetzler has drawn this confession from me, because it is really the only respect in which I have trusted to theory. As to the other point, the shape of the vanes has been the source of endless experiments. I made an enormous number of changes before I arrived at this shape, and even little details in the shape have come from experiment. I made hundreds of vanes in the experimental stage, and I am pretty sure that if that type of mill-wheel is to be used the vanes are the right shape.

Mr. E. E. Ries—Prof. Forbes mentioned at the outset that his attention was drawn to the devising of this meter by the fact that no meter existed for measuring alternating currents. Now, during the elaborate discussions we have listened to this evening nothing was said about its application to alternating currents. Many would like to hear from Prof. Forbes as to its use in that connection, and if the meter is specially adapted to alternating currents where other meters heretofore devised are not applicable to that purpose.

Prof. Forbes—I should be very pleased to answer any such inquiries where there are points which I have not touched upon sufficiently. Meters in the past have been constructed by the use

Digitized by Google

of, I think, only two principles of electrical action; the one being electro-chemical action and the other, electro-magnetic action. Several instruments have been devised with electro-magnetic action as their basis; but those which were sensitive enough to be practical were obliged to contain iron in their construction. I do not know of any meter which has been brought into practical form which does not depend on one or other of these two principles—the electro-chemical or the electro-magnetic principle. In an alternating current, the current is, of course, alternately going in opposite directions, and in any electro-chemical arrangement which may be used, whatever is done by the current when it is going in one direction is undone by the next alternation of the current. So that it seems to me hopeless to think of designing a meter upon electro-chemical action. The designing of a meter on electro-magnetic action is a far more hopeful thing; though even in continuous current meters I believe the difficulties have not been altogether gotten over; but in using alternating currents the phenomena of self-induction come in, and not only that but also the fact of your having iron. The intensity of the magnetization of the iron depends upon the speed of the alternations; so that as a matter of fact it has been found in every meter which has iron in its construction that the indications of the meter, even if you keep the current perfectly constant, are totally different when the speed of the engine varies; that is to say when the number of alternations per second is changed. So that if you were testing such a meter you would test it at one speed and you would get at its constant, if it had a constant, and then you would give it to your consumers, and, of course, you would not run your engines at that speed; you would run at a totally different speed, which would favor your suppliers. I think it is immoral to suggest such a thing as that; it lends itself to fraud. That is the objection to the electro-magnetic meters, that they give totally different indications even with the same current, when the speed of alternations is changed.

Mr. F. L. Pope—Like a gas meter when you change the pressure?

Prof. Forbes—Yes; like a gas meter when you change the pressure. It was thinking of these things, and thinking also of other effects of the electrical current that made me conclude that the only thing which would do was heat. I have often thought of the question of meters before, and although your president has been kind enough to say that I have invented one or two things I always try not to invent, if possible. Because that is not my business. My profession is consulting work, But sometimes it is irresistible, and when a man defies you to do a thing which you know you can do, it is totally irresistible. I have been thinking over the matter a good deal before, but I never had made up my mind how I was going to do it, but so soon as this defiance was put before me I immediately hit upon this way of doing it. The reason then why this is suitable to alternating currents is that it measures the heat generated; it measures the energy which is used up; it measures a certain fraction of the energy which is being used up in the lamps, and that is what we want to measure, and it will do so whether we are using alternating currents or continuous currents.

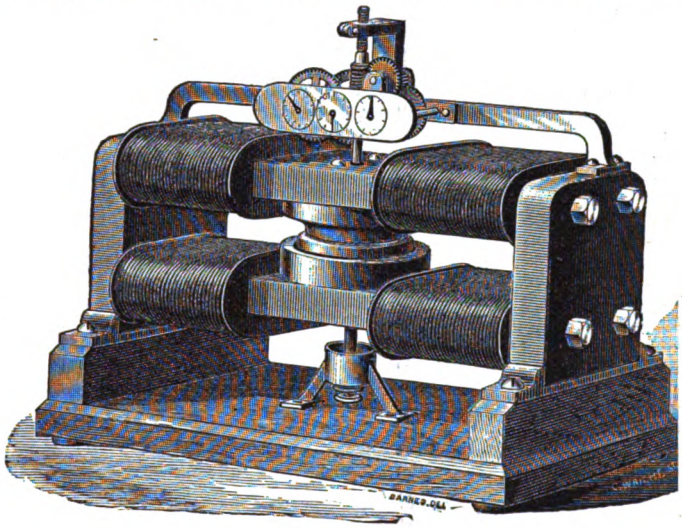
Mr. Ries—The speed of the alternations per second has no effect?

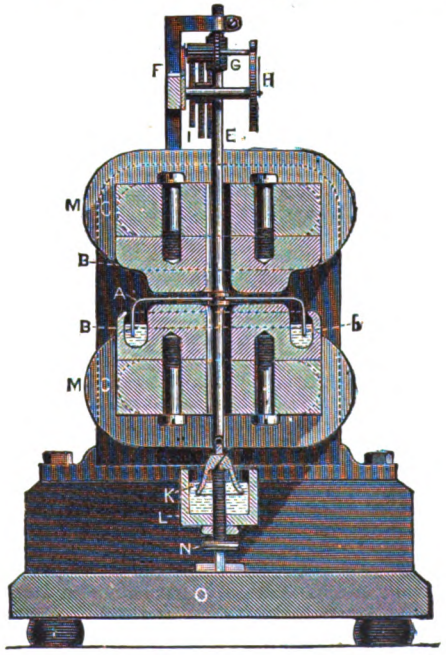
Prof. Forbes—It has no effect upon this. This simply measures the energy—a certain fraction of the energy of the lamp.

The President—We have with us this evening a gentleman who has done more than anyone else to elevate the standard of electrical instruments of precision in this country. I allude to Mr. Edward Weston. (Applause.) The subject has already developed many points of great interest, and I have not the least doubt that Mr. Weston can contribute very largely to our information on these points, and also touch upon others that have not yet been brought forward.

Mr. Edward Weston—I do not know that I can add very much to what has already been said in regard to the instrument of Prof. Forbes. I think it is an extremely ingenious and beautiful instrument. There has been already a great deal of time and a large amount of money spent on electric meters for direct currents, and I can say with Prof. Forbes that I do not think we have had any current meter of any value whatever. The electro-chemical system, in use by a very prominent company here, was put out with a great deal of confidence in the results to be obtained from it. I think anyone looking at the principles involved would condemn it from the start. You are to take a small fraction of the total current, and a very small fraction indeed, and pass it through an electrolytic cell, the temperature of which varies from time to time, its resistance is never constant, and pass the bulk of the current through a resistance which is practically fixed. The change in the resistance of the metal would be but a small proportion of the change in the resistance of the electrolyte. Now, in such an instance as that, you are measuring a very small fraction of the current passing, and whatever error you have you are multipling that error by the inverse of that fraction. If you are measuring $\frac{1}{1000}$ you are multiplying your error by 1000. Any one who has had much to do with electro-metallurgy knows that the cells are constantly changing; that to keep the deposit regular and uniform, to keep the resistance of the solution uniform they must be constantly attended to. There is not an electroplater in the country who does not once in a while go in and stir up his baths. Such an instrument is of no real value. We may, therefore, dismiss those instruments entirely from consideration, I think.

A great deal of work has already been done on magnetic instruments; that is instruments which depend upon the magnetic attraction of the current through a wire—or the current through a wire going around an iron core. In those instruments we have all the defects which have been referred to as being possible to exist in this instrument here to-night, manifested a thousand times more, with numerous others that do not exist in this instrument at all. I can speak feelingly on the matter because I have given a great deal of attention to it, and have thought once or twice I had something very good, and have been finally obliged to abandon it. If any one will take the record of the patent office on electric meters, he will see there has been no small amount of time and thought and money spent on that problem. Practically we are in the same position we were before. We had nothing except the electro-chemical meter, which is, as it seems to me, entirely worthless. Instruments have been built which are approximations, but nothing in comparison with this of Prof. Forbes, and if they were they would not be of such universal application as this instrument. This instrument is applicable to either alternating or direct currents with the same practical degree of accuracy, a thing very much to be desired, particularly in the present state of the art of distribution. I will refer a little to some instruments that have been built in my own laboratory, just to give you an idea of the ingenuity and skill displayed in working out this instrument of Prof. Forbes, and how nicely it overcomes all the difficulties. (Mr. Weston here made upon the black-board sketches of the instrument shown in the cuts above.)





Digitized by Google

We have here an ordinary magnet M, M, with the so-called consequent poles, which in this case are in the form of discs instead of being curved out for the insertion of an armature. These poles are brought as close together as they possibly can be. *b* is an annular chamber running around the pole, in which mercury was poured. A mercury cup L, was also placed on the base of the instrument, in which was inserted a cork float, K, to get as little weight on the pivot, which entered the stem E, here, as possible. This stem passed up right through, connected with the disc A, at the centre, and then engaged a wheel-work, at G, similar to the one that Prof. Forbes has for the purpose of registering the number of revolutions of the disc. Now, if this magnet, which was wound with very fine wire, was so proportioned as to be saturated with the minimum current that would be likely to flow with the difference of potential on the circuit, if the core was kept constantly saturated, then a current passing in to the stem E, would go through the disc readily, down through the annular cup and out through the frame of the magnet, the magnets being placed in derived circuits so as to keep them constantly at the point of saturation. Under those circumstances, of course, we should have a series of radial currents flowing out from the centre to the periphery or *vice versa*. Such being the case, the disc would commence to rotate and record the number of revolutions on the little wheel-work or registering apparatus employed with it. This instrument was the result of a great deal of hard work. It had been absolutely abandoned. I could not find anything that was really satisfactory, and I came to this last of all. It stands on my laboratory table now. It has not been touched for two or three years. The instrument, however, within certain limits, was really admirable, but those limits were so narrow as entirely to prohibit its use for practical work. When the speed varied the element of friction in the mercury came into play here, and very seriously changed the rate of revolution of the instrument. I do not know whether Prof. Forbes has done any work on the friction of a mass of metal revolving in mercury?

Prof. Forbes—I did a good deal of that at one time.

Mr. Weston—If you did, you will understand the difficulty. Nothing was accomplished. Now, when I come to see an instrument like this of Prof. Forbes, after the amount of work that has been spent on meters, it makes me somewhat ashamed to think that I gave so much time to a thing of the kind I have described. I may say that it has already given rise to a very neat form of current instruments in which, instead of having the disc rotate, it was fixed, a large index was brought out from the disc, in which case it was absolutely proportional to the number of lamps in circuit. For a station ammeter I do not know of anything that equals that to-day. It shows one lamp when there are 300, 400, or 500 on just as it shows one lamp by itself. Prof. Forbes has here the simplest instrument that could be built, I think. I do not see how you could improve it very much except in detail. The principles are correct, and I must congratulate him very highly indeed upon the success of the instrument.

Mr. Ries—After Prof. Van der Weyde's suggestion, which was the first one made this evening, about that hole in the roof, it occurred to me that perhaps another principle besides those mentioned by Prof. Forbes might be utilized in the construction of a meter of this class. Prof. Forbes mentioned electro-chemical action, electro-magnetic action and caloric, or heat, as the basis for a measuring instrument of this kind. Now, if we could obviate the friction due to the revolution of these vanes in the air and place them in a vacuum like Crooke's radiometer, and instead of utilizing the principle of heat, use that of light to give motion to the vanes, I do not know whether that would not make a very delicate apparatus. It suggests a different direction in which to work. You might perhaps take these vanes and place them in a dark cell, surround them with a strip of platinum wire or carbon filament and use the variations in light to change the number of revolutions per second, and that could be recorded by an apparatus similar to that used by Prof. Forbes. I simply offer that as a suggestion.

Mr. Weston—I did not speak of the general class of meters. There are such meters as are dependent on the action of clock work. A good deal of work has been done on them. I think Mr. Gardiner took one of the first patents. In this case, I think, the clock work was to keep the gear wheels moving at uniform rates, and the device for transmitting that through the recording apparatus was to enable a change to be made in the rate of recording. Of course there has been a great variety of instruments of that class designed. Then a class has been designed based upon the quantity of gas generated by electrolysis. That can be used; but the same objection holds in that that holds in the other one, that you cannot put that instrument in the direct circuit. It must be in a derived circuit and you must then measure the gas, which introduces a great many errors which have to be compensated for. Then there have been other instruments in which it has been proposed to use strips of paper running under a stylus which could be moved more or less by a magnetic current. But you can see, when you sift them all down that there is not one which is applicable to any system of work that is now in use. The instrument before us appears to me to be so applicable. Some people may say that is a very delicate instrument; well, there is a great deal of very delicae work about electric lighting, and the sooner we get men who are delicate enough to handle it the better we shall be off. You cannot wait for men to be educated, nor depend upon men entirely. You have got to run on with the art, and the men must grow up with it. A few years ago there were no ammeters. Volt-meters used to be ridiculed. Everything was rule of thumb. People are beginning gradually to see that it is necessary to use instruments. They find it on the balance sheet. I would no sooner think of running a manufacturing establishment where electrical apparatus is made without delicate measuring apparatus than I would think of running a machine shop without delicate measuring apparatus. It is just as foolish to try to get along with a foot rule as your standard in a shop without using standard gauges. The man who works to $\frac{1}{1000}$th of an inch, which should be the absolute limit on all first-class work, is the man you want to employ. He will save you money, because he will do your work the same way every time, and there will be no tinkering and pottering to get things together.

The President—It is not at all our practice to call upon gentlemen to speak, but I must say that I think I do but utter a general desire when I request Mr. Howell to favor us with a few remarks. He is working in a department which has been more than once alluded to this evening, and with which he is very well conversant.

Mr. Howell—Mr. chairman, I was very much surprised to hear what Mr. Weston said. I am surprised that he does not know that there is a temperature correction in the Edison meter. The Edison meter has been in use industrially for five years, and I say without hesitation, and I am in a position to know the opinion of the practical men who are using the Edison meter, that they think a great deal more of it to-day than they did at first, and the more they use it and the more they know of it, the better they like it.

There is one thing about that meter of Prof. Forbes which now occurrs to me as the result of experience with instruments sent out for general use. There is one peculiarity about every American electrician—he has got to know what things are made out of, and if you do not show him he will find out for himself. Now that instrument shows itself. You can look at that and see what every part is, and you do not need to take it apart. I have sent out a great many instruments. The first thing a man does with them is to pull them apart and see what they are made of. There is no necessity for pulling that instrument apart, you can see all through it.

There is one thing I would like to ask Prof. Forbes, and that is the effect of lowering the shade. I see he has a shade there very much higher than the instrument apparently needs. I would like to know if that is necessary to allow for air circulation.

Prof. Forbes—Yes; it is more sensitive with a higher shade. That is about the limit. I have gone through dozens of shades to see what is the right size and shape, and that is the one I fixed upon.

Mr. Howell—The impression that instrument makes upon me, and upon a good many I should think, is that there would be a difficulty in shipping it, and getting the men who have to put it up and use it to do so properly. I know that the men who will use those meters, the men who do our meter work in electric lighting are not men in whose hands I would like to put an instrument of that sort. How is that shipped, may I ask, Prof. Forbes?

Prof. Forbes—I packed the glass case separately when it came over. On that occasion I took off the vanes. I had three parcels for that instrument, one containing the clock work and all the brass work you see there; another containing the mill-wheel and another containing the glass shade. They have traveled in England very large distances with that arrangement in action which I pointed out before by means of which the vanes are pushed up against a stop. The person who was going to use it had nothing to do except tightening up a screw as hard as it could go, and then it was free to work. There was absolutely nothing to be done except that, and I think I should do that in future if I replaced that glass shade with a metal cover. I have not replaced it with a metal cover, because you can see it work. I like the glass shade, but I daresay a metal shade with a window will in practice be the thing that will be adopted, in which case the whole thing will be perfectly safe to pack up in one piece. I shall certainly not allow the workman who uses it to touch the mill-wheel. I shall have that arrangement which is on it now for lowering the vanes on to the point.

Mr. Weston—I take it, gentlemen, that the instrument exhibited here is not intended to be the instrument in use. We know that people do a good deal to get around meters. Gas companies will tell you that people will punch a hole through. But, of course, it is practicable to protect that as well as we can protect anything.

In regard to the electrolytic method by the direct current I may say I am aware, and I have been aware for a long time, that

Digitized by Google

Mr. Edison has had a temperature correcting device in circuit that will work within certain limits. I still say, and I say it without any fear of being proved incorrect, that such a meter cannot work successfully and practically within the limits that it ought to work to, and I think that is the universal testimony of consumers at any rate. I suppose there will always be more or less complaint by consumers about all kinds of meters, but I think they have been pretty well founded in that case, because I think the meter is incapable of doing as good work as we want a meter to do. I do not mean to say you cannot make a meter that will work.

Mr. F. B. Crocker—I ran roughly over the amount of heat that would be generated in Mr. Forbes' instrument, and it came so high that I should like to run over the figures now and see if they are right. He says the resistance is a tenth of an ohm,

Prof. Forbes—Under a tenth of an ohm, I said.

Mr. Crocker then went through a calculation based upon a current of 20 amperes with a drop of 2 volts, and arrived at the conclusion that the quantity of air enclosed in the glass shade of the meter would gain in temperature at the rate of 400 degrees per minute, and said: "It is a very high figure, I cannot believe it is right, but we know that the capacity of the amount of air in that shade for heat is very small, and we also know that the amount produced in a resistance of a tenth of an ohm by 20 amperes of current is quite large. Therefore perhaps that figure is approximately right."

Prof. Forbes—I would suggest that Mr. Crocker instead of taking that line would simply find how much energy is used in the meter when 20 lamps are burning, and find out how much energy is used in the lamps when 20 lamps are burning, and divide one by the other and get the percentage. Settle upon the percentage more than which you are not going to use, and you have it. I should think very much over 2 per cent. or so would be very undesirable to use. In some cases it might go up to 3 or 4, possibly, but I should think as a general rule you would find 2 per cent. as much as one would care to use.

Mr. Crocker—I did not mean to criticise the efficiency of the apparatus. I did not mean that Prof. Forbes' meter used up any considerable fraction of the current. I merely meant to bring forward as an interesting point exactly how much heat is produced in the meter in a given time, and to calculate it as well as I was able to with the figures I happened to have in my mind.

Prof. Forbes—Then I would point out that theoretically you have to take in another point, and that is that there is continual radiation going on, and that during constant running there is no addition to the heat contained in the instrument. It arrives at a constant condition when the heat generated in the wire is equivalent to the heat radiated from the surface of the glass. From numerous experiments both in Sir William Thomson's laboratory and also by Professor Tait, we have got at the rate of radiation, and it is very easy to go on with the calculation a step further than done just now and calculate what is the temperature which would be reached when the radiation from the surface is equal to the heat generated from the wire. The problem looked at simply as a theoretical question of interest can actually be worked out by going a step further than Mr. Crocker has just stated.

Mr. Wheeler—What is the approximate temperature of the shade after running a few minutes?

Prof. Forbes—Running at its full, it is 120, perhaps.

Mr. Wheeler—Even at that low temperature it must get enough higher than the surrounding air to radiate 2½ heat units.

The President—While these calculations were being made as to the condition of the air in that globe, I was very forcibly reminded of the condition of the air in this room, and it made me wish for the time, not so far distant, I hope and believe, when both the civil engineers and ourselves will have a meeting hall worthy of the two societies.

The discussion being at an end, though by no means exhausted, I think nothing remains but to ask Prof. Forbes to close it with such remarks as occur to him as proper, and that being done we will adjourn to the next room where a collation awaits us.

Prof. Forbes—Mr. President, I really have very few remarks to make except to say that I feel that this discussion has been of great value to all of us. Very interesting points have been raised and I have heard suggestions which have interested me very greatly. Of course in working at this instrument one started from theoretical notions, but one gave them up very soon, and one had all sorts of resources at one's hand to vary the forms of those curves some of which I have already shown you. I should like to show you the curves which I got when I first made this instrument. The curve ought to be simply a horizontal line. One of the curves which I first got was of about this shape (drawing a very irregular curve on the black-board), and yet I had the greatest hope even when I got that. By two changes I was able to reduce the line down to a horizontal, and there were numerous other changes. In the course of working that instrument out I learned more about convection currents than I knew there was to learn, and really one has power now to handle them as one pleases.

I have no more remarks to make except that I thank every one here for the pleasant discussion we have had this evening. I think it has been very instructive, and I have felt throughout, the same kind, cordial sympathy that was shown in England. I did not expect to find everyone ready to look upon it in the way in which Sir William Thomson did, without any sign of regret that it happened to be done by another. I thank everyone here most heartily for the cordial way in which they have received this stranger. (Applause.)

On the motion of Mr. J. H. Pendleton, the Institute offered its hearty congratulations to Prof. Forbes upon his beautifully simple and valuable invention, as well as its thanks for his luminous paper and his exhibition of the coulomb meter before it.

The members of the Institute and guests then spent an agreeable hour in an informal reception to Prof. Forbes, during which a collation was served.

ANNUAL REPORT

OF THE

PRESIDENT OF THE WESTERN UNION TELEGRAPH COMPANY

FOR THE YEAR ENDED JUNE 30, 1887.

CAPITAL STOCK.

The capital stock of the company outstanding is $81,199,852.06, of which $21,282 belongs to and is in the treasury of the company. It was increased during the year to the extent of $1,200,000 for the special purpose of taking up the dividend scrip of April, 1886, which did not amount to quite that sum. A small proportion of the capital stock is, however, still represented by certificates of indebtedness for which capital stock certificates have not yet been issued.

BONDED DEBT.

The bonded debt at the close of the year was as follows:—

Bonds due March 1, 1900, 6 per cent	$891,324.00
Bonds due May 1, 1900, 7 per cent	4,920,000.00
Bonds due May 1, 1902, 7 per cent	1,336,000.00
	$7,147,324.00
Less balance of sinking funds, appropriations not yet used for redemption of bonds	364,893.04
	$6,782,430.96

During the year, sterling bonds due March 1, 1900, to the amount of £2,000, and building bonds due May 1, 1900, to the amount of $37,000, were redeemed by the sinking fund trustees.

BUSINESS OF THE YEAR.

Surplus, July 1, 1886		$4,309,833.53
The revenues, expenses and profits of the year ended June 30, 1887, were as follows:—		
Revenues	$17,191,909.95	
Expenses	13,154,628.54	
Profits		4,037,281.41
		$8,347,114.94
From which there was applied:		
For dividends	$811,864.43	
" interest on bonds	493,074.40	
" sinking funds appropriations	39,991.00	
		1,344,929.83
Deducting which, leaves surplus, June 30, 1887, of		$7,002,185.11
The expenses for the year were:		
For operating and general expenses		$9,077,445.42
" rentals of leased lines		1,899,953.74
" maintenance and reconstruction		1,673,670.11
" taxes		278,534.44
" equipment of offices and wires		224,964.83
Total expenses as above		$13,154,628.54

RECAPITULATION.

The net profits for the year were		$4,037,281.41
Out of which there has been paid:		
Interest and sinking fund	$533,065.40	
Dividend	811,864.43	
And added to the surplus principally invested in new property	2,692,351.58	
		$4,037,281.41

A handsome increase in gross earnings over the previous year has been realized, notwithstanding the more extended competition and further reduction of rates, whilst of the considerable increase in expenditures the greater part was for extensive and thorough reconstruction of important trunk lines, which may now be maintained at little cost for some years. As these lines have been rebuilt of larger and stronger poles to carry additional wires, much of the cost might properly have been charged as a betterment to new property account. But it is not the habit of the company to charge anything to the construction and purchase of new property that is not solely and entirely new and additional.

There has been an increase of 4,104,723 in the number of messages handled during the year over that of the previous year, being, as the table will show, the largest increase in traffic, ever made by the company in any one year over the year previous, except in

Digitized by Google

1881, when the American Union and Atlantic and Pacific companies were taken in, notwithstanding the large increase of leased wires to the press associations and private parties.

Though there has been the largest percentage of increase in Pacific Coast and other long-distance messages, yet the average rate received per message has been reduced to 30¼ cents, as against 30 9/10 last year, with a corresponding reduction in the cost to the company of handling messages to 23¼ cents per message, as against a fraction under 24 cents the previous year.

In ascertaining the receipts and expenses per message, all revenues not derived from the transmission of messages over land lines, and all expenses not pertaining thereto, have been eliminated. It is, therefore, an inevitable conclusion, that every message transmitted, enveloped and delivered by a messenger, at whatever distance, for 10 or 15 cents, is done at a loss. Even purely city messages, where office rents have to be paid, cannot be handled for 15 cents with any profit. The number of messages stated are the messages actually handled, long and short, averaging, with date, address and signature, from 17 to 20 words each, with the press service calculated at one message for each 30 words transmitted, which has always been the basis of statistics as to messages.

GENERAL STATEMENT.

The following exhibit shows the revenues and disbursements of the company for 21 years from July 1st, 1866:—

Surplus of income acc't, July 1, 1866..	$275,357.24	
Net revenues for 21 years, from July 1st, 1866, to June 30th, 1887.....	86,037,797.65	
Making an aggregate, June 30, 1887, of		$86,313,154.89
During this period there was applied:—		
For cash dividends.....	$47,141,615.26	
For scrip dividend.....	1,199,852.06	
For cost of 59,606¼ shares of Western Union Telegraph stock, purchased and owned by the company, which was distributed to stockholders in 1879.....	3,302,198.90	
For cost of 72,010 shares of Atlantic and Pacific Telegraph stock, purchased and owned by the company, the proceeds of which, in Western Union stock, were distributed to stockholders in 1881.....	1,806,250.00	
For interest paid on company's bonds	8,683,338.89	
For cost of 396 4/100 shares of Western Union stock, purchased and owned by the company, which were cancelled to make the capital stock, after the issue of the new stock in 1881, exactly $80,000,000.....	26,836.00	
For amount reserved for interest on bonds and for sinking funds, accrued to June 30th, but then not yet due and payable.....	106,086.64	62,266,177.75
Leaving a surplus of.....		$24,046,977.14
Which is represented as follows:—		
Construction of new lines, erection of additional wires, patents, etc., prior to October 1, 1881.....	$9,396,160.08	
Purchase of telegraph lines and of the stocks of companies leased by the Western Union Co. (upon which interest or dividends are paid as rental) prior to Oct. 1, 1881.....	2,448,182.66	
Gold and Stock Telegraph Co.'s stock (18,905 shares).....	1,176,009.00	
International Ocean Telegraph Co.'s stock (15,170 shares)	961,606.42	
Brooks' Underground Telegraph Co.'s stock (1,000 shares).....	95,000.00	
Southern Bell Telephone and Telegraph Co.'s stock (1,687 shares).....	84,325.00	
Sundry other stocks and bonds.....	93,739.68	
Western Union bonds redeemed and cancelled.....	1,446,809.27	
Sinking funds (portion not yet used for redemption of bonds, exclusive of interest allowed by trustees).....	313,623.82	
Broadway and Dey street building.....$2,365,639.52		
Less amount provided from the proceeds of bonds issued.....	1,802,202.00	
	563,437.52	
Real estate other than above..... ..	283,608.50	
Supplies and material on hand unissued.....	182,290.08	
Surplus, June 30, 1887.....	7,002,185.11	$24,046,977.14
On account of these assets a stock distribution was made in 1881 to the amount of...		15,526,590.00
Deducting which leaves a balance of..		$8,520,387.14
There has been expended in the construction and purchase of telegraph lines and other telegraph properties since October 1, 1881....		$9,348,318.20
Of which there was provided by the sale of bonds.....	$1,000,000.00	
And by the sale of telegraph and telephone properties.....	143,976.87	
And there has been capitalized by the issue of a stock dividend.....	1,199,852.06	
Leaving a remainder of expenditures out of earnings for construction and new properties.....		$2,343,828.93
		$7,004,489.07

There was also expended for construction and new property between January 1st and October 1st of 1881, $1,225,915.22, which was appropriated out of earnings, and carried into the quarterly balance sheets up to the latter date.

The total amount expended since January, 1881, in the construction and purchase of new properties, added to the plant is $10,574,233.22, of which only $1,143,976.87 was provided from other sources than the revenue of the company from earnings and investments; $1,225,915.22 was directly appropriated out of the earnings of the first three quarters of 1881; $1,199,852.06 was capitalized by issue of the stock dividend in April, 1886; and the remainder, $7,004,489.07, has been advanced to the construction account from the surplus earnings of the company.

Of the $47,141,615.26 paid to stockholders in cash dividends since July of 1866, $26,007,687.92 have been paid in cash dividends from the net earnings of the company since January of 1881, and in addition thereto $10,574,233.22 have been advanced and paid within the same period for new and additional properties, on account of which latter $1,199,852.06 have been distributed to stockholders in capital stock.

This aggregate of $36,581,921.14 has been paid out of the net earnings of the company over and above its fixed charges for interest on bonded debt and sinking fund, except $1,143,976.87 derived from the sale of bonds and other securities.

The following table exhibits the mileage of lines operated, number of offices, number of messages sent, receipts, expenses and profits, for each year since 1866.

STATISTICS.

Year.	Miles of poles and cables.	Miles of wire.	Offices.	Messages.	Receipts.	Expenses.	Profits.
1866..	37,580	75,686	2,250	.....	$	$	$
1867..	46,370	85,391	2,565	5,879,582	6,568,925.36	3,944,005.63	2,624,919.73
1868..	50,183	97,594	3,219	6,404,505	7,004,560.19	4,362,849.32	2,641,710.87
1869..	52,099	101,584	3,607	7,084,693	7,316,918.30	4,568,116.85	2,748,801.45
1870..	54,109	112,191	3,972	9,157,646	7,198,737.96	4,910,772.42	2,287,965.54

1874..	71,585	175,785	6,188	16,329,256	9,262,653.98	6,755,733.83	2,506,920.15
1875..	72,833	179,496	6,565	17,153,710	9,564,574.60	6,335,414.77	3,229,157.83
1876..	73,532	183,832	7,072	18,729,567	10,034,983.66	6,635,473.69	3,399,509.97
1877..	76,955	194,323	7,500	21,158,941	9,812,352.61	6,672,224.94	3,140,127.67
1878..	81,002	200,202	8,014	23,918,894	9,861,355.28	6,309,812.58	3,551,542.70
1879..	82,987	211,566	8,534	25,070,106	10,940,640.46	6,140,200.37	4,800,440.09
1880..	85,645	233,594	9,077	29,215,500	12,782,894.53	6,948,956.74	5,833,937.79
1881..	110,340	327,171	10,737	82,500,000	14,393,543.85	8,485,264.13	5,908,279.72
1882..	131,000	374,368	12,068	88,842,247	17,114,165.92	9,996,096.92	7,118,070.00
1883..	144,294	432,726	12,917	41,181,177	19,454,902.98	11,794,553.40	7,660,349.58
1884..	145,057	450,571	13,721	42,076,226	19,632,033.60	13,022,583.00	6,610,435.70
1885..	147,500	462,283	14,184	42,066,583	17,700,833.71	12,005,900.58	5,700,824.13
1886..	151,832	480,607	15,142	48,249,807	16,208,688.35	12,378,783.42	8,919,835.13
1887..	156,814	524,641	15,658	47,394,530	17,191,900.95	13,154,028.54	4,037,281.41

The foregoing table exhibits the growth and increase of property and business year by year, for 21 years. Nearly 5,000 miles of line, over 35,000 miles of wire, and 516 offices, and their equipments, were added to the plant during the current year. Of these additions, about 2,000 miles of line, and 5,000 miles of wire were purchased, and the remainder newly constructed; and all paid for in cash out of surplus earnings in the treasury.

The construction account has been unusually large, because of the great extensions of new and branch railroads, compelling extensions of telegraph lines on new routes and into new territory. The demand for private wires has also compelled the erection of additional wires on trunk lines.

The number of messages handled shows a larger percentage of increase in traffic than in any one year since 1881, which, with the increased exactions of prompt service, involved the necessity of erecting additional wires on all the principal trunk routes.

Considering the amount of business that must have been done by other companies, there can be no business in the country that has developed, and is developing, such rapid growth and increase as the service of the telegraph.

PRESS SERVICE.

About 92 per cent. of our toll revenues are derived from commercial and family and social messages, and 8 per cent. from the press. The news service delivered by this company's wires during

Digitized by Google

the year—counting one delivery at each place served—foots up some 740,000,000 words, of which 578,000,000 words were for the various Press Associations and 162,000,000 words were special reports for individual newspapers.

The 578,000,000 words for Press Associations were delivered to and published by an average of 2¼ newspapers at each place where they were taken off, which added to the special reports would make some 1,467,000,000 words of press report received and published by the various newspapers throughout the country over the wires of this company during the year.

The average rate received for special reports transmitted and delivered was a fraction over one-half cent per word.

The average rate received for the Associated Press reports delivered (counting one delivery at each place) was about 10½ cents per 100 words.

In the larger cities where these reports were delivered by leased wires to an average of four or five papers the cost to each paper for transmitting the reports was from 2½ to 3 cents per 100 words.

This is undoubtedly the cheapest telegraph press service of any country in the world, and especially so when it is considered that the average distance the reports are transmitted by us is three times as great as that of other countries.

Although the service has been steadily improved, and it is believed now comprises the best telegraph service rendered by any telegraph system in the world, we still continually realize that our greatest competitor is time, and that just in proportion that we can overcome time in the transmission and delivery of messages will our business be increased.

The table appended[1] exhibits the assets in the treasury, as verified by the report of a committee of the Board after personal examination, and shows very few and immaterial changes from that of the previous year. They are set down at their par value, but most of the leading telephone properties are worth a great deal more.

The ensuing year, of which the approximate footings of the first quarter are already known, promises very much better results. The additional wires erected on trunk lines and through routes have chiefly been of hard copper, affording greater conductivity, and enabling a better service than ever before. Undoubtedly a large increase of revenues over those of the past year, herein reported, would be realized, even without the important and valuable acquisitions so recently made. The facilities and advantages afforded by the addition of the Baltimore and Ohio system, it is confidently believed, will largely increase the revenues. This acquisition and others made since the close of the fiscal year, and not included in any of the figures of this report, will swell the company's plant to about 162,000 miles of lines and over 580,000 miles of wires. Respectfully submittted,

NORVIN GREEN, *President.*

THE AMERICAN STREET RAILWAY ASSOCIATION.

ANNUAL MEETING.

The American Street Railway Association held its sixth annual meeting at the Continental Hotel, Philadelphia, October 19, 20 and 21. The most noteworthy feature of the convention was the amount of time and attention given the consideration of electricity as a motive power. Electrical interests were well represented by the presence of Messrs. E. V. Cherry, F. J. Sprague, H. McL. Harding, A. K. Stiles, C. J. Van Depoele, G. W. Mansfield, C. E. Stump, A. Reckenzaun, R. W. Blackwell, T. C. Martin, E. E. Ries, A. H. Henderson, E. H. Hastings, A. H. Chadbourne, G. H. Condict, H. A. Foster, J. M. Pendleton, E. J. Bagnall, W. H. Knight; to which list may be added the names of Wm. Wharton, Jr., and Calvin A. Richards, both of whom enjoy high repute in street railway circles, and have pronounced views in favor of the use of electricity for urban passenger traffic.

At the first session Mr. Wharton read an extremely instructive and valuable paper on electricity as a motive power, which we print elsewhere. (See p. 443.)

A paper on Street Railroad Construction was read by Mr. Richards, in the course of which he said:

"The time is fast approaching, if not already here, when electric motors will come into general use for the propulsion of our cars. When accumulators or storage batteries are used, our cars will have to carry an increased weight of 3,000 to 4,000 pounds. It is probable, also, that in time we shall find it profitable to replace our present cars with longer ones, capable of seating a larger number of passengers; all this will require heavier rails and better road, and we shall have to construct our tramways when building new tracks, or reconstruct our old ones for this purpose.

"A section of rail weighing from 55 to 60 pounds, with the cross ties placed four feet apart, will be sufficiently stiff to answer the purpose. Great care should be exercised, however, to have every part of the track construction well and solidly done, especially at the rail joints, and the whole track rigidly held in place, so that inaccuracies in this respect will not cause the motors to leave the track, nor settle it and throw it out of place, by the increased weight and speed of our cars."

1. We omit the table.

On Wednesday afternoon, Mr. F. J. Sprague was unexpectedly called upon to address the meeting. In a brief but pointed address, he set forth the relative merits of the overhead, conduit and storage battery systems, with much clearness and suggestiveness. He also discussed the location of motors on cars and their connection to the driving axles—and expressed opinions decidedly favorable to the use of two motors under each car, one to each axle of a four wheeled car, and one to each truck of an eight wheeled car.

On Thursday, Mr. C. J. Van Depoele addressed the meeting on the general subject of electric railways, and in illustration of the growth of electric traction, submitted some account of the work of his own company, as follows:

ROADS RUNNING.

Location.	Miles.	Cars.	Power.	Total power cost per day.
Windsor, Ont.....	2	2	Steam, rented....	$4.00
Detroit, Mich.	2	8	" "	6.00

Dayton, O.....	6	12.....	"

Mr. E. E. Ries briefly described his method of increasing the tractive adhesion of driving wheels, after which Mr. R. W. Blackwell made an address, chiefly devoted to arguments against the use of storage batteries. He presented his criticisms in the name of the Bentley-Knight Electric Railway Co. The argument was as follows:

"We will assume that the storage battery is beyond the experimental stage, capable of driving a car eight hours without recharging. Granting the most favorable premises, we will make a short practical comparison between the storage and direct systems, both as to operating expenses and first cost. We will also assume that a set of street car batteries will weigh 3,200 lbs.; that they will give a return of 65 per cent. of the electrical energy expended in charging; that a set which will run eight hours can be charged in 10 hours, and that a set will run 12,500 miles without renewal of the batteries or extensive repairs.

"1st. *Cost of Operation.*—Two great losses are chargeable against the economy of the storage system, viz.: Loss in conversion of energy in the battery and the additional weight carried on the car. In the direct system, electricity from the generating dynamo is transmitted to the motor on the car by the line conductors. In the storage system, electricity from the dynamo is used to charge the batteries, which, in turn, supply the motor. In the latter system the loss is conceded to be 35 per cent. In the former system, it is a matter of simple arithmetical calculation to make the loss inappreciable. It should never exceed five per cent. however long the line. This leaves a difference of 30 per cent. against the storage system.

"A greater loss is entailed by the heavy load of batteries which the storage system car must carry. It necessitates a heavier car construction and a heavier motor, all of which adds to the weight. In practice two motors are often used. The additional weight entailed by the storage system easily reaches 4,000 pounds per car. The motor and driving mechanism for a car, run under the direct system weigh 1,600 pounds. The equipment where batteries are used is necessarily heavier on account of the added battery weight to be moved, but we will keep the same figure for both. A car weighs nearly 5,000 pounds. In Boston (1886), the average number of passengers per car mile was 10, so that the average load may be put at 1,400 pounds. We then have the following summary:

	Storage system.	Direct system.
Car.....	5,000 lbs.	5,000 lbs.
Motor, etc.....	1,600 "	1,600 "
Passengers.....	1,400 "	1,400 "
Batteries, etc.....	4,000 "	.....
	12,000 lbs.	8,000 lbs.

"That is, 50 per cent. more power must be expended to propel the storage car, and 30 per cent. more power to overcome the loss of conversion in the batteries, making a total of 80 per cent. greater cost for power than the direct system. This means not only 80 per cent. more coal consumed, but 80 per cent. added to the size and cost of the steam and dynamo plant in the generating station.

"There are additional losses in the storage system which are less

Digitized by Google

easy to compute, but which are hardly less serious than those mentioned. Twelve thousand five hundred miles are given as the life of a battery. Now, 100 miles per day is not an excessive mileage for an electric car, so that the battery must be renewed, wholly or in part, every 125 days, or three times per year. What this would cost it is impossible to say, but it is plainly a serious item. On the other hand the depreciation of an overhead wire, or a conduit, is very slight, not more than 3 or 4 per cent per annum. The handling of storage batteries is also a very considerable item. To transfer 3,200 lbs. into and out of a car two or three times a day is not a slight matter, while the shifting and removal necessary to a large plant must be added to it. None but skilled labor could be employed in handling, recharging and taking care of the batteries. That has been conclusively proved.

"2d. *First Cost of the Storage System.*—There is little reliable data on this point, but, putting a very moderate estimate upon it, it far exceeds that of the most expensive direct system.

"There should be at least three sets of batteries for each car—a considerable increase in the motor capacity—80 per cent. more dynamo and steam plant in the generating station, and twice the floor space, since each car must have a stand for charged and discharged batteries. This could not cost less than $2,500 per car, which is to be balanced against the conduit and line conductors of the direct system. The cost of the latter varies, of course, with the number of cars per mile. Taking a well-known road in Boston, however, which has 700 cars and 70 miles of track, there are ten cars per mile, which, equipped with conduit and conductors at $4 per foot, would cost $2,000 per car. As a matter of fact, one-fourth of this mileage could be equipped with overhead wire at $2,500 per mile, which would bring the cost to $1,650 per car.

"An important fact, which we have left out of this computation, is that most existing roads must be equipped with new and heavier track to fit them for the weight of storage cars. The present rail will stand an addition of 1,600 lbs. to each car, but not an addition of 5,600 lbs. (The most widely-advertised storage car run in this country weighed over 6¼ tons.) These facts are plain and simple, and, in view of them, it is difficult to see how the introduction of the storage system can be seriously contemplated when conduit and elevated conductor roads on the direct system are feasible. As we have said before, the superficial appearance of the storage battery for street cars is very attractive. It is a simple electrical problem to charge a battery and run a car for an occasional trip. A boat equipped with a battery has crossed the English channel, while for lighting railway trains, where weight and expense are no object, and the work easy and constant, it has a certain value, but for practical street car work, it has just enough promise to make it a dangerous and insidious deceit. The storage power, however, is a disease which users of electricity must go through as a child has the measles. The electric lighting interests went through it some years ago at an enormous expense, and to-day not one of the large electric lighting companies is supporting the storage battery. If this paper, hurriedly written and far from complete, will in any degree mitigate the malady to the street railway interests, it will have attained its end."

On Friday the members of the association, by invitation, visited the establishment preparing by the company, of which Mr. Wm. Wharton, Jr. is at the head, and which is to be known as the Electric Car Co. of America, and which has secured the services of Mr. A. Reckenzaun, so widely distinguished for his services in developing electric traction, particularly the storage battery method. After some successful experiments with a new car, not yet fully completed, witnessed by the members of the association and other guests, an elegant luncheon, provided at the works by Mr. Wharton, was served to the company. During the lunch, Mr. Wharton, speaking of the use of storage batteries for electric traction, said that he did not feel "sanguine" but "certain" on the subject, and that he intended to press forward on that line and to be in the lead even if alone.

THE ELECTRICAL ENGINEERING DEPARTMENT AT CORNELL UNIVERSITY.

THE equipment at Cornell in the line of electrical engineering bids fair to become, if it is not already, the most complete in the country and probably in the world. It has been almost wholly contributed by friends of the University at the suggestion of the Director of Sibley College and others interested in its progress. The last and most important addition to the collection, that of the Westinghouse 650-light alternating current dynamo, exciter, lamps and other material required in establishing the plant, has already been mentioned. The list of dynamos now includes the Edison, the Gramme, the Mather, the Westinghouse alternating current, the Westinghouse continuous, a number of Weston and minor makes and all sizes from a little toy machine made in our own shops to the 50 or 60 h. p. machines just added to the list.

There comes with this liberality on the part of the friends of the University an embarrassment of real importance: there is no immediately available room for the installation of these machines. The dynamo room now appropriated to the purpose is hardly large enough for the "cradle" used in conducting experiments on a single machine. The Weston machine is tucked in one corner, and the Edison and Mather machines are temporarily placed in the middle of the floor and driven as best can be done from there. There is actually no room even to lay down the new machines now *en route* from Pittsburgh, still less to place them for use. In this emergency the Director has obtained permission from the Trustees to make temporary provision for them by throwing the existing toilet rooms into the machine shop, thus securing a space some 15 or 18 feet by nearly 40 in which to place all these machines. It has long been considered advisable, on the score of safety and convenience, to remove all heavy machinery from the main building, and this transfer of the dynamo room will give opportunity to effect other improvements there in time. Professor Morris is already arranging new toilet rooms and getting ready to tear down the brick partitions which have been found to be in the way of the new arrangement. Professors Van Vleck and Smith are preparing plans for the belting and countershafting, in consultation with Professor Nichols, and the work is to be proceeded with at once. The space now given up to this machinery must, however, in time be required for the extension of the machine shop, and it is only a question of time when a building must be constructed for this conrse and its collections. Nearly forty students now enter the course annually, and it is only second to the regular course in mechanical engineering in importance in the Sibley College organization. The expenditure of all that may be needed to make its material part complete, aided as it is so effectively by its friends outside the University, will be more than justified.

Professor Thurston estimates that about $100,000 should be expended in its permanent establishment; $60,000 on building, including $15,000 on water and steam power, each of which should give 150 h. p., the one for use in ordinary work, the other whenever experimental work compels the utmost possible regularity of speed; and the balance, $40,000, in supplying needed additions to the equipment of apparatus of exact measurement for heavy currents and to furnish the income needed for running expenses, including fuel, one workman and an assistant to the professor of physics who should be placed in charge of this valuable property; which, although a part of the Sibley College establishment, is really managed by the department of physics in all except its power-supply. It is not impossible that, as Mr. Cornell used to say. "There is some one walking around who wants to provide this" now greatly needed laboratory. It is certainly an opportunity for some wealthy and public spirited friend of the university and of this part of its work to immortalize itself, while doing a noble work for his fellows.—*The Cornell Sun.*

OBITUARY.

Gustave Robert Kirchhoff.

Gustave Robert Kirchhoff, the German scientist, and inventor of the spectroscope, died October 17th. He was 64 years of age. Born in Koenigsberg, and graduating in medicine at the university of his native city, he went to Berlin, where he practiced his profession until 1850, when he was appointed professor of physics at Breslau. Four years later he took the same chair in the faculty at Heidelberg, and in 1875 he was appointed to the same professorship at Berlin, and elected a member of the Academy of Sciences. Before this he had made for himself a noted name in the scientific world by his researches and discoveries in the field of electricity and his studies of the elasticity and tension of steam. In 1859, with M. Bunsen, he made the wonderful discovery of spectrum analysis. This discovery, applied to the investigation of the physical nature of the celestial bodies, gave birth to a new and very interesting science—physical astronomy, to which a number of savants, notably M. Janssen, in France, and Mr. Lockyer, in England, have devoted themselves with important scientific results. Kirchhoff published his own discoveries in this field in a work entitled "Studies of the Solar Spectrum and the Spectra of Simple Bodies," issued in Berlin in 1866.

O. E. Woodhouse.

Mr. O. E. Woodhouse, senior partner of the electrical engineering firm of Woodhouse & Rawson, London, died at Brighton, October 21. Mr. Woodhouse was born in London, October 21, 1855. At King's College, London, he acquired a knowledge of physical science which well qualified him for his career as an electrical engineer. Leaving college, he began his work by entering the shops of Messrs. Hunter & English, where he passed three years. In 1877 he entered the railway service, taking a position with the Great Eastern Railway Co., and afterwards with the London and Northwestern Railway Co.'s locomotive department, where he continued till early in 1881. In the summer of 1880 Mr. Woodhouse visited the United States and Canada, where he spent six months in examining engineering and scientific works. Soon after his return to England in 1881, he entered into partnership

Digitized by Google

with Mr. F. L. Rawson in the business of general electrical engineering, in which field the firm of Woodhouse & Rawson has since achieved distinguished success. Such thoroughly trained and energetic workers in the field of electrical engineering as Mr. Woodhouse can ill be spared from a vocation in which the work to be done increases faster than competent hands can be found to carry it forward.

REVISION OF THE PATENT LAW PROPOSED BY THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

"The members of the National Electric Light Association, an organization of companies and individuals engaged in the electric lighting business and branches of industry collateral thereto, have felt, through sad experience, the great need of certain reforms in the patent laws of the United States, in consequence of which the following bill will be introduced into the Fiftieth Congress, and an attempt be made to secure its passage. The association would call the attention of patentees and all those who have the industrial prosperity of our country at heart to aid them, in this effort, to put our patent system on a footing which will secure the beneficient results, of which such a system properly organized and administered is capable."

J. F. MORRISON,
President National Electric Light Association.
Brush Electric Light Co. of Baltimore.
FRANK RIDLON,
Sun Electric Light Co., Woburn, Mass.
F. J. SPRAGUE,
Sprague Electric Railway and Motor Co., N. Y.
WALTER C. KERR,
Westinghouse, Church, Kerr & Co., N. Y.
ARTHUR STEUART,
General Counsel National Electric Light Ass'n.
CHAIRMAN
COMMITTEE ON LEGISLATION.

A BILL CREATING A COMMISSION TO EXAMINE AND REPORT TO CONGRESS NEEDFUL REFORMS IN THE PATENT LAW.

Whereas, The Patent Laws of the United States are deemed to be in such a condition as to require revision; therefore,

Be it enacted, by the Senate and House of Representatives of the United States, in Congress assembled:

Section 1. That a commission be, and the same is hereby created, to consist of three suitable persons to be appointed by the President of the United States, who shall hold office until a final report of this commission is submitted to and accepted by Congress, and who shall receive for their service a compensation of $5,000 each per annum.

Sec. 2. It shall be the duty of this commission to examine thoroughly the patent laws of the United States, and those of other countries, and their practical operation and effect, in meeting the needs of the public and fulfilling the purposes for which they were created; to formulate a report to be submitted to Congress which shall set forth the results of this investigation and their conclusions therefrom, with reference to changes in, or additions to, the present law, pertaining to patents. The report shall also contain a draft of an act which will provide for the changes found necessary by the investigations of the commission.

Sec. 3. The commission is authorized to employ such clerical force as may be necessary for the proper conduct of its work and to incur such other expenses for stationery, printing, etc., as may be found expedient.

Sec. 4. The salaries of the members of this commission as well as all expenses legitimately incident to its work, shall be paid from the surplus in the United States Treasury to the credit of the patent office. All expenditures by or for said commission, other than the salaries of the members, shall, however, be under the control of and authorized by the Secretary of the Interior.

TELEGRAPHING TO AND FROM MOVING TRAINS.

The induction telegraph with which the Lehigh Valley railroad has been equipped by the Consolidated Railway Telegraph Co. as far as Easton, has proved completely successful. An exhibition of its operation was made October 6th to a large party of gentlemen interested in electrical and railroad work, who were invited to make a trip to Easton and return, by the Consolidated Railway Telegraph Co. During the trip some 400 telegrams were sent and received to and from New York and other points, and an opportunity was afforded to all the guests to inspect the apparatus and witness its operation. The system has been described heretofore in various journals. The entire transmitting apparatus has been so simplified and condensed as to be mounted on a lap-tablet, including space for message blanks. On the occasion of the excursion an extra receiving telephone was provided for the use of the guests, of whom all who were familiar with Morse signals were surprised and delighted by the distinctness of the signals. The system has now been in regular use on the Lehigh Valley road nearly six months, and there is no longer any doubt of its entire practicability.

A PERMANENT TECHNICAL EXHIBITION AT ST. PETERSBURG.

The Association of Engineers of Ways and Communication of St. Petersburg, have issued a prospectus for a permanent technical exhibition in the Russian capital, open to exhibitors in any part of the world, and including exhibits classified as follows:

1. Machines, implements, tools, apparatus, etc., having connection with any branch of engineering.
2. Samples of building material.
3. Models, drawings, technical books, pamphlets, etc.

For the space occupied the exhibitor is charged at the following rates: One square foot, 20 roubles a year; two square feet, 35 roubles a year; three square feet, 45 roubles a year; four square feet, 30 roubles a year; and for every square foot exceeding, five roubles a year is charged extra, payable in advance for six months. The models and plans of new inventions occupying not more than two square feet, will be admitted gratis for the period of two months.

In order that the exhibition may serve as a useful medium between the exhibitor and the visitor of the exhibition, the administration will give to all inquiries its full attention, but they must be in writing, and relating to engineering and its kindred branches.

The administration will issue lists, drawings, etc., indicating latest improvements in all branches known to the administration, and, at the same time, execute orders on rates of regular commission houses. The exhibition objects will have to be provided with detailed descriptions indicating their use, or be described by catalogue, including selling prices if to be sold.

Persons visiting the exhibition can have all the information desired by applying to the superintendent, who will always be present during the hours in which the exhibition is open to visitors.

The electric section of the association gives especial attention to telegraphs, railroad signals, bells, telephones and electric lighting.

A. Warschawsky, 14 Dey street, New York, the general agent for North and South America, is prepared to furnish full information to intending exhibitors or others.

TELEPHONE EXCHANGE STATISTICS.

The report of the secretary, at the meeting of the National Telephone Association, at Pittsburgh, Sept. 26, on exchange statistics showed that of exchange subscribers New York had 6,881; Chicago, 4,577; Brooklyn, 3,297; Boston, 2,130; Baltimore, 2,105; Philadelphia, 2,420; Pittsburgh, 2,286; Providence, 2,417; Washington, 1,362; Buffalo, 1,767; Detroit, 2,585; Cincinnati, 2.900; Milwaukee, 1,732; Minneapolis, 1.387; Louisville, 1,661; St. Paul, 1,025; New Orleans, 1,148; New Haven, 1,227; Albany, 1,258. No figures were obtained from Kansas City, San Francisco, and a few other large cities. New York, it appeared, had just doubled its subscribers since 1882, and in this respect is nearly paralleled by Chicago. The number of daily exchange connections in New York is 84,750; Chicago, 44,292; Cincinnati, 45,000; Detroit, 33,146; Brooklyn, 17,508; Boston, 17,345; Baltimore, 19,275; Philadelphia, 17,098; Pittsburgh, 18,492; Minneapolis, 16,000. The daily calls per subscriber average in New York, 12.3; in Cincinnati, 15.5; Richmond, 12.9; Detroit, 12.8; East Saginaw, 13.0; Minneapolis, 15.5. The number for New York last year was only 6.5, indicating an increase of work for the exchange, per subscriber, of nearly 100 per cent. The number of subscribers' wires per operator was 157 in New Orleans; 84 in New York; 84 in Richmond; 95 in Boston; 98 in Baltimore; 80 in Washington. New York had 755 trunk lines; Chicago, 369; Boston, 213; Brooklyn, 221; Cincinnati, 260; Jersey City, 69; Pittsburgh, 78; Providence, 39. New York showed a gain of 155 trunk lines over 1886. New York had 43 daily connections per trunk; Detroit, 155; Reading, 76; Worcester, 80; Louisville, 40; Pittsburgh, 69; Chicago, 75; Williamsport, 48. In the matter of exchange wires, Providence showed 322 "direct" and 675 "circuit;" St. Paul, 469 and 210; Washington, 478 and 300; Worcester, 57 and 215; Minneapolis, 579 and 281; Portland, 45 and 316; Hartford, 176 and 193; New York, 6,842 and 8; Philadelphia, 1,897 and 132; Baltimore, 1,078 and 372. The cost of one connection in New York was .0078; in Philadelphia, .0037; in Brooklyn, .0041; in Chicago, .0040; in Denver, .0055; in Washington, .0037; in New Orleans, .0018; in Minneapolis, .0016.

GAS ENGINES EMPLOYED IN A CENTRAL STATION PLANT.

At Spencer, Mass., a Ball arc-light plant of 60 lamps is run entirely by gas engines. Three Otto engines, of 15 nominal h. p. each, are used. The plant is owned and operated by the Spencer Gas Co., who thus manage to keep the business of lighting the town, while utilizing their own product. Very favorable reports are made of the successful and economical performance of the system at Spencer.

THE ORLANDO GAS AND ELECTRIC LIGHT CO. will erect an electric light plant at Orlando, Fla.

THE SPENCER (MASS.) GAS CO. has placed in its works three 15 h. p. gas engines, with which it intends running its electric light plant.

THE DULUTH ELECTRIC LIGHT CO. has increased its capital stock $50,000. A new building to cost $5,000 will be put up. The plant will be increased to 175 2,000 c. p. lights; a new 150 h. p. Corliss engine will be put in, and two new dynamos added. A $20,000 addition to the City Hotel will be built.

THE KENSINGTON ELECTRIC LIGHT CO., Kensington, Ill., has been incorporated, with a capital of $20,000. Messrs. Wm. Birdsall, W. B. Williams, Erastus Gates, Jas. O'Brien and Jno. Beaton, are named as corporators.

THE HAUSS ELECTRIC LIGHT CO. will erect an electric light plant at Chattanooga, Tenn.

THE CHICOPEE ELECTRIC LIGHT CO. will erect an electric light plant at Chicopee, Mass.

THE NEW ALBANY ELECTRIC LIGHT AND POWER CO., New Albany, Ind., expect to put in a $40,000 electric lighting plant.

Foreign.

Germany.—The work in connection with the extension of the supply from the central electric light station known as the Städtische Elektricitätswerke in Berlin is rapidly approaching completion. The Royal Theatre has just been fitted with 1,500 glow lamps, which are supplied from the mains of that station, and the Royal Opera House is now receiving an installation of glow lamps, so as to be ready for the coming season. The total area at present supplied from the station is approximately a square of 1,600 feet sides, but further extensions are contemplated. The distributing plant has been put down in a most substantial manner. Briefly described, it consists of a network of mains, various points of which are joined to the station by feeders. These junctions are placed in special cast iron feeding boxes, and in addition to these there is a large number of distributing boxes where the service wires to the different houses are joined to the mains. The sectional area of the main conductors varies between .24 and 1.4 square inch. The cables are all lead covered, with an outside serving of iron tape for greater protection; and in places where special precautions are necessary, such as street crossings, or in the neighborhood of gas and water pipes, the cables are drawn through iron tubes. Where the streets are straight and of sufficient width the different cables have been laid side by side; but where sufficient space could not be found they are arranged above each other, with wood distance pieces between them. This somewhat elaborate system of underground street mains, says *Industries*, although rather costly, has the advantage of equalizing the potential throughout the district, and of permitting easy access for purposes of repair or the connection of new subscribers. In order to distinguish the cables at any place each has been wrapped round at every 7 feet run with a short length of lead tape bearing a distinctive stamped mark.

COLUMBUS, O.—The electric railway is constructed upon the system of Prof. John H. Short, of Denver, Col., formerly of Columbus. It is called the series system, because the same current is sent through each car in succession, as is done in the arc system of electric lights. This road will be the second ever put in under this system. Two trains of cars will be run. The cars will have a carrying capacity of 120 passengers each. The speed will be about 10 miles an hour.

DAYTON (OHIO) WHITE LINE STREET RAILWAY CO.—Work was begun on this new road August 1st, and it is expected that the road will be opened by November 1st. They will use the Van Depoele system, having part overhead wires and part underground conduit. The total length of track will be 8½ miles of 4 ft. 8 in. gauge, 38 lb. rail, 16 cars, 13 motors. The capital stock of the company is $200,000, and the officers are: president, John A. McMahon; secretary, Charles D. Iddings; treasurer, Michael A. Nipgen.

BINGHAMTON, N. Y.—The electric railway on Washington street, running to the state asylum, has now been in operation about four months and has proved entirely satisfactory to the owners. The six motor cars run on an average, over 60 miles a day each. One hundred and seventy-five thousand passengers have been carried since the use of the electric motors was begun, more than twice as many as were carried by horses during a similar period. The electric outfit is from the Van Depoele company, and the managers of the road speak in high terms of their satisfaction with its performance. The road has grades as high as seven per cent. which are got over without difficulty.

ST. CATHERINES, CAN.—The St. Catherines, Merritton & Thorold Street Railway Co. ran its first electric car over its road October 5, and since that date it has run on schedule time with the horse cars without interruption. The line, of nearly six miles, follows the Welland canal closely, and is full of curves and grades. There are twenty-three grades, the steepest being 6.33 per cent., the lowest .87 per cent., averaging about 4 per cent. The road is extremely tortuous, having no less than thirty-three curves. Mr. E. A. Smyth, the president of the road, expresses his unqualified satisfaction with the performance of electricity as a motive power for street cars on his road, and expects soon to have twelve cars fully equipped and running. This road employs the Van Depoele motors and an overhead conductor, and its installation adds one more to the rapidly-growing list of street railways successfully equipped by the Van Depoele company. The railway company have built a new power station for themselves, leasing water power from the Canadian government on the Welland canal, paying them at the rate of about one dollar per horse-power per annum. They have over 400 actual h. p. at their water-wheel. Having such an abundance of power, the company have arranged to run several motors along the line for various manufacturers, so that by the first of January next it is expected that the cost of running the cars with electric power will be reduced to about 30 cents per day per car. A 100 h. p. generator is now in operation, and another is intended to be placed shortly. The motor used on the car is of 15 h. p.

THE WEST END STREET RAILWAY CO., BOSTON, MASS.—The trials of the experimental electric car, recently received from New York, have proved very satisfactory. Further tests are going forward in order to determine the most economical arrangement of the motor for the particular work required. The car will probably be put in regular passenger service on the Cambridge line early in November.

NEW INCORPORATIONS.

The Sterling Electric Light and Power Co., Sterling, Kas. Capital stock, $12,000. Jno. K. Skiles, and others, incorporators.

The Kankakee Electric Co., Kankakee, Ill. Capital stock, $10,000. William S. Reed, and others, incorporators.

The Peru Electric Light and Water Supply Co., Peru, Ill. Capital stock, $8,000. W. K. Hoagland, and others, incorporators.

The Catskill Electric Light Co., Catskill, N. Y. Capital stock, $20,000. Manly B. Mattice, and others, incorporators.

The Oneonta Electric Light and Power Co., Oneonta, N. Y. Capital stock, $15,000. Harlow E. Bundy, and others, incorporators.

The Bessemer Electric Light and Power Co., Bessemer, Ala. Capital stock, $50,000. E. A. Burke, and others, incorporators.

The Canastota Electric Light and Power Co., Canastota, N. Y. Capital stock, $10,000. W. H. Patten, and others, incorporators.

The Mauch Chunk Electric Light Co., Mauch Chunk, Pa. Capital stock, $1,500. H. W. McClure, and others, incorporators.

The East Berkeley Electric Light Co., Berkeley, Cal. Capital stock, $30,000. J. L. Barker, and others, incorporators.

The Mexico Electric Light and Power Co., Mexico, N. Y. Capital stock, $8,000. W. H. Weed, and others, incorporators.

The Sanford Light and Water Co., Sanford, Me. Capital stock, $6,000. E. M. Goodall and George H. Nowell, incorporators.

The Cambridge Electric Light and Telephone Co., Cambridge, Ohio. Capital stock, $15,000. J. C. Steele, and others, incorporators.

The Edison Electric Light Co., Salida, Col. Capital stock, $15,000. William W. Roller, and others, incorporators.

The Iron Mountain Electric Light Co., Iron Mountain, Mich. Capital stock, $25,000. Arthur D. Moore, and others, incorporators.

The Kinsley Street Railway and Electric Lighting Co., Kinsley, Kas. Capital stock, $100,000. C. A. Read, and others, incorporators.

The Fenton Electric Light Co., of Fenton, Mich. Capital stock, $10,000.

The Cooperstown Light and Power Co., Otsego, N. Y. Capital stock, $20,000. Messrs. J. W. Hult, Dudley Farlin, Charles D. Hammond, and others, are incorporators.

The Edison Illuminating Co., Orange, N. J. Capital stock, $100,000. Eugene S. Kass, and others, incorporators.

The Owego Electric Light and Motor Co., Owego, N. Y. Capital stock, $12,000. John Jones, and others, incorporators.

The Citizen's Mutual Light, Heat and Power Co. Utica, N. Y. Capital stock, $50,000. Geo. D. Dimon, and others, incorporators.

The Citizen's Electric Light and Power Co., Wellsville, Ohio. Capital stock, $20,000. E. G. Whitacre, and others, incorporators.

Digitized by Google

The Peninsular Electric Light and Power Co., Houghton, Mich., capital stock, $50,000. President, Hon. Jay A. Hubbell, secretary and treasurer Jas. B. Sturgis, general manager, Jas. R. Dee. They use the Thomson-Houston system, one 45 and three 30 light arc machines, and have 60 to 70 series incandescent lamp on the circuits.

MANUFACTURING AND TRADE NOTES.

THE WHEELER REFLECTOR CO. issue a finely illustrated catalogue of their reflectors, exhibiting forms adapted for all methods of lighting, including daylight reflectors for windows opening on alleys or very narrow passages. They show a number of patterns specially designed for electric lamps, both arc and incandescent.

CONSIDERABLE interest has been shown recently with respect to the use of the "P. & B." compounds, in several branches of elec trical work. The compound has been used for about a year for electric light plants in a good many directions, with very good results it is said. It has been used for painting mouldings in damp places, for splices on wire and for switches and cut-out boxes in damp places, and for back-boarding, The compound seems to be a good preservative against moisture. It has also been used on wire, going through brick walls, where the wire is tied to the knobs, and generally on all wood work in damp places. It is said to possess high insulating qualities, and has been used by the electrician of the N. Y. and Brooklyn Bridge for the past year for insulating the electric light wires that are run on iron poles. The Standard Paint Co., 59 Maiden Lane, who are the manufacturers of the P. & B. compounds, have received letters from other electric light companies, who have tested and used their compounds and who all speak highly of its insulating properties. It has also been found useful for coating battery jars. The compound is said to resist strong acids and alkalis, and to be thoroughly waterproof. A good waterproof and insulating paint should find large use in electrical construction.

MESSRS. SCHIEREN & CO. report sales of electric leather belting during the past week to the following parties: Natick Electric Light Co., Natick, Mass., 42 feet, 10 inches double; Skowhegan Electric Light Co., Skowhegan, Me., 29½ feet, 8 inches double; Mahoming Electric Light Co., Youngstown, O., 47 feet, 8 inches double—47 feet, 10 inches double; Portsmouth Electric Light Co., Portsmouth, N. H., 65 2-12 feet, 4 inches double; Chas. C. Clausen, New York, 62 feet, 1 inch double; Monadnock Mills, Claremont, N. H., 300 feet, 3 inches double.

THE WAINWRIGHT MANUFACTURING CO., of Boston, with works at Medford, has shipped its feed-water heaters during the month of August to the following places: two to New York city, two to Philadelphia, one each to Bangor, Me., New Britain, Conn., Newark, N. J., Summerfield, Md., Cleveland, O., Decatur, Ala., Waukesha, Wis., and St. Paul, Minn. It reports that orders and inquiries as to its specialties are constant and increasing.

THE W. L. DENIO FIRE ALARM CO., Rochester, N. Y., are making and introducing a thermostat, using a closed circuit. The thermostat consists of a strip of metal fusible at a low temperature (155° to 160°). There is an obvious advantage in using a closed circuit in any protective apparatus; its greater consumption of battery being more than counterbalanced by the greater safety due to its capacity to indicate automatically any failure of battery.

A DUPLEX AIR COMPRESSOR for Japan is included in last month's shipments of the Clayton Air Compressor Works, of Brooklyn, N. Y., whose machines are now in use in Russia, Australia, Mexico, West Indies, Spain, Canada, and most of the South American republics. For the most part, however, the sales are for use in this country, where the Clayton Air Compressors are highly appreciated by miners and contractors.

A material increase in orders is reported since these works opened an office and salesroom at 43 Dey street, New York.

THE CAMPBELL ELECTRICAL SUPPLY CO., of Boston, have appointed as their New York agents, Messrs. Knapp & Hague, No. 52 Fulton street, who are well known in this city, and they will undoubtedly secure for that company a large business in their now well-known "Line Wire."

THE PHOSPHOR-BRONZE SMELTING CO. (LIMITED), of Philadelphia, are introducing a "Phosphorized Anti-Friction Metal," for heavy pressure and high-speed bearings. It is used in the same manner as Babbitt metal, and is claimed to possess the desirable qualities of fluidity when melted, freedom from dross and shrinkage, and low specific gravity, and to fill more bearings than most other metals. It has been used for some years by several large consumers.

THE ELECTRIC LIGHT RADIATORS made by Messrs. J. Hoare & Co., Corning, N. Y., are much liked by all who have used them. Their effect upon an incandescent light is extremely beautiful. They are very attractive, particularly for use in domestic lighting.

THE GAYNOR ELECTRIC CO. has been organized and established at Louisville, Ky., for the manufacture of the "Rapid Fire Alarm and Police Signal System" and general electrical goods. They will also be dealers in general electrical supplies. The company was incorporated September 3d, 1887. The directors are, Chas. R. Long, John J. Barret, Thos. F. Gaynor, Jno. H. Sutcliff and C. A. Warren.

THE EXCELSIOR SYSTEM of Electric Lighting is on trial at Tarrytown, N. Y. Mr. Edward P. Thompson, of this city, was appointed by Mr. George Silver and other gentlemen of the town to inspect and report upon the merits of the system before its final acceptance. A favorable report has been submitted by Mr. Thompson, and it is expected that Tarrytown will continue to be lighted by electricity. Forty-four lamps are in circuit at present operating at 1,500 c.p., with a Payne & Sons' steam engine of 80 horse-power.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions, 11 Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Sept. 20th to Oct. 11th, 1887 (inclusive).

Alarms and Signals:—*Fire Alarm Box*, B. S. Flanders, 370,328, September 20. *Electric Burglar Alarm*, J. B. Yeakle and A. Steuart, 370,439, September 27. *Electric Signaling Apparatus*, J. P. Tirrell, 370,831. *Fire-Damp Annunciator*, A. Berghausen, 370,851. *Fire Alarm and Police Telegraph System*, A. M. Neeper, 370,885. *Thermostat*, W. H. H. Barton, 371,121, October 4. *Electric Signaling Apparatus*, W. Glascow and S. S. Stevens, 371,445, Oct. 11.

Clocks:—*Electric Alarm Clock*, E. J. Colby, 370,932, October 4.

Conductors, Insulators, Supports and Systems:—*Underground Conduit for Electric and other Railways*, E. E. Ries, 370,283, September 20. *Electric Cable*, F. Borel, 370,528, September 27. *Subterranean Electric Line System*, G. W. LeVin, 370,955. *Conduit for Electrical Distribution*, T. Wallace, 371,111, October 4. *Insulating Clamp for Electric Conductors*, T. E. Adams, 371,161. *Electric Wire Conduit*, J. Lynch, 371,202. *Plastic Composition for Insulating Electric Wires, &c.*, W. W. Barnes, 371,406, October 11.

Distribution:—*Electrical Transmission of Power*, T. A. Edison, 370,125, 370,126, 370,127, 370,128, 370,129, 370,130, and 370,131, September 20. *System of Electrical Distribution*, F. A. Wessel, 370,434. *Regulating Device for Alternate Current Circuits*, E. Thomson, 370,573, September 27.

Dynamos and Motors:—*Dynamo-Electric Machine*, W. Lahmeyer, 370,794, October 4. *Method of, and Apparatus for Starting Electric Motors*, L. Daft, 371,436. *Reversing Mechanism for Electric Motors*, F. E. Fisher, 371,443, October 11.

Galvanic Batteries:—*Primary Battery*, M. Bailey and J. Warner, 371,244, October 11.

Ignition:—*Electric Gas-Lighter*, J. J. McGowen, 370,801, October 4.

Lamps and Appurtenances:—*Signal and Pyrotechnic Electric Light*, A. C. Ferguson, 370,052. *Manufacture of Filaments for Incandescing Electric Lights*, T. A. Edison, 370,124, September 20. *Electric Lamp*, J. J. Skinner, 370,423 and 370,424. *Electric Arc Lamp*, E. Thomson and E. W. Rice, Jr., 370,572, September 27. *Process of Treating Electric Light Filaments*, E. P. Thompson, 370,992. *Incandescent Electric Lamp*, same, 370,993. *Process of Manufacturing Filaments for Incandescent Electric Lamps*, same, 370,995. *Process of Evacuating Globes for Incandescent Electric Lamps*, same, 370,994 and 370,996. *Method of Evacuating Incandescent Electric Lamps*, same, 370,997. *Process of Forming Filaments for Incandescent Electric Lamps*, same 370,998. *Manufacture of Incandescent Electric Lamps*, same, 370,999. *Process of Bending Filaments for Incandescent Electric Lamps*, same, 371,000. *Process of Treating Filaments for Incandescent Electric Lamps*, same, 371,001 and 371,002. *Incandescent Electric Lamp*, same, 371,003, October 4.

Measurement:—*Electric Meter*, T. A. Edison, 370,123, September 20.

Medical and Surgical:—*Voltaic Inner Sole*, G. A. Fullerton, 371,189. *Electric Therapeutic Belt*, W. L. L. Pierce and W. J. Pierce, 371,356, October 11.

Metallurgy:—*Process of Separating Metals from their Ores*, D. W. Birmingham, 370,366, September 20. *Amalgamator*, J. A. Sperry, 371,523, October 11.

Miscellaneous:—*Electric Welding and Tempering Metals*, E. E. Ries, 370,282, September 20. *Fusible Link for Automatic Fire-Extinguishers*, O. B. Hall, 370,390. *Electric Speed Regulator for Revolving Motors*, F. Van Rysselberghe, 370,575. *Apparatus for Wiping Metal-Coated Wire*. C. E. Matteson, 370,710, September 27. *Electric Spinning or Twisting Machine*, A. S. Kimball and G. L. Brownell, 371,199. *Process of Coating Iron with Tin or its Alloys or other Metals*. E. I. Braddock, 371,248. *Apparatus for Forming Sheet Metal by Electro-Deposition*, E. Emerson, 371,256. *Apparatus for the Transmission of Electrical Energy*. G. Kornmuller, 371,331. *Galvanic* Ring, H. N. Rowell, 371,521. *Induction Coil*, E. Smith, 371,524, October 11.

Railways and Appliances:—*Electric Attachment for Locomotives*, N. F. Chase, 370,243, September 20. *Coupling for Electro-Pneumatic Brake System*, J. F. Carpenter, 370,605, September 27. *Electric Car-Brake*, W. M. Schlesinger, 370,894. *Railway Signal*, P. Milroy, 371,147, October 4. *Electric Locomotion*, L. Daft, 371,253, October 11.

Storage Batteries:—*Secondary Battery*, O. C. Flick, 370,134, September 20. A. Reckenzaun, 371,358, October 11.

Telegraphs:—*Telegraphy*, T. A. Edison, 370,132. *Printing Telegraph*, R. J. Sheehy, 370,357, September 20. *Repeater for Harmonic Telegraphs*, F. Van Rysselberghe, 370,576. *Phono-Multiple Telegraphy*, same, 370,577. *Printing Telegraph*, S. D. Field, 370,691, September 27. *Telegraph Receiver*, Charles Selden, 370,808. *Printing Telegraph*, R. J. Sheehy, 370,978, October 4. *Method of Operating with Electrical Conductors*, J. E. Watson, 371,531, October 11.

Telephones, Systems and Apparatus:—*Adjustable Support and Automatic Switch for Telephones*, S. P. Jermain, 370,193. *Auditory Transmitter for Telephones*, M. H. Allison, 370,240. *Telephone System*, F. C. Watkins, 370,293, September 20. *Telephone*, H. V. Hayes, 370,477, September 27. *Resonant Attachment for Telephones*, E. A. Balloch, 370,847, October 4. *Telephone System and Apparatus*, G. T. Woods, 371,241. *Telephone Switch*. W. M. Goodridge, 371,260. *Mechanical Telephone*, W. H. Eastman, 371,439, October 11.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

NEW YORK, DECEMBER, 1887.

Beginning with the number for January, 1888, *the double title of* THE ELECTRICIAN AND ELECTRICAL ENGINEER, *will be discontinued, and the Journal will appear under the single title,* **THE ELECTRICAL ENGINEER.** *A whiter paper will be used for the letter-press, and the cover will be of a more agreeable color than at present. It is believed that these changes will be acceptable to subscribers and readers.*

PATENT OFFICE REFORM.

WHILE approving entirely the specific reforms sought in the administration of the patent law and the practice of the Patent Office as formulated by Mr. Arthur Steuart, chairman of the legal committee of the National Electric Light Association at the meetings of that body in February and August last (see THE ELECTRICIAN AND ELECTRICAL ENGINEER, March and September) and more fully set forth in the pamphlet recently issued by the Association, we are constrained to doubt seriously the wisdom of introducing to Congress the bill, prepared and published by the Electric Light Association, to create a commission for the general revision of the patent law. The text of the proposed bill was published in our November issue. Its passage through Congress would throw open for consideration and revision the entire patent system of the country. Right here lies our doubt as to the wisdom of presenting the bill to Congress. Neither the time nor the public temper seem favorable to a result desirable for the best interests of the industrial community. The presidential election will occupy in large measure the attention of congressmen and senators during the coming year. Such periods are not usually conducive to sober, rational and intelligent consideration of measures so important and complicated as a revision of the patent law. Probably no feature of the national polity is less understood, in its legal basis and its practical conduct, by the general public, or even by the average member of Congress, than the patent system There is a somewhat widespread popular impression, shared by many who have no excuse for not knowing better, that a patent is a sort of prize or bonus, bestowed as a reward by the government upon certain more or less meritorious persons, in recognition of their inventive faculty, and by virtue of which they levy tribute on their less fortunate countrymen. The fundamental principle of the patent law—clearly set forth in the constitutional provision on which the whole system is based,—to wit,—an equitable, or at least, an expedient contract between the public and the inventor, founded on an exchange of benefits, has made its way but feebly into popular apprehension. Neither has the general public an adequate conception of the large part performed by the patent system in the industrial development of the United States, much of which comes home to everybody in the comforts and conveniences of daily life. There is a well marked tendency in many quarters, particularly among people whose thought, or want of thought, is tinctured with the granger influence of the West, to regard the patent system as chiefly a support for oppressive monopoly, and to attack it on every occasion. Whether or no such feeling has been justly aroused in particular instances is not relevant to our present subject, *i. e.*, the wisdom of submitting a revision of the entire patent law to the Congress about to convene. That such a feeling of hostility to patents exists, although chiefly founded on unreason or misapprehension, is very certain; and that many members of Congress will be peculiarly amenable to its influence under the political condition of the coming year seems not less certain. Moreover, to not a few attentive observers there has appeared in United States Supreme Court decisions in recent patent causes, an inclination to minimize the efficiency and scope of patent protection.

These considerations call for very careful attention on the part of those who seek improvement in the patent system, and suggests very grave doubts of the expediency of pressing such a measure as that proposed by the National Electric Light Association.

The specific reforms advocated by the Association and sought to be incorporated in a revision of the patent law by the proposed commission are substantially as follows:—

A thorough preliminary training and a secure tenure of office for examiners, thus securing greater efficiency and immunity from political influence.

Occupancy of the entire Patent Office building by the department from which it takes its name, thus providing adequate space for the business of the office.

The establishment and maintenance of a properly equipped laboratory for experimental demonstration of the operativeness and utility of inventions.

The setting up of a court, within the Patent Office, to

Digitized by Google

have the jurisdiction at present distributed between the Board of Examiners in Chief, the Examiner of Interferences and the Commissioner of Patents—thus relieving the commissioner entirely, and the examiners in part, of judicial functions, and providing also a court before which many questions that now come before the United States Circuit Courts could be determined.

These changes in organization and practice would unquestionably result in greater efficiency and uniformity in conducting the business of the Patent Office, and so redound to the advantage of inventors and of industrial enterprises based upon patent protection ;—but, is it reasonable to expect their accomplishment through a congressional commission for a general overhauling of the patent law and practice?—We fear not. We are not unmindful that our present views on this topic may seem inconsistent with our brief commendation of the action of the Electric Light Association in our November issue, but we aim less at consistency than at the expression of our strongest convictions on a subject so important as that now under consideration. We believe there is good reason for apprehension that the creation of a commissioner to revise the entire patent system, will invite the attack of prejudice and ignorance upon the system as a whole ; attacks which under present political conditions are likely to enlist the co-operation of many politicians, in and out of Congress, and that the result might prove to be a material impairment of the efficacy and scope of the patent system in developing the industries of the country, and securing compensation to meritorious inventors.

Reform of the tariff on imports by commission has fared but ill at the hands of Congress. Is there any reason to expect less abortive results in the case of the patent system? The latter is a subject of greater difficulty and complexity than the former, and is quite as closely, if not more closely, related to the industrial interests of the land ; yet it is less clearly understood in both theory and practice than is the tariff. There is a sort of mystery about it in popular imagination, something magical, that creates a fortune for the individual lucky enough to get the seal of the Patent Office upon his invention. Probably few persons instructed by experience, study or observation in the working of the United States patent system, and realizing the extent to which it has stimulated the discovery and application of new principles and improvement in the useful arts, upon which all our industry is based, would approve any fundamental changes in the patent law. There seems to us to be danger of such changes in opening the question of a general revision.

STREET-RAILWAY TRACTION IN NEW YORK.

It is authoritatively announced that the Third Avenue Surface Railroad Co. has definitely determined to commence the work of putting in a cable traction system, for operating its street-car line between the City Hall and Harlem bridge, as soon as the courts have decided that it may lawfully do so. The estimated cost of the cable plant, which we understand is to be similar to that now in use upon the Tenth avenue line of the same company, is stated to be $1,500,000.

This determination upon the part of the management of such an important street railway line, will doubtless cause some little surprise in electrical circles, especially in view of the rapid advance which has been made during the past year or two in the application of electricity to this class of traffic. Yet upon consideration, it is difficult to see how any other conclusion could have been reached, in view of the fact that it was apparently necessary that some decision should be reached at once. While no well informed electrical engineer has any doubt that it is entirly feasible to construct and maintain an electric plant of the dimensions required in the present case for less than one-half the sum which will have to be expended upon the cable, yet, at present, it cannot be said that there exists a single electrical establishment in this country, which could be depended upon to undertake the work of furnishing equipment for such a line as the Third avenue, for a fixed sum and to be delivered within a fixed time, and to guarantee its successful and satisfactory operation. Hence it is not to be wondered at, that the Third avenue company, having an enormous and practically constant traffic which has outgrown its present facilities, and a line nearly eight miles in length, with almost no curvature—conditions most favorable for the economical application of cable traction—should prefer to adopt it, especially as responsible engineering firms stand ready at any moment to undertake the work.

Nevertheless, we venture the prediction, that within five years, the managers of the Third avenue company will have cause to regret the decision, which under existing circumstances, it has practically been forced to make. It would hardly afford the Third avenue people much gratification to see a parallel line doing the same or even better work with a plant whose first cost and operating expenses were not more than one-half that of their own. Yet the probability that this will come to pass within a very few years is so great that it practically amounts to a certainty. The notion which prevails in some quarters, that electricity is less economical when employed on a large scale than on a small one, is an utter fallacy, and should not find credence for a moment among capable electricians. The cable traction system in practice is a vast improvement over horse-power, a remarkable triumph of mechanical ingenuity and constructive ability ; but it is not the final solution of the street railway problem, except under very special conditions, such for example as those which exist in San Francisco or Kansas City. As our English cousins would say, it is simply a question of *£. s. d.*, and from this point of view the ultimate result cannot be doubtful.

Those people—perhaps a considerable class—who like a brand new dramatic poem with their matutinal eggs and coffee were doubtless made happy by the recent journalistic enterprise of the New York *Times* in having Mr. Swinburne's poem cabled from London entire over night, and printing it next morning in its news columns. The not inconsiderable number of plain people who are accustomed to finding the morning's news in the leading pages of their newspaper, and who prefer their dramatic poetry in fair type and good paper before the evening fireside, may have felt somewhat aggrieved, not to say defrauded, on taking up the issue of the *Times* with "Locrine" spread over its first two pages. But the *Times* "beat" its contemporaries—none of them had the poem in its columns. It does not matter in the least whether or no many people wanted to read it ; and herein lies the solace for such honest folk as permitted themselves to feel swindled, and were perhaps tempted to profanity, by the exploit of the *Times*. If they will only bear in mind that the "journalism" of the day consists in large part in devising and executing "beats" on one's neighbors, they will suppress their annoyance and join in the felicitations which the *Times* has been bestowing upon itself and the Western Union Telegraph Co. since its noteworthy feat.

TRANSMITTING SPEECH BY INTERRUPTED ELECTRICAL CURRENTS.

BY C. J. KINTNER.

(Late Principal Examiner Class of Electricity, U. S. Patent Office.)

PERHAPS no better apparatus exists or will ever be devised for demonstrating the absolute correctness of Professor Bell's undulatory or wave theory than the instruments which bear his name and are so largely in public use to-day.

Two of these instruments connected in a metallic or all-wire circuit act respectively as a magneto generator and a magneto motor; the one setting in motion when spoken to currents of an alternating nature varying in volume, and the other responding to them so that its diaphragm correctly reproduces speech to the listener.

If, therefore, we analyze the action of the transmitting diaphragm we have the substantial action of its fellow at the receiving station; the vibrations being, however, diminished copies of those made by the transmitting diaphragm. If a pure musical tone entirely free from harmonics be uttered into the transmitter, the diaphragm will vibrate in such manner that the excursions from front to rear will be described in equal times, there being no irregular changes of velocity during any part of the excursion. This action gives a wave curve of regular rise and fall with equal distances between the wave crests. With such a tone, there are two, and only two dead points during each complete vibration of the diaphragm, but at each of these dead points the current on the line is nil, and a reversal takes place in each instance after said points are passed.

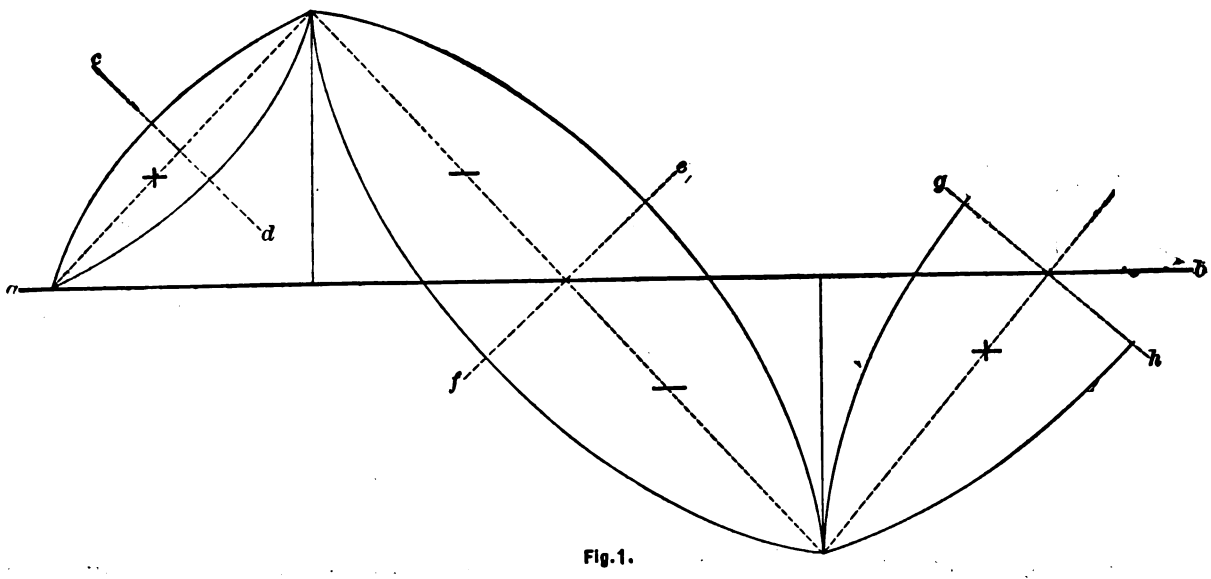

Fig. 1.

Figure 1 represents graphically the form of such waves and the volume of current flowing during any particular phase of the diaphragm; $a\ b$ being the medial line or position of the diaphragm at rest, plus currents appearing for the advance of the diaphragm, and minus currents for the retraction. The volume of current varies regularly from dead point to dead point, and has maximum values at $+\ c\ d$; $-\ e\ f$ and $+\ g\ h$. These currents may be represented algebraically by the following equation:—

$$c = \frac{V t}{d^2}.$$

Where v is the velocity of the diaphragm; t, the time elapsed since the diaphragm passed the medial line, and d the distance of the diaphragm from the core of the magnet at any point of its excursion. But v may be assumed to be constant for any interval of time, since the power due to this particular sound wave is a constant so that the velocity tends to be of a constantly accelerated nature, but is in fact opposed by a constantly increasing power in the opposition of the diaphragm under its increasing elastic stress. This equation shows that the current is nil at the start and that there is generated during the advance of the diaphragm, a plus current of constantly increasing volume until the value of d has diminished sufficiently to change its volume, when it will decrease till the first dead point is reached where it is again nil. Now a reversal takes place in the motion of the diaphragm and a minus current is set up which increases in volume, until d grows sufficiently large and v sufficiently small by reason of the increased elastic strain of the diaphragm to stop such increase, after which it decreases until the second dead point is reached when the current is again nil, thus alternating gradually varying impulses are set up in the line, or more properly alternating waves, which merge into each other so gradually, that like the swinging of a clock pendulum it is impossible to ascertain just when they begin or cease. In the transmission of this pure tone actual breaks of exceedingly small duration in the flow of the current may occur at these dead points, and not materially mar the tone copied at the receiving instrument, for the reason that the vibrations have symmetrical or regular recurrence. If this had been the whole problem in the transmission of speech by electricity it would have been very simple, and Philip Reis would have solved it when he invented his musical telephone. But there is another element which enters into the problem when we come to transmit composite tones like those of the human voice. This element was the stumbling block in the path of Reis, and it was Professor Bell's magneto instrument that led him to discover it. I refer to the overtones or divisional tones into which the fundamental tones merge. These tones exist, and are detected by delicate ears as low as the fourth order. Each order necessarily complicates matters and makes the problem the more difficult, but the magneto telephone solves the whole matter by causing its diaphragm to shape or conform itself to the resultant power of the sound waves, and each overtone on the advance of the diaphragm causes it to be retarded sufficiently to reverse the direction of the current or to diminish its effect, or if of such a nature as to aid the fundamental tone, then increased volumes are added to the fundamental volumes for the smallest imaginable fractions of a second, while any overtones on recessions of the diaphragm cause corresponding retardations and reversals or advances of the diaphragm on its back vibra-

Digitized by Google

tion. In other words, the diaphragm passes from the point of absolute rest to its fundamental dead point by a succession of direct, differential direct, and differential retrograde motions due to the combined action of the fundamental tone and overtones of all the orders. By this combined action of the fundamental tones with the overtones a prevailing plus impulse of electricity is generated, which is decreased and increased materially in its volume at specified points, which I denominate the overtone dead points by the reverse and direct action of all such overtones. As a matter of fact this direct current impulse is actually overcome at some points of the diaphragm's excursion. On reverse action a similar series of effects occur giving a minus fundamental impulse aided and opposed during its progress by the direct and reverse actions of the overtones which occur on that side, that is to say, during the back action of the diaphragm due to its elastic effect. With this action of the diaphragm there is found upon the line a series of electrical waves made up of a plus fundamental current, aided or retarded as the case may be by overtone currents of various orders combined in effect; and minus fundamental waves similarly aided or retarded during the back action of the diaphragm. In one sense of the word these currents are intermittent at stated points, but it may be asked if they are intermittent, who can tell where they commence and where cease. One fact is patent: namely, that there is no apparent actual intermission, and that the current volume changes during all the phases of the diaphragm in accordance with all of the sound waves both composite and simple. Strictly speaking, Professor Bell is theoretically right in calling the electrical effects waves, for there is no positive discontinuance of current which can be detected at any time, and their rise and fall in volume and regularity are entirely analogous to those of liquid waves even though one set be plus and the other minus. In fact, in actual liquid waves we have the same positive or upward action and negative or downward action, so that the simile is not a bad one. In figure 2, I have shown the form of electrical waves due to the combined action of the fundamental and overtones, *a b* being the medial line of the diaphragm. From *a* to *c* the diaphragm is advancing under the action of a fundamental tone, but at *c* it is checked by the action of one or more reverse overtones. This combined action of the advanced fundamental tone and reverse overtones diminishes the volume of current by reason of the resultant action of the two tones, as shown by the cross-section at *x x*. From *c* to *d* an increase due to the fundamental again occurs, but at *d* the combined overtone effect reverses the direction of the diaphragm and a minus current of small volume is generated, the diaphragm going back to the point shown by the ordinate *d*2. From *d*2 to *d'* the fundamental gives an increased current volume which is aided by a positive or plus overtone at *d'*, giving an increased current as shown by the cross-section at *z z*. Similar results take place at the other points of the diaphragm's excursion, as will be seen at *f g h l j*, etc. An analysis of this figure shows that there is a gradual rise and fall in the current volume for the fundamentals not unlike that shown in figure 1, but it also shows that the overtones vary this rise and fall, sometimes increasing and sometimes decreasing the volume of current due to the fundamental. Of course the figure is not mathematically accurate in its graphical representation of the currents generated, but it is sufficiently accurate to show the correct nature of the currents generated or set up by a magneto telephone.

If the diaphragm is sufficiently delicate in the transmitter every peculiarity of the sound waves is accurately copied, and it in turn by the action described, creates or sets up electrical waves entirely similar to the sound waves. No form of contact telephone with which I am familiar will give such accurate results as these magneto instruments; because contact telephones cannot be made so delicate, and also for the reason that they act to change the volume of an existing current and must be more or less clumsy in their construction and action, while the magneto sets up only the current actually needed; the diaphragm being free to copy accurately every peculiarity of the sound waves. The nearest approach to the perfect action of the Bell instruments is found in the microphone, but even it, fails in many respects because of imperfections, such as bad contacts, irregular conductivity, sparking, dust, etc., etc.

Fig. 2.

With this discussion of Professor Bell's theory, I am prepared to pass to the problem of transmitting speech by actual impulses or breaks, and shall endeavor to show in the next article that it is entirely possible, provided the current impulses or breaks correspond to the overtones as well as the fundamentals in the voice of the speaker. I do not maintain, however, that the speech will be as pure as that transmitted by the magneto instruments, as indeed, it is not with many contact telephones now in use, but I shall show that it is still possible to transmit speech which shall serve commercial purposes and not infringe Professor Bell's 5th claim before referred to. (See ELECTRICIAN AND ELECTRICAL ENGINEER, vol. vi., No. 71, p. 451.) The method relied upon will be, by current impulses equal in volume but differing in duration in direct proportion to the fundamental and overtones combined; the instrument for executing this method being such that the electrodes shall vibrate in direct unison with the diaphragm during all its phases.

(To be continued.)

TESTS OF THE JULIEN ACCUMULATOR.

BY GEORGE B. PRESCOTT, JR.

THE following electrical measurements of the Julien accumulator, were made in order to determine its adaptability to a certain class of work, and to that end, it has been sought to ascertain with as much accuracy as possible, its precise rate of doing work, the total amount which it is capable of performing, and its efficiency under various conditions, as a transformer of energy. For this purpose I employed five of the standard cells of the following dimensions, as determined by my own measurements, viz.:

Weight of cell complete	38 lbs.
" grids and active material	27.5 lbs.
" electrolyte	4.5 "
" glass containing jar	6 "
Number of positive plates	9
Dimensions " "	$5\frac{1}{16} \times 5\frac{1}{8}$ lbs.
Active surface of positive plates	4.25 sq. feet.

Three of the above cells were furnished directly from the works, especially for this test, and the remaining two were received from the works at the same time by Mr. Weston. These latter were incorporated into this test as it was deemed that greater accuracy could be attained by the use of a larger number of cells. It is assumed, of course, that all were thoroughly formed and in prime condition.

Three of the cells were filled with dilute sulphuric acid (free from nitric acid), of the density of 15° Baumé; the electrolyte of the remaining two cells had a density of 23° Baumé. The degree of density of the electrolyte had no perceptible influence upon the E. M. F. of the accumulators, and the conditions of the test were such as to make it inconvenient to determine whether the regularity of discharge was influenced by this condition.

The cells were charged by a Weston dynamo driven at a uniform speed, and were discharged through german-silver wires adjusted to suit the required conditions. E. M. F. and potential difference (P. D.) were measured by means of a white pattern Thomson quadrant electrometer, standardized by Weston-Clark standard elements. All readings are given in legal units, and time was accurately noted. Current was measured by a magnet ammeter, reading to within two-tenths ampere, which was carefully calibrated at the beginning of the test.

The cells were never discharged at a rate exceeding 30 amperes, as that was the limit of reliable reading on the ammeter; but the general results are such as to indicate that the normal out-put of these cells should not be allowed to exceed that rate if anything like a reasonable efficiency is desired. No doubt this out-put may be momentarily increased up to 40 or 50 amperes without immediately endangering the stability of the cell, but such increase will always be obtained at a large sacrifice of its efficiency.

Five complete tests—charge and discharge—were made, the results of which are given in detail in the accompanying sheets numbered 1 to 5 inclusive, from which the general characteristics of the action of the cells—such as gradual fall in P. D., etc.—may be easily noted. The general results are recapitulated in sheet 6. The significance of these figures is so obvious that I hardly need to point out to you the general conclusions to be drawn therefrom.

The first charge was discontinued about one-half hour after gas began to be freely evolved from the cells, and the rate of charging was approximately that given by the makers, viz., 18 amperes. The discharge was maintained at about 20 amperes, and the test showed a return of nearly 70% of the total energy absorbed. The second and third tests were also made at the normal rate of charging, which was, however, carried to a higher point than in the first test, and continued for a longer period after gas began to be evolved. They were discharged at the rate of about 30 amperes, and while a somewhat greater out-put was shown over the preceding tests, the energy returned fell off to 61%. In the fourth test the charging was accomplished at the normal rate, but was continued for several hours after the evolution of gas, and until nearly 400 watt-hours of energy had been expended in each cell. The total out-put thereby obtained did not, however, exceed that of the preceding tests in which much less work had been done in charging—the efficiency falling to 54%—thereby clearly indicating that the limit of charge is not much over 300 watt-hours per cell. The out-put might be slightly increased by increasing this charge at a low rate, but under the necessary practical conditions of quick charging, any increase would be obtained at such an enormous loss that it would be, commercially, out of the question.

The fifth and last test was carried out without special regard to makers instructions, although, with the exception that the density of the current was greater, the general effects were about the same as if the cells had been charged at constant potential. The charging current was kept at 26 amperes until there was a mild evolution of hydrogen, and then gradually decreased so as to maintain the evolution of gas about constant. When the current had thus been reduced to 10 amperes it was allowed to stand at that strength until the gas began to be freely evolved, when the charge—according to my belief—having reached its economical limit, was discontinued. The evolution of gas represents the expenditure of energy, and as it is dissipated beyond the reach of recovery such evolution means direct loss, and the charge cannot be carried beyond that point without a corresponding loss in the efficiency of conversion. I have not seen this point noted in any of the numerous papers on accumulators which I have read, but I assume that it must be obvious to every one. The high efficiency of 95% shown by this last test is chiefly due to the low rate of discharge, which never exceeded 10 amperes, but was largely increased by the discontinuance of the charge at 260 watt-hours before the loss of much gas. It was, no doubt, still further raised by the cells having recovered somewhat from the previous discharge, which had been effected at a high rate, and thus an abnormally large out-put was obtained although discharged to the same potential in both cases. That is to say, when the cells are discharged at a high rate their potential falls suddenly to the normal limit. When discharged slowly the potential falls gradually to the limit. In the former case, after remaining open for a while, there is considerable recovery, as illustrated by re-discharge No. 3 (see table), whilst in the latter case there is hardly any. Therefore, it would appear that the efficiency given for test No. 5 is higher than its true efficiency, owing to an excess of residual charge that could not easily be allowed for.

The effect of lapse of time between the charging and discharging of the accumulators, could not be accurately determined without extending the tests for a considerably longer period of time. The difference in loss of efficiency between an immediate discharge and one after the lapse of 15 or 20 hours (see tests 2 and 3) is, however, very small, although if the cells are not thoroughly insulated, it might amount to considerable.

From the figures of the tests and the preceding considerations it is obvious that almost any degree of efficiency may be obtained from these accumulators. In fact, it is well known that the maximum efficiency of any accumulator is attained when the rate of charging and of discharging is a minimum; in other words, when the power expended or rate of doing work is a minimum. It is therefore necessary to adopt some standard working rate for these cells, and then determine their capacity and efficiency on the basis of this rate of working. The normal out-put of the cells should not—as already determined—exceed 30 amperes, and as the average E. M. F. of the cells is about two volts, it is obvious that the average rate of working must not exceed 60 watts per cell. At this rate

Digitized by Google

the capacity of the cells will not exceed 110 ampere-hours (see tests), and as the average P. D. during discharge is 2.03 volts, the total work done by each cell will not exceed 225 watt-hours.

Again, considering the figures of the tests, and taking into account the system of working the accumulators which you have in view, their efficiency at the above rate of working will be somewhat between 60% and 70%. For ordinary working on the assumption that abnormally large discharges will be balanced in effect by abnormally small ones, the efficiency of the accumulators will probably closely average 65%, and I think this figure a safe one to estimate upon.

On the above basis the following figures are self-explanatory :—

FOR A SINGLE CELL.

Rate of working.....	0.0804 h.p.
Time of working at this rate	3.75 hours.
Total work.....	0.3016 h.p.
Battery per h. p. hour....	126. lbs.

Thus 38 cells will weigh 1,444 pounds, and will develop 11.46 h. p. hour, which, expended at the rate of 60 watts per cell, is equal to 3 h. p. for 3.82 hours. Any loss in secondary conversion must, of course, be deducted from these values.

As to the permanency of the cells, both as regards mechanical durability and electrical efficiency, time alone can report.

THE DESIGN AND CONSTRUCTION OF DYNAMO-ELECTRIC AND ELECTRO-DYNAMIC MACHINERY.[1]

BY DR. WELLINGTON ADAMS.

Member St. Louis Academy of Science, and Engineer's Club of St. Louis.

It has taken many scores of years for the development of thermo-dynamics to that degree of precision which that science has now reached. The science of dynamic-electricity, which has now reached fully as great a degree of precision as that of thermo-dynamics has, however, been almost entirely developed within the last decade. It has not, however, like the fabled Minerva, sprung up in a night fully developed from the brain of any one man, but on the contrary has been evolved by a process of evolution from the brains of some of the brightest intellects and most scientific engineers of our times, each one in turn adding a mite toward the creation of what is now justly recognized as one of the exact sciences. But 10 years have elapsed since Monsieur Gramme introduced to the scientific world that wonderful piece of electric machinery bearing his name, with all its involved mysteries. It seems but yesterday when dynamo-electric machines were constructed in a purely empirical manner by throwing together a lot of iron and copper, with but few of the underlying principles governing their operation even partially known to either the designer or constructor. This method soon gave way, however, under the hand of practical experience, to rules of thumb which were jealously guarded by their various authors as a means of protecting competing manufacturers. Next came the flooding of current scientific literature with various explanations as to the action of these machines, and next appeared well founded theories from which have been developed an accurate knowledge of the laws governing the operation of all classes of dynamo-electric machines, until at the present day we have at our command practical formulæ, and a knowledge of the subject so accurate as to enable any one versed in the science to design on paper any given type of machine, and to predict its power and the character of its current, with that certainty which attends the design and construction of either thermo-dynamic or hydraulic machinery. In reaching this point, many a pretty theory has been exploded, and many a step retraced. We are now no longer dependent upon empirical methods, upon rules of thumb, and upon traditional practices. It is not even sufficient now to be able to make one particular kind or type of machine so that it will work; but we must also know the why and the wherefore of every step, for in this way only are we enabled to generalize, and from a few practical examples construct all possible varieties. For a long time our text books and the current electrical literature was filled with intricate formulæ, involving integral calculus and other intricate branches of higher mathematics, all of which involved the use of certain constants which had to be predetermined for each particular machine, and for each particular type of machine; there were no generalizations, no universally applicable formulæ, no general constants, so that these formulæ were practically useless and the electrical engineer was compelled to resort to rules of thumb and traditional practices. To-day, however, it is quite different, we can now with mathematical precision calculate the best size, shape, and exciting power of a pair of field magnets, the exact speed at which a given machine must run to produce a certain electric output. To do this, however, we are obliged to resort to other laws and to other theories than those propounded by Lenz, Jacobi, Dub, Muller, and others, concerning the magnetic moment of cylindrical electro-magnets. For those formulæ and theories upon which we rely to-day, we are indebted to Frohlich, Deprez, Thomson, Hopkinson, and Kapp. Just as the first makers of steam engines knowing nothing of the mechanical theory of heat, were yet able to make fairly good engines long before Joule, Clausius, Rankine, and Zeuner, showed us how to make excellent steam engines, so Gramme, Siemens, Brush, Edison, and others made fairly good dynamo-electric machines before Frohlich, Deprez, Thomson, Hopkinson, and Kapp unravelled the mysteries and fundamental principles of dynamo-electricity to that extent which has redered it possible to construct an almost theoretically perfect dynamo-electric and electro-dynamic machine. The present state of the art is due almost entirely to that conception which looks upon an electric current and a magnet as emitting lines of force which, in their passage through different media, meet with a resistance proportionate to and dependent upon the character of the matter they traverse. For the latter conception we are almost exclusively indebted to the Messrs. Hopkinson and Mr. Kapp. Whether such lines do really exist or not is of but little moment for our purpose, since it suffices to know that by means of iron filings we can make such lines visible and study their properties. According to this conception every wire carrying a current is surrounded by a multitude of circular lines arranged like concentric rings around the wire (see figure 1), which lines gradually diminish in number as the distance from the wire increases. If we could have a single magnetic pole, that is, a piece of steel having only one polarity, and that a north pole, for instance, this pole would, if brought near a wire carrying a current of electricity, revolve around it; but since a magnet with only one pole is an impossibility, and since the same force which urges the north pole in one direction will urge the south pole in the opposite direction, the magnet as a whole cannot revolve around a straight wire, but will set itself at

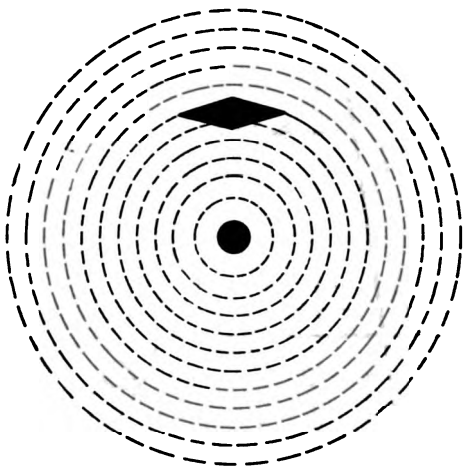

Fig. 1.

right angles to it. In what direction the lines of force run around the wire we cannot say, but to fix our ideas we may consider those lines positive which would carry a north pole around the wire in the direction of the hands of a watch if the observer sees the wire from the end and if the current flows from the observer. If we place a piece of paper over such a magnet and at right angles to such a wire, the lines of force made visible by iron filings will now appear as somewhat distorted circles crowded densely into the poles of the magnet. Within the magnet they are not so well defined as upon the outside of it, but as near as can be judged from rough experiment no lines are lost in the middle, the same number of lines that enter at one side of the magnet finding their way out at the other. This follows also when we come to consider the fact that we cannot have one free magnet or a magnet with unequal poles. Whence it follows that every line of force must be a closed line; an open magnetic line of force, that is, a line with no ends, being as much of an impossibility as a continuous current in an open circuit. According to our nomenclature, a positive line of force goes in the air from the north to the south pole, and in iron from south to

1. Read before the Engineer's Club of St. Louis, February 16th, 1887.

Digitized by Google

north. If, instead of a steel magnet, we had experimented with a piece of soft iron, we should also find that through its presence, the originally circular lines around the wire would have become somewhat distorted and crowded together at the ends of the piece of soft iron, which like a steel magnet will set itself at right angles to a straight wire carrying a current. The total number of lines made visible by filings would, under these circumstances, be considerably increased, even on the side of the wire opposite to that where the piece of iron is placed, and if we should increase the current we would still further increase the number of lines. This experiment, therefore, shows that the number of lines would thus be dependent upon the strength of current, and that one and the same current will yield more lines if a piece of soft iron be placed in its neighborhood, and also that the lines pass more easily through iron than through air. This latter circumstance leads us to the conception that every medium offers a certain resistance to the passage of these lines of force, and the inverse of that resistance is what is called the "magnetic permeability" of the medium, which, according to Thomson, in the case of iron, is from 40 to 20,000 times as great as that of air. In other words, if we should surround this straight wire by a cylinder of iron, the same current would yield within that space, from 40 to 20,000 times as many lines of force as when the space contained air only. Experiment also shows that not only that portion of the wire which is in immediate proximity to the magnet affects the latter, but also the portion above and below, and if we retain our conception that no part of the current can act upon the magnet, except by a line of force which must actually get through it, we are forced to conclude that the lines must be closed curves of three dimensions, *i. e.*, curves in space. With a straight wire, infinitely long, the angle of inclination through which a line may be deflected, varies between zero and 90 degrees, but from the experimental fact that a current cannot exert any influence on a magnetic pole situated in a straight line with the current, it follows that 90 degrees is the limit through which a line of force can be deflected, and if so deflected its influence is infinitesimal. The importance of this fact will be seen later on, when we come to consider which parts of the windings upon field magnets are useful and which are useless. The nearer the magnet is to the wire the greater is the force which tends to set the magnet at right angles to the wire. Magnetic poles of the same name or sign repel each other, and from this we may conclude that parallel lines of force running in the same direction repel each other. Each line of force tends to shorten itself; whence it follows that lines of force encircling a free wire, form concentric circles, for the circle is of all possible curves the shortest for a given diameter. When lines of force in different planes cross each other at an angle, they tend to become parallel, but of opposite sense, and thus to eliminate each other. Let us now briefly summarize these propositions.

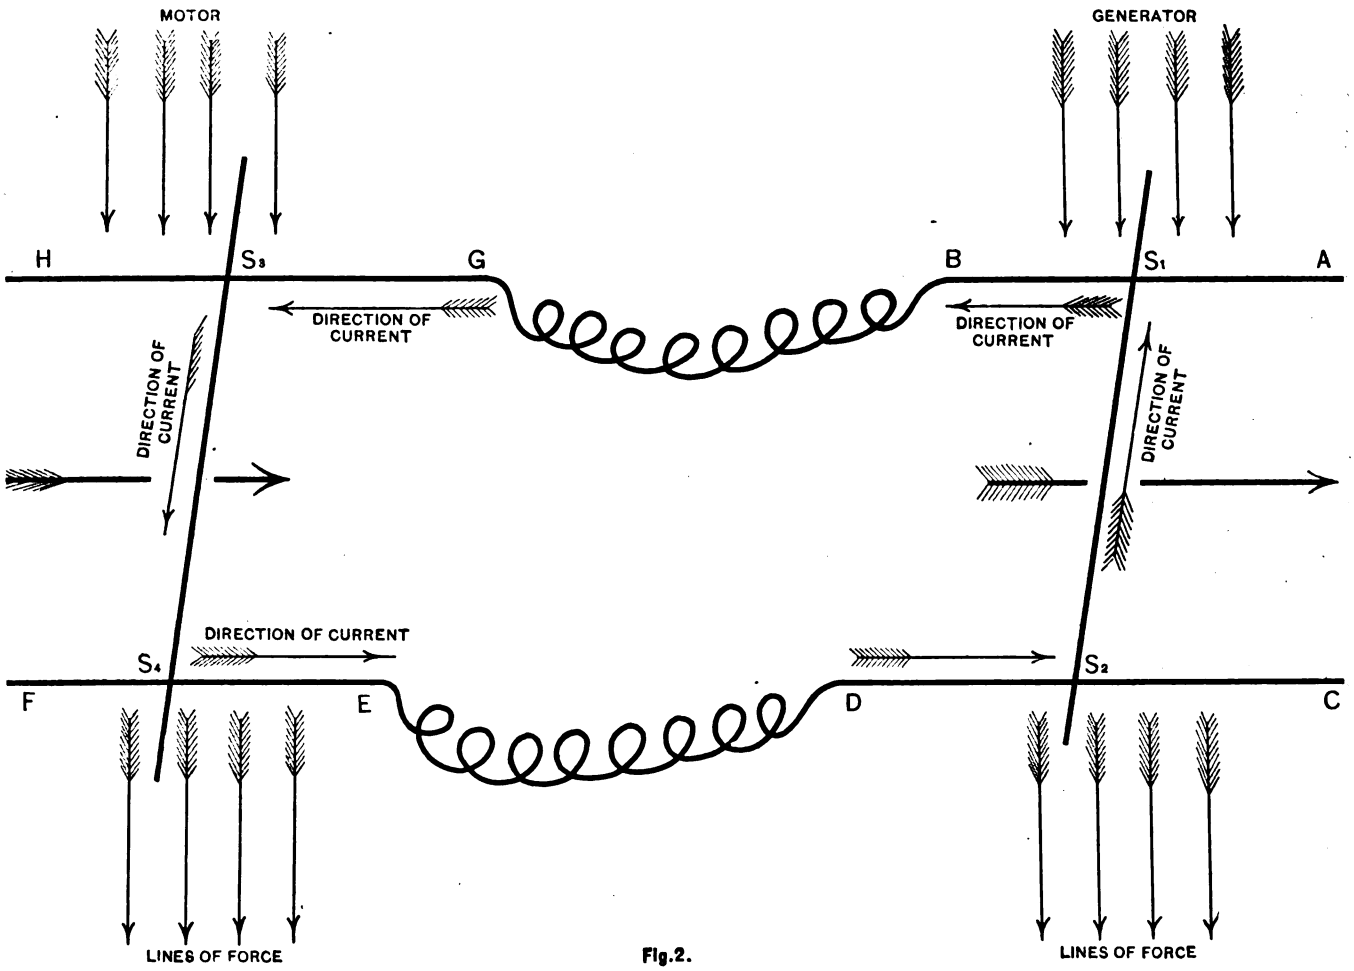

Fig. 2.

1. A line of force must be a closed curve.
2. It has a tendency to shorten itself, becoming stronger the shorter it is.
3. It need not be a plane curve, part of it can be bent off at any angle short of 90 degrees.
4. Lines of force find less resistance in iron than in air, and a greater number of lines can run through iron than through an equal space of air.
5. Parallel lines of the same sense repel each other, and parallel lines of opposite sense attract and eliminate each other.
6. Lines crossing at an angle have a tendency to set themselves parallel to each other, but in opposite sense. Upon these conceptions is founded the accepted theory of the operation of the dynamo, and upon this theory the formulæ which we are about to consider are based. It is

Digitized by Google

well known that if a closed wire is moved so as to cut lines of force, a current of electricity will flow in such wire so long as the movement lasts. Suppose, for instance, we have a straight wire traversed by a current and we approach to it another straight and parallel wire forming part of a closed circuit, then the current induced in the latter will be in opposite direction to that in the fixed wire, and if we remove the wire the current will be in the same direction. A knowledge of these laws has rendered it possible to establish a rule for determining the direction in which a current will be induced by the cutting of lines of force. Imagine a man substituted for a portion of the wire, with his face turned so that the lines of force run towards him, which is equivalent to looking towards the north pole, then, if he move laterally to the left, the current will flow from his feet to his head, while if he move laterally to the right, the current will flow from his head to his feet. The rate at which lines of force are cut by a wire determines the amount of current generated; in other words, the number of lines of force cut per second by a single wire determines the amount of current generated in such wire.

Let us assume the simplest possible example of a dynamo-electric machine as represented in figure 2, which very beautifully and clearly illustrates the fundamental principles involved in both a dynamo-electric and an electro-dynamic machine. Let A, B, C, D, in this figure, represent two straight parallel wires placed in a magnetic field of given uniform intensity, I. This means that every square centimeter of surface contained within the two wires, is traversed by I lines of force running at right angles to the plain, A, B, C, D. The ends, A, C, of the wires may be connected with a galvanometer and the circuit completed by a sliding wire, s_1, s_2, which is moved in the direction of the arrow with the velocity of v centimeters per second. If d represents the distance between the two parallel wires, the area enclosed by the circuit will be increased through movement of the slider, at the rate of dv, square centimeters per second, and the number of lines of force enclosed by the circuit will be increased at the rate of dv I lines per second. The slider, therefore, cuts $d\,v$ I lines per second, and in doing so, there is created a difference of potential between the points, s_1, s_2, which in absolute measure is equal to $d\,v$ I units of E. M. F. We can, therefore, say that e equals $d\,v$ I, where e equals electromotive force of the current generated in the slider. A unit of E. M. F. will be produced if each of the three factors d, v and I are equal to unity—that is, if the parallel wires are one centimeter apart, each square centimeter containing one line of force, and the velocity being one centimeter per second. Assuming then, that the slider has a resistance which is equal to r, but that the galvanometer and the parallel wires have absolutely no resistance, then in that case, the current which will be indicated by the galvanometer, which is assumed to be in the circuit, will be expressed by $\frac{e}{r}$, a unit current will be created if e equals r. In a unit field, d I equals one, and, therefore, r equals v, if $d = 1$. The resistance of the slider can, therefore, be expressed in terms of velocity, as so many centimeters per second, at which it must be moved across a unit field in order to produce unity of current. These units are all based upon the C. G. S. system, and, therefore, in order to trace the connection between the expressions and formulæ already presented and the commercial formulæ to follow, we must first consider the relation which exists between these absolute units under the C. G. S. system, and the commercial units of volt, ohm, and ampere employed in commercial practice; the volt equals 10^8 absolute units of electromotive force.

One ohm equals 10^9 absolute units of resistance.

One ampere equals 10^{-1} absolute units of current.

One commercial unit line of force, according to Kapp, equal 6,000 absolute unit lines. Therefore, to produce in our slider a difference of potential of one volt, it would have to be moved across a magnetic field of unit intensity at a speed of 1,000 kilometers per second. This being an impossible speed we must reduce it in some way, and this can be done by employing a stronger magnetic field, or by increasing the distance between the parallel wires, or by both. Let us now fix these ideas by assuming that the speed of the slider be limited to 10 meters per second, corresponding to about 22 miles per hour, which is a very moderate speed for the periphery of an armature in a dynamo machine; then to obtain one volt the product d I must equal 100,000, which may be obtained by employing a slider one meter long in a magnetic field containing 1,000 lines of force to the square centimeter, or by a slider 10 centimeters long in a magnetic field containing 10,000 lines of force to the square centimeter, or with any other combination which will give the same number of lines of force cut per second. Just what is the maximum number of lines obtainable per square centimeter is not definitely known, some placing it at 11,000 and others at 14,000. In commercial practice, however, such an intensity of field is never reached, the best machines having but from 4 to 8,000 lines of force per square centimeter of armature core. So that it will be seen that to construct a dynamo-electric machine we have but to arrange in the most favorable manner for the cutting of lines of force by a conductor, and that the greater the number of lines cut per second, whether by reason of a combination involving a large number of wires upon the armature, a high velocity of the armature, or a large number of lines of force per square inch, the greater will be the electrical output of the machine. Upon these theories, fundamental principles, expressions and units are based the commercial formulæ which we use in the design and construction of commercial machines. Of course when we come to design these, very many details and considerations come in to form a more intricate problem—such, for instance, as the use of iron within the field coils and within the armature coils, the same being added to concentrate the direction of flow and to prevent leakage of the lines of force to be cut, and also for the purpose of affording a medium to be traversed by said lines of force which will offer the least possible resistance, so that as small an amount of energy as possible will be required to create the magnetic field. We have then to consider the quality and the amount of iron employed and its mechanical and geometrical arrangement. The same fundamental principles and the same considerations come in play when designing an electro-dynamic machine, as the other half of the plate before you serves to illustrate. When the slider s_1 s_2 in the generator is moved in the direction of the arrow, the slider s_3 s_4 in the motor will also move in the direction of the arrow, providing the connections be made and the currents flow in the direction indicated in this diagram. If there were no mechanical or electrical resistances, the slider in the motor would move with the same velocity and to the same extent that the slider in the generator is moved.

It must now be apparent to you that we can arrange a variety of combinations with regard to velocity, intensity of field, and length of slider or wire or number of wires, and yet secure the same current from each combination, providing the resistance of the circuit in each combination remains the same; and the art of designing a dynamo consists in selecting a suitable combination of these factors in any given case, with the smallest internal resistance, and whereby the least possible energy shall be expended in producing the required intensity of field, or number of lines of force to be cut.

From what has already been said, it must also be apparent that while we can construct a dynamo machine without employing iron, as in the ideal machine just considered, yet it is necessary to employ this material in order not to expend an undue amount of energy in pro-

Digitized by Google

ducing the required intensity of field in any given case. Now, therefore, when we come to consider the design of a practical dynamo-machine, questions like the following arise: How shall we arrange matters and things so as to

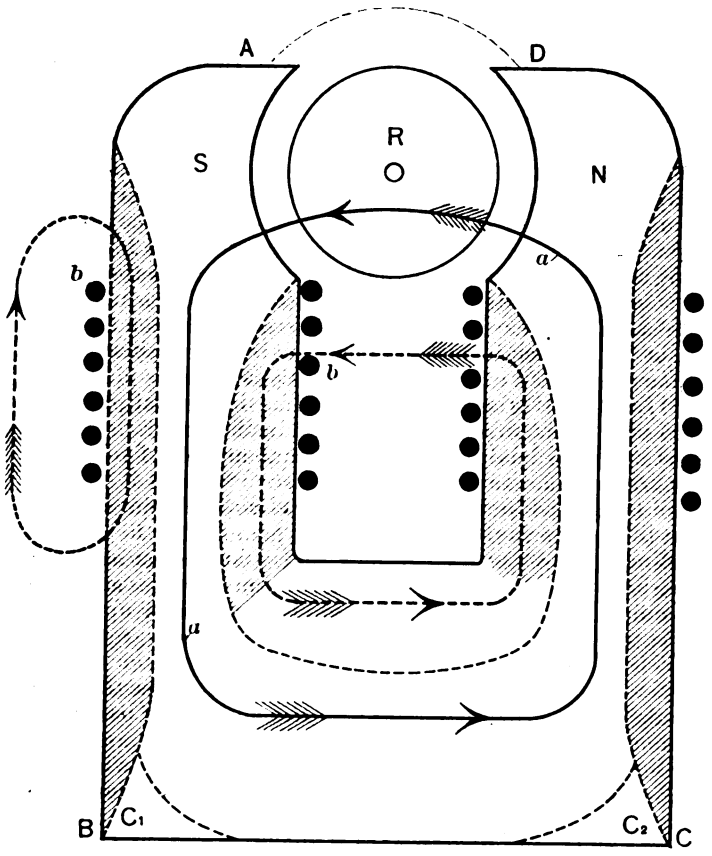

Fig.3.

reduce as much as possible the resistance of the magnetic circuit, and hence the resistance to the flow of lines of force? How shall we arrange our material so as to concentrate our lines of force into a compact field of great intensity? How shall we avoid leakage of lines? What will be the actual resistance of the magnetic circuit as finally arranged? What then must the exciting power be in order to overcome this magnetic resistance and produce a field of the required intensity. And, finally, how are we to calculate the E. M. F. to be obtained from any given arrangement or combination?

Before considering these questions, however, let us for a moment study an analogy in the case of the battery and electric circuit represented in figure 4, and while studying this plate observe its resemblance to figure 3, which represents a single horse-shoe magnet dynamo-electric machine.

In figure 4 Ra represents a certain resistance (corresponding to the magnetic resistance of an armature core). $\frac{Ra}{2}$ represents a certain resistance in the circuit (corresponding to the two air spaces around an armature in a dynamo). P. P. = the poles of the battery (corresponding to the poles of a dynamo). Rf = the internal resistance of the battery (corresponding to the magnetic resistance of the magnetic circuit in a dynamo field). P = the internal E. M. F. of the battery (corresponding to the exciting power or ampere-turns in a dynamo). z = the total current produced by the battery (corresponding to the total lines of force created by the field of a dynamo). z_1 = the resultant current created by the battery in the external or useful circuit (corresponding to the number of useful lines of force passing through the armature of a dynamo). Then in the case before you, according to Ohm's law, $z = \frac{P}{Ra + Ra + Rf}$. Let us now suppose this battery to be submerged in a badly conducting medium, as water, for instance. Some of the current will then flow through the paths indicated by the dotted lines, which represent a certain leakage. The useful current passing through Ra will therefore have been reduced to the extent of this leakage. It is apparent that the greatest leakage will occur between the poles, where the difference of potential is a maximum; therefore, in a given medium having a definite resistance and with a given arrangement of battery the total loss through leakage is approximately proportional to the difference of potential between the poles. Now, suppose the latter to have a value of p_1, then the current lost $\delta = \frac{p_1}{\rho}$, where ρ represents the average resistance of the surrounding medium for this particular configuration of battery. Calling the total current produced in the battery z, then $z = z_1 + \delta$. Now, if it were possible to create an E. M. F. (P) of the battery of any desired value between zero and that value which will, notwithstanding the leakage, produce the maximum current (z_1) required at Ra, then we can determine what E. M. F. is required for each value of z_1 between zero and maximum. And to do this we first determine by Ohm's law the difference of potential at the poles, by this equation, $p_1 = (Ra + Ra)\, z_1$. Then the loss by leakage through this equation $\delta = \frac{p_1}{\rho}$; then the total current produced by this, $z = z_1 + \delta$. Then the loss of E. M. F. (p_2) occasioned by the internal resistance (Rf) of the battery, by this equation—$p_2 = Rf\, z$; and, finally, the total E. M. F. (P), which, of course, will be $p_1 + p_2$. Now,

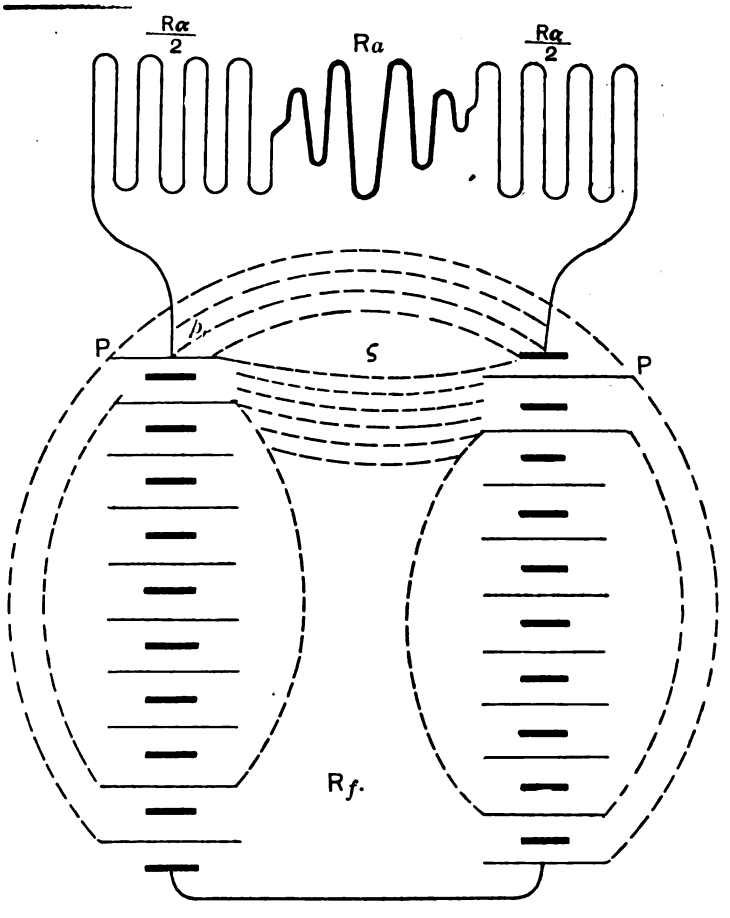

Fig.4.

as I have already stated, we may consider this submerged battery as analogous to a horse-shoe magnet-dynamo, because the latter is always surrounded by a medium through which magnetic lines of force may pass, and in this analogy

Digitized by Google

the total E. M. F. of the battery corresponds to the total exciting power applied to the field magnet, while the currents z, z_1 and δ correspond respectively to the number of lines created within the magnet core, the useful lines passing through the armature, and those lines lost by leakages. Now, from what has been stated, it follows that knowing the value of ρ and of p_1, we can readily calculate the value of δ, or the lines of force lost by leakages in any particular form of battery or field magnet. The value of ρ in any given case being expressed by the equation $\rho =$ a constant $+ \frac{la}{A\,a\,b\,a}$, where the constant represents the specific resistance of the medium occupying the space between P. P., which has been determined by experiment to be 1,440 for air, iron being 2; and where la represents the average distance between P. P., and where $A\,a\,b\,a$ represents the area of the polar surface at the points where lines of force may leak or escape. For similar types of dynamos the value of ρ is inversely proportional to the linear dimensions of the machine, and can be found by dividing a constant by the diameter of the armature.

The value of p_1 will, of course, be represented by $P = P_2$, where P is the total E. M. F., in the case of a battery, or the total exciting power in the case of the field magnet of a dynamo, and where p_2 is the E. M. F. consumed by the internal resistance of the battery, in the case of a battery, or in the case of the field magnet of a dynamo, the exciting power consumed by the magnetic resistance of the field core. Hence, it is possible in any given case, knowing the geometrical and mechanical data, to determine the useful lines and the lost lines, or to determine the exciting power necessary to produce the required useful magnetic lines of force for the production of a required E. M. F., or of a required current through a given electrical resistance.

It now only remains to consider the analogy of electric resistance to magnetic resistance. All substances and media have a constant specific electrical resistance into which we multiply the ratio of length divided by area to find the actual electrical resistance in any particular case, the specific electrical resistance of any substance forming a constant co-efficient as a multiplier. But, in the case of magnetic resistance, which is also a quantity proportional to the ratio of length divided by area, the co-efficient with which the ratio of length to area must be multiplied (the specific resistance) is not a constant, but varies with the density of lines flowing through the iron, the maximum resistance or the point of maximum magnetic permeability being reached at the point of absolute saturation.

Now, in the formula $z = \frac{P}{R\,a + R\,a + R\,f}$, already given, the two resistances $R\,a$ and $R\,f$ are, for very low degrees of magnetization, found by determining the average distances through which the lines flow in the armature and in the field magnet, and dividing by the respective areas, the ratio in each case being multiplied by 2, which latter numeric represents the initial specific magnetic resistance of the best annealed wrought iron. This empirical formula is, however, only correct for low degrees of magnetization, and consequently for comparatively weak exciting powers. In other words, it is assumed in this formula that the degree of magnetization is not pushed beyond what Thompson calls the dia-critical point of magnetization, *i. e.*, to a point equal to one-half the maximum magnetic permeability of the iron used in any given case. To make this formula universally applicable to all kinds and qualities of iron and to all degrees of magnetization or to different magnetic densities and exciting powers, Mr. Kapp has recently introduced a tangent function, to which your attention will be called presently.

Now, a dynamo-electric machine is simply a mechanical arrangement for placing in the smallest possible space the greatest possible number of wires or convolutions of a wire so as to cut the greatest possible number of lines of force with each revolution of the armature, and thus generate the greatest amount of current with the least possible length of wire, the current so generated being used to energize the field and so create the lines of force which are to be cut. Our principal object must be also the production of a field, with the least possible expenditure of energy for its production, and we must also strive to keep down the resistance of the armature both by having the conductor short and of as large cross-sectional area as possible, since the internal resistance of the machine is a measure of the energy consumed in the machine. When we start to design a dynamo with these objects in view, the following questions arise:

What relationship must the field bear to the armature?

What ratio of iron in field to that in armature?

What ratio of copper in field to that in armature?

What ratio of copper to the iron in field?

What ratio of copper to iron in armature?

How many sections shall the armature be composed of?

How many turns to each section shall there be?

What size of wire should be used in the armature?

What size of wire should be used in the field?

What should be the cross-sectional area of the iron in the armature?

What should be the cross-sectional area of the iron in the different parts of the field?

What should be the thickness of the insulation between each convolution of wire and between the iron and the wire and between each section of the armature?

At what speed should the armature be run?

Where must the brushes be placed?

What relationship should exist between the number of convolutions in the armature and the number of convolutions on the field?

How large should the pole pieces be?

To what extent should the pole pieces encircle the armature?

How shall we design the machine to give under certain given conditions a required current or a required E. M. F.?

All these and many more similar questions present themselves when we start to design a dynamo-electric machine. As I have already stated, these questions have up to within a very short time been met by rules of thumb, it being one man's practice to place four times the amount of material in the field as he had in the armature by weight, while another would make the length of wire on the field bear a certain relationship to the length of wire in the armature. The relationship between the amount of wire and the amount of iron both in armature and the field being so adjusted as to produce about the same depth of wire as the iron core was thick. With such knowledge and under such practice it was impossible to pre-determine the output of a machine. Now, however, we have practical formulæ at our disposal, and experimentally determined constants, which are capable of general application, so that we may with scientific accuracy predict the current that a given machine will produce, the electromotive force it will create, its resistance when running, the extent to which it will become heated when running, the speed it should run at, the energy lost in the field and in the armature, the losses from electric, magnetic, and mechanical friction, and hence the electric and commercial efficiency, the power it will require to run it, and, in fact, everything it is desirable to know.

With these premises I think we may now proceed to consider our commercial formulæ, according to which practical dynamos can be designed by simply introducing the proper numeric values for the different algebraic factors involved; for we have now reached a point where it must be apparent that in order to create a given E. M. F. we have but to provide mechanically for the cutting of a definite number of lines of force per second. Now, to determine what number must be cut, we employ this formula:

Digitized by Google

$$\text{E } a = \frac{z_1 \text{ N } t \; n}{1{,}000{,}000},$$

which on solving for z_1 gives us :

$$z_1 = \text{E } a \left(\frac{1{,}000{,}000}{\text{N } t \; n} \right),$$

where

E a = The total internal E. M. F. produced in the armature,

z_1 = The available lines of force passing into the armature core from the field.

N t = The total number of convolutions of wire wrapped around the armature core of a size or area capable of carrying the required current, allowing at least two square inches cross-section area for every thousand amperes.

n = The allowed speed of the armature in revolutions per minute.

And this formula when substituting $2\,a\,b\,m$ for z_1, becomes :

$$\text{E } a = \frac{2\,a\,b\,m \text{ N } t \; n}{1{,}000{,}000}; \text{ or, } z_1 = \text{E } a \left(\frac{1{,}000{,}000}{2\,a\,b\,m \text{ N } t \; n} \right),$$

where,

$a\,b$ = The cross-sectional area of actual iron in each magnetic circuit of the armature core.

m = The number of lines of force allowed to each square inch of cross-sectional area of armature core. Which should not exceed ten.

In this short paper it is impossible for me to go into the question as to how this formula has been reduced to this simple form, and the reason for dividing by one million. Suffice it to say that this latter has been brought about by changing from the absolute or C. G. S. system of units to the commercial one, and by changing from centimeters per second to revolutions per minute.

Now, having found by this formula the number of lines of force which must flow into the armature core, or be cut, in order to produce a required E. M. F. with a given number of convolutions on the armature, and speed of same, it becomes necessary to determine the amount of exciting power, or, in other words, the number of ampere-turns which must constitute the field in order to create the said required number of lines of force which the armature must cut. This we determine by means of the following formula, which it will be observed, contains the tangent function, already referred to as a means of providing for the saturation factor :

$$z = \frac{\text{P}}{1{,}440 \times 2 \frac{\delta}{\lambda\, b} + \frac{l}{a\, b} \times \frac{tan\left(\frac{\pi}{2}\sigma_1\right)}{\frac{\pi}{2}\sigma_1} + \frac{2\,\text{L}}{\text{A B}} \times \frac{tan\left(\frac{\pi}{2}\sigma_2\right)}{\frac{\pi}{2}\sigma_2}}$$

Where,

z = The total number of lines of force produced by the field, which should be slightly greater, say from 2 to 5 per cent., when the field is of good design, than z_1, so as to allow for the lines lost by leakage.

P = The total ampere-turns upon the field.

δ = The distance between the polar surface and the outer surface of the armature core.

$\lambda\, b$ = The superficial area of the polar surface, determined by multiplying λ, the arc spanned, by σ, the breadth of the surface of the field poles presented to the armature.

l = The mean length of that portion of the magnetic circuit formed by the armature core.

$a\, b$ = The cross-sectional area of the actual iron in the armature core.

σ_1 = The maximum number of lines of force per square inch which the iron in the armature core will carry at the saturation point, divided by the actual number which we may determine to allow per square inch. The latter should certainly not exceed one-half that number which would produce saturation, which number for the various kinds of iron will be given further on; ordinarily, in a good Norway wrought-iron armature σ would equal 2.

L = The mean length of that portion of the magnetic circuit formed by the core and yoke of the field magnet.

A B = The cross-sectional area of the field magnet core, assuming that the yoke is at least as large as the remainder of the field circuit. It should be as much larger as other circumstances will admit.

σ = The maximum number of lines of force per square inch which the iron in the field magnet core will carry at the saturation point; divided by the actual number which we may determine to allow per square inch. All that was said in this connection concerning σ_1 holds good here also.

Solving for P we have :

$$\text{P} = z \left(1{,}440 \times 2 \frac{\delta}{\lambda\, b} + \frac{l}{a\, b} \times \frac{tan\left(\frac{\pi}{2}\sigma_1\right)}{\frac{\pi}{2}\sigma_1} + \frac{2\,\text{L}}{\text{A B}} \times \frac{tan\left(\frac{\pi}{2}\sigma_2\right)}{\frac{\pi}{2}\sigma_2} \right)$$

Which immediately gives us the number of ampere-turns which we must have upon our field in order to produce that number of lines of force which we have found by our first formula that the armature must cut in order to produce the required E. M. F.

These formulæ when slightly modified to suit the varied conditions apply alike to cylinder, disc and drum armatures and to bipolar and multipolar machines, and to the different types of fields. In cylinder and disc armatures N t = the number of complete convolutions on the armature ; while in drum armatures N t = twice that number of convolutions.

Comparing these formulæ with the old ones of Fröhlich and Thompson, you will readily see what a great step has been taken towards an absolute and practical basis of dynamo construction.

Fröhlich's old formula for determining the strength of field is :

$$\text{M} = \frac{i}{a + b\, i}.$$

Where,

m = Effective magnetism.

i = Exciting current in series dynamo.

a & b = Constants to be determined experimentally for each machine.

And Thompson's modification of Fröhlich's formula is :

$$\text{H} = \frac{\text{G K } o \text{ s } i}{1 + \sigma \text{ s } i}.$$

Where,

H = Strength of field.

G = A geometrical constant to be determined experimentally in each individual case.

K o = Magnetic permeability when $i = o$.

S = Convolutions of conductor on armature.

σ = Saturation coefficient to be experimentally determined in each individual case.

Leaving at least two series of experiments to be performed in order to determine the value of the constants in each particular machine. While Kapp's beautiful formula gives one a clear and definite idea of the whole problem, and of the part each element performs, and enables one to determine the strength of field from the electrical, magnetic and mechanical data alone for any design of dynamo.

Let us now take an example and practically apply these

Digitized by Google

commercial formulæ. Assuming that we are required to construct a dynamo that will produce a ten ampere current through a circuit having a resistance of forty ohms. Then the required E. M. F. will be $10 \times 40 = 400$. Then $\frac{2\,a\,b\,m\,\text{N}\,t\,n}{1{,}000{,}000}$, must equal 400, assuming that there is no internal resistance in the machine, and, therefore, no E. M. F. consumed therein—an impossible condition in practice, of course, but we will assume it here for the sake of brevity and clearness.

Now it must be clear that a variety of combinations may be arranged whereby the required number will be created, for example, let us assume $a\ b$ to $= 100$, $m = 10$, $\text{N} = 50$, $t = 10$, and $n = 400$; or, let us halve n and make it 200, by doubling N t. Then with either combination we secure the required 400 volts. So that we have now determined how many convolutions there must be upon the armature, how fast it must run, the cross-sectional area of its core, and the number of lines of force that must enter it, which latter is two thousand.

We have now to provide a field for this armature equal to 2,000 commercial lines of force. Now, of course, the magnetic density of ten lines per square inch fixes the amount of iron to be used in the magnetic circuit of the field—the cross-section of each circuit depending naturally upon the number of magnetic circuits provided. It is now only necessary to determine what the exciting power or number of ampere-turns in the field must be in order to produce the required 2,000 lines, and this is done by multiplying the 2,000 into the expression already given, after first substituting for those algebraic factors, the numeric values acccording to the geometry of the particular field in question. Let us now assume these values to be as follows:

$$2{,}000 \times 1{,}440 \times \frac{2 \times 0.5}{10 \times 2_0} + \left(\frac{40}{200} \times 3\right) + \left(\frac{2 \times 24}{200} \times 3\right) =$$

Approximately 16,000 ampere-turns. Then since the current is ten amperes, and the field in series with the armature, there must be a total of 1,600 convolutions on the field magnets, composed of wire capable of carrying ten amperes without unduly heating.

The following are the constants for the magnetic saturation of different kinds of iron:—

	C. G. S. OR ABSOLUTE UNITS.	COMMERCIAL UNITS.
Charcoal iron well annealed (wires)...	150,000	25
" " " " (discs)....	132,000	22
Field magnets, hammered scrap.	108,000	18

I had hoped to be able to present something regarding the mechanical, geometrical and electrical details of construction, but I find the limits of this paper will not admit of it.

2829 Olive Street, St. Louis, Mo.

CHEAPNESS OR ECONOMY?

BY THOMAS D. LOCKWOOD.

THE "Cheap John" in applied electricity dies hard. In fact he doesn't die at all. He is like the party of the second part in the far-famed *hydra*static researches of Hercules; and as fast as you cut off his head in one place, it reappears with an increase in the difference of potential in another.

When I was quite a small boy I took much delight in reading romances of the frontier, and while in a general way I now deprecate as much as anybody, the tendency of our boys to revel in the literature of the buccaneer and the Indian scout, I am compelled to own for the purposes of this article, that at the special period of my life to which I allude, my main reading was "Mayne Reid;" and in the soberer judgment of middle age I believe the romances of that author to be as good and clean, and as desirable for youth as any stories of warfare and enterprise can be.

Now it doubtless seems singular to preface a practical article for a prominent electrical journal, by reminiscences of border tales, but it is not done without a purpose. Of course before sitting down to write this article, I had revolved the subject in my mind; and thinking over the antics of the Cheap John, raised an involuntary mental vision of the parallelism of the said antics, with an episode in one of the Mayne Reid novels, in which a party attacked took refuge, each man behind a tree; and as they were successively driven from one tree it was merely to retreat to another. This pillar to post style of operation is a characteristic of the Cheap John. The C. J. in electricity is of two kinds—one sort consisting of those who—like the late Sir Joseph Porter, K. C. B.,—mean well, but do not know; and the other their converse colleague who know but do not mean well. Inasmuch as the resultant effects of both are the same, both are equally noxious. But the first species is, of the two, to be preferred; for him there is hope; for the latter none, as a Calvinist would say "either in this world or the next." But between them, they cover both sides of the medal.

The electrical Cheap John started into existence with the telegraph, and flourished amazingly in that arena for a long time, especially in America; for until the Yankee finds that he really is out of pocket by original parsimony, he does not believe in laying any more out on an enterprise than just enough to set it going; and will not expend enough of either money, time, or care to set it going at its best; for whatever his motto may be, his moving principle is "Millions for repairs but only a cent for construction"—while the tendency of the sturdy Briton is to build for the centuries to come. It took therefore the successive attacks of Varley, Pope, Brooks, and many others, plus an immense amount of costly experience, before the cheap idea was dislodged from the telegraphic systems of the country. Even then it was and is difficult to keep it permanently out of the field, and wherever any construction was to be undertaken outside of the big corporations, there the Cheap John would be found, ready to suggest that spruce house top fixtures were as good as pine; that blue vitriol of the cheapest grade, was as good as the purest; what difference can a little iron make? That Perizzite covered wire was better than kerite, because it peels so easy you know; that a large wire was an utterly useless expense, and that to pay $80 per month for an operator when you could get any number for $45, was little less than an outrage on the finest feelings of the human race.

These samples of imbecile reasoning being but samples, cannot be expected to do justice to the capacities of Cheap Johnism, but are to be taken only as a small index of his powers. In many cases the people who guide or control the purse strings of even great telegraph corporations, are still unable to look at many items from any other point of view, than that of first cost. Hence the evil I am decrying is only scotched,—by no means killed. In telegraphic construction however, great improvements have been made, and it is fully recognized in that field that to do good work and substantial work, money must be liberally expended, and that good construction with the best materials means the best service, and in the end at the lowest aggregate cost.

Driven from the telegraph tree, the Cheap John would have been sorely bested for a second retreat, and would have been compelled to look for minor fields of usefulness, had it not been for the opportune appearance of the telephone, and the immense impetus thereupon and thereby

Digitized by Google

given, to the extension of electric circuit construction through the land. It is hardly necessary I think that I should here recount in detail the operations of the enemy in his new sphere. It is sufficient to say, that he has fully maintained his ancient reputation, and has successively, and in a temporary way successfully, combated the use of line wire of sufficient size; insulators of all kinds, especially good ones; good batteries if they cost a little more than poor; well made and designed apparatus; and efficient labor if it has to be well paid for. The ground taken, is not in the latter feature usually stated so frankly as it is in some of the former; it is usually assumed in a tacit way that any kind of construction will do for this work; and that as a corollary of this premise, any kind of men will do as constructors, etc.

Perhaps no man has more consistently and stoutly fought these ideas than myself. I have endeavored, and as long as I am in the electrical field will continue to endeavor, to maintain as an axiom, that "whatever is worth doing at all is worth doing just as well as it can be done;" and I insist, moreover, that this is the only true and permanent economy.

The above principle in telephony also is daily becoming more generally acknowledged, and acted upon; the trees which shelter Cheap John in this part of the field are daily becoming fewer in number, and smaller in size so that only small men can hide behind them.

Where now shall the great ones hide their diminished heads?—"Eureka!" say they,—"Here comes the electric light." This has indeed proved a very paradise for the fraternity—who like lotus eaters and tramps, only ask to be let alone. Perhaps the last statement is a little too strong and I do not want to exaggerate; they *do* ask to be permitted to use painted wire and to call it "insulated" wire; they *do* want to run earth return circuits instead of metallic circuits; they *do* ask to use wooden bases for their instruments instead of stone, rubber or slate; and a few more small favors of that kind. And for a while it did look as if the Cheap John had found his permanent refuge in the electric lighting business of the country, where the ridiculously particular constructionist, and the conscientious builder and the skilled electrician might cease from troubling, and where John might be at rest. Again however he is to be dislodged.

Some of the best men practicing in the electrical profession have got into the lighting department, and they clearly see, and deplore the evils of false economy, and have taken and will not fail to take radical steps to uproot the practice.

It will need persistent and persevering effort but it will be done. It will not be done all at once, or in all places at once. Sporadically, the Cheap John will for many a long year yet, continue to operate in lighting, but the handwriting is already on the wall, and in this field also he is being driven from tree to tree, and a good and encouraging feature in the warfare is that the trees are being cut down, so that our friend the enemy, cannot make a detour and occupy many of them. But he is an enemy of resource, and has no trouble in descrying another clump of trees in the electric railway. Here again he is in his glory. He has his war paint on, and although each apparent triumph only assures him ultimately a more complete and irretrievable defeat; although also with him in more senses than one, "the path of glory leads but to the grave" little he recks of that—for the apostle of cheapness of all men lives but in the present.

It seems pretty clear at the present time, that those who are arranging for electric railways are restricted to a quite limited number of modes of getting the electric energy to the motor. We may use a conduit with a slit in it like the mechanical cable roads, and, carrying our conductors in that, run our connecting links, as trollies or brushes, through the slit; or we may adopt the third rail and trailing brush, or its equivalent; we may use secondary batteries and thereby practically carry boiler as well as engine with us; or we may run an overhead circuit and have vertical conductors reaching up to the supply circuit, and by a contact trolly traveling on the wire take off current for the motor carried by the car. I am not going to discuss the comparative merits of these plans. The secondary battery plan seems the most finished, since a certain amount of power is always at the disposal of the motor, and my own opinion is that this plan will constantly gain ground. The test of endurance has yet to be made. Next to this, when well constructed, I think the most practical and promising plan, is that involving the overhead wire. But such a chance for the advocate of parsimony and cheapness is too good to be overlooked.

The overhead circuit wire may be considered as carrying a current of considerable volume under an electromotive force of, say, from 500 to 600 volts. In too many cases (I had almost said in nearly every case) this circuit consists of a single wire. Let us reflect upon the meaning of this. What does a single conductor carrying a current involve or imply? We all know that it implies first of all "an earth return." That is, the dynamo is grounded and the circuit finds its complementary ground through the cars. It also implies destruction and injury—perhaps death, in case of even a slight accident to the single supply wire. It means a tremendous shock to anybody accidentally or inadvertently touching this supply wire, or any conductor connecting with it. It means that whenever this wire, or any part of it, falls, or whenever a telephone or telegraph wire falls over it, a possible loss of property or life. For it must be remembered that we cannot even go through the form of covering this wire (not to say insulating it), because the contact trolly must have a bare conductor to travel on. A consideration of this subject opens up a long vista of lateral possibilities in view of a single serious occurrence of the character foreshadowed above. The public does not discriminate. The press does not discriminate. One accident involving loss of life by reason of the criminal carelessness in the employment of a single wire circuit for this purpose, would do a great deal of harm to every electric light and power interest within a great area of country, besides generating an immense amount of distrust of even perfectly harmless appliances. But this is a rather narrow way of surveying the subject; one human life outweighs all the commercial interests in the country; at least to those who have a direct interest in that life; and in this phase of the subject centres the vital importance of guarding this latest tree from the occupancy of the Cheap John.

As long as his delinquencies only culminated in the waste of property it was well enough to keep still; but when human life is involved (and the Cheap John himself will concede that the human form cannot, when alive, be treated to a strong current of electricity under an E. M. F. of 600 volts with safety) it behooves those of us who stand for the right to use our pens and tongues in protest. My brethren, these things ought not to be. When the remedy is so easy as it is—when it is only necessary to run two parallel wires instead of one; to insulate carefully the lines and dynamo, and to add an additional trolly and connecting wire to the motor, surely this in all cases should be done. It should be made compulsory, for the apostle of parsimony cannot be trusted with an option.

An issue which is of a minor character also needs a brief notice. It starts from the same source and idea: viz.—cheapness at any price. This is the construction of low priced, non-ballasted and irregular roadbeds; soft and spongy foundations, and light rails. I know of a road which is all up hill and down dale, a constant succession of dive holes and "thank you ma'ams;" which is muddy up to the rail surface, and which has rails weighing 35 pounds only, to the yard;—while the man that laid it, knows, if he knows anything, that he should have regular and gradual grades; stone ballast, and rails 65 pounds to the yard. An electric street railway needs just as good

Digitized by Google

and substantial a permanent way as a steam railroad ; the traffic is usually as heavy in the aggregate, making up in constancy and frequency of travel, what it lacks in the direct weight at any one time, of the vehicles traversing it. But the usual statement of the Cheap John is, "that it hardly costs anything," and that "the use of electricity will compensate for any constructional weaknesses."

Of course the moneyed man who invests is not an electrician, and he thinks the advocate of cheapness is, so he accedes to every proposition.

All electricians who believe in the future of electricity ought to unite in a war of extermination against cheapness in applied electricity, wherever they see that it involves inefficiency, and danger.

The Cheap John must reform or go.

The Cheap John cannot reform, therefore—The Cheap John must go.

RECENT IMPROVEMENTS IN APPARATUS FOR OCEAN CABLING.[1]

BY CHARLES CUTTRISS.

In order that the improvements embodied in the instrument you may have seen at the American Institute Electrical Exhibition may be clearly appreciated, it would be well, perhaps, if I were to mention briefly the instruments previously used on the Atlantic and other long submarine cables.

The mirror galvanometer was undoubtedly the first commercially successful instrument ever used on an Atlantic cable, and you are all so familiar with it as a measuring instrument that a description will be superfluous, but perhaps it will be well to point out its defects as an instrument by which messages are received : Firstly, it requires two operators to work it, one to call out the signals, the other to write them down. At a first glance there would not seem to be much room for errors on the part of the *writer*, as the operator is called who writes the message, letter for letter, from the other's dictation, but you will see they *can* easily be made when your attention has been drawn to the similarity in sound between "B," "P," "V," "M," "N," and other letters when rapidly called out. This similarity of course depends largely upon the more or less clear enunciation of the speaker. The liability to misunderstand a letter on the part of the writer tells severely against the *rapidity* of the service as well as its accuracy, for this reason : supposing the writer misses a letter in a code message ; he has no possible way of telling from the context what it should be, he cannot interrupt the receiver to ask him to repeat it, therefore his only course is to omit it and trust to his reader's recollection of the particular word at the end of the message. If he should not remember it, they must then delay the traffic by getting the word repeated from the distant station.

In order to avoid this liability to misunderstand one another, some operators got into the way of calling out the letter and immediately following it with some short word whose initial letter would correspond with the one called out, such as "n" for "nuts," "m" for "mutton," etc.

Another cause for delay arose from the fact that some readers would never trust to the correctness of their writer, but would always stop at the end of a message to scan it over in order, if possible, to detect any error that might have been made. While all these things added to the delay in transmission, one can hardly blame the clerks, for if an error was discovered at headquarters it meant a fine of $\frac{1}{12}$, $\frac{1}{8}$ or $\frac{1}{4}$ of a day's pay, in which all three of the clerks—the transmitter, receiver and writer—had to participate. It was impossible to lay it at the door of any particular one, as each of them would most emphatically deny the soft impeachment of the possibility of *his* making an error.

These causes of delay are now obviated by the use of the recorder, as the operator can always take a second glance at any doubtful signal. Were it not for this liability to error on the part of the mirror clerks, I doubt if that instrument would have been so entirely superseded by the recorder, for its simplicity is a great recommendation. It requires very little skill in its adjustment, and with clerks that work well together, its speed is as great as, if not slightly greater than, that of the old form of recorder.

During the years 1868 and 1869, while I was in Sir William Thomson's laboratory in Glasgow University, his first siphon recorder was constructed. I well remember the instrument, the electro-magnet of which was a ring of iron about one foot in diameter, one inch thick and six inches deep. The signal coil was rectangular in shape, about six and one-half inches long by two inches wide. The electro-motor for drawing the paper slip was an ordinary five or seven armatured wheel with two electro-magnets. It was provided with two bands, one of which

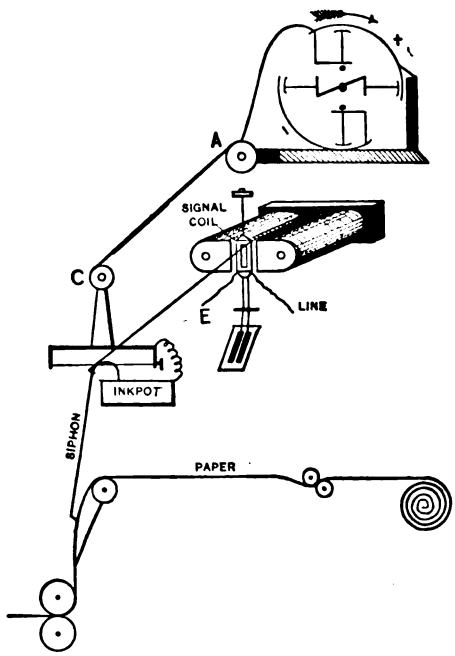

FIG. 1.—"MOUSEMILL" AND SIPHON RECORDER.

turned some wheel work, which drew the paper slip, while the other rapidly revolved a small generator or replenisher which produced by induction static electricity for maintaining the electrification of the ink. This replenisher worked on the same principle as those used for maintaining the potential of the Leyden jar of Sir William's quadrant electrometer. The whole arrangement looked like a medley of different instruments selected at random from a laboratory supply ; yet each had its different part to perform, and it was wonderful to see the results that were obtained, when they were working harmoniously together under the direction of the masterly mind of the man who organized them, and who stands peerless as an inventor, a scientist or a patient instructor.

Some three years later one of the most improved recorders was sent out to the cable station at Duxbury, Mass., and as you may not be acquainted with its construction I will describe it briefly in order that you may more readily understand the changes that have been made in it up to the present time.

The upper part of the diagram represents the "mouse mill," as it is commonly called, which generates the static electricity that is conducted from the drum A containing

1. Read before the New York Electrical Society and the American Institute of Electrical Engineers, Nov. 15th, 1887.

Digitized by Google

a coil spring, along the moist spring and thin wire which you see stretched from A to C; the ink pot is supported on a baked wood arm and is metallically connected with the frame to which the siphon is suspended, this in turn being connected with the milled nut C. Between the respective poles of a strong electro or permanent magnet, there is an oblong piece of soft iron the purpose of which is to concentrate the magnetic lines of force into two fields, through which the two sides of the rectangular signal coil pass. The signal coil which is connected to the cable is suspended by fine silk cord, and care is taken that it hangs perfectly clear from all the iron of the magnetic circuit. Attached to the bottom of the signal coil will be seen two strong silk fibres which pass behind a brass bar, into which a series of shallow notches are cut. To the ends of the fibres are attached lead weights which slide in grooves that are tilted slightly out of the perpendicular, the lower ends being the nearest to the observer; by this arrangement the fibres pass at a slight angle partly around the serrated brass bar, and consequently are held securely from any lateral displacement in any one of the notches in which they may be placed. These weights and fibres hold the signal coil in the magnetic field and prevent its moving in any direction other than a circular one, with the suspension cord as an axis, and any movement in this direc-

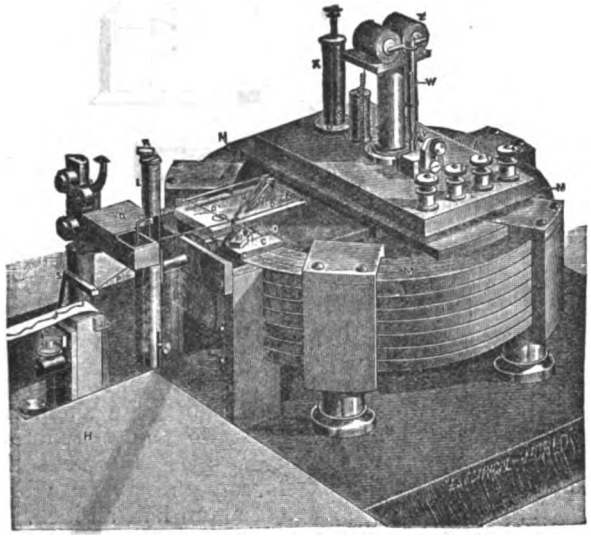

FIG. 2.—THE CUTTRISS RECORDER.

tion is resisted by the two fibres supporting the lead weights, which tend constantly to keep the coil in the centre of the magnetic fields, and, therefore, the movements of the coil are controlled almost entirely by these fibres.

The siphon is attached, as shown, to a brass frame, from the bent ends of which is stretched a fine brass wire kept under a constant strain by a curved spring at one end. To the other end of the spring is attached a milled nut by which the wire can be twisted so as to put a lateral strain on the siphon and its carrier. A small lug projects from this carrier and to it is attached the fibre, the other end of which is fastened to one corner of the signal coil. The signal coil is now twisted slightly in a direction such as to draw the fibre, and with it the siphon, away from the observer. If now the milled head on the brass frame is turned so as to bring the end of the siphon again toward the observer and into the centre of the paper slip which passes in front of its lower point, every motion of the signal coil must be followed by the siphon; and as the fibre is attached so near the strained brass wire the movements of the signal coil will be greatly multiplied.

The marking of the siphon is done as follows: The mouse-mill generates static electricity, which being conducted along the string and wire from A to C electrifies the ink contained in the ink pot, and as the ink pot is insulated, the only way that the electricity can escape is by means of the column of ink contained in the siphon. It does not discharge as is commonly supposed across the air space between the siphon point and the moving paper slip, but the electrified ink draws the siphon which contains it bodily toward the paper (which is slightly damp) until they touch, when the siphon is immediately discharged to earth, and by its elasticity flies back to its former position, by which time a sufficient charge of electricity has accumulated to again attract it to the paper. These movements to and from the face of the paper, which are termed the "vibration," take place at a speed determined by the natural rate of vibration of the siphon, and is generally between 80 and 100 per second; hence we can obtain a record of the potential of the cable as many as 80 times a second; and as these potentials are determined by the operator sending at the distant station they constitute the signals at the receiving stations.

The arrangement adopted in this instrument to regulate the supply of static electricity to the ink pot was by interposing a piece of moist string between the spring drum A and the milled head C. This string had a fine wire attached to one end, so that by turning the milled head in one direction the length of the moist string interposed between the two points could be varied and likewise the electric discharge to the ink pot.

This arrangement worked very well at Glasgow, where the atmosphere is to a great extent saturated with moisture; but in this country the string was soon dry, and then the ink would not be electrified, and consequently the record would fail. To remedy this defect I made use of the brush discharge by connecting an adjustable wire provided with a sharp point to the drum A, and a flat piece of brass to the milled head C. This was found to work perfectly, and that principle has been adopted in all electrified ink recorders made since that date. But we soon began to experience a greater trouble than the one before spoken of, and one that still exists in all recorders using static electricity as a means of vibrating the siphon; that is, the great difficulty experienced in generating a supply of static electricity during damp weather, and in keeping the arm that supports the ink pot dry. Everything will work beautifully in nice, fine weather, but during the moist, clammy dog days of August, and the foggy days that are liable to come on at most cable stations without a moment's warning—then it is that trouble of the most aggravating description falls upon us. Suddenly the record fails. Examination shows that the generator or supporting arm of the ink pot has got damp. Lamps are lighted and placed near the instrument, *sometimes* with a satisfactory effect, but oftentimes not. In the latter case there is nothing for it but to stop working the recorder and go over to the mirror instrument while the generator is being dismounted and thoroughly dried; but meanwhile valuable time has been lost, and business has been delayed.

Everything imaginable was tried in order to overcome this difficulty, but without success, and at last we realized that in order to make the instrument more reliable, we must find some way of obtaining a record without depending upon the electrification of the ink.

The first suggestion came from Mr. John Gott, the superintendent of the St. Pierre station, namely, to make the siphon a shade larger than usual, and put a few camel hairs in the tube at its marking point, and, as it were, paint the record on the paper slip. This worked very well, but the siphons would occasionally clog up, as we were at that time using commercial writing ink. The hairs acting as a strainer would arrest the larger particles. When you realize the smallness of the tube, the bore of which is only $\frac{1}{100}$ of an inch in diameter, the wonder is *not* that it got clogged up, but that the ink would flow through it at all. The next step in advance was taken one day when the hairs accidentally came out of a siphon, the point of which happened to be particularly smooth and square with the

Digitized by Google

paper; it was then found that a very good and reliable record was made by carefully adjusting the paper up to the point of the siphon until it touched it. The paper was then drawn slightly backward again; the capillary attraction being sufficient to keep the siphon from leaving it, while at the same time the friction was greatly reduced. This manner of recording has been used ever since that day on the D. Y. section of the "69" cable, and it has also been adopted on many others whose length does not exceed 1,000 miles, but they must have a conductor of low resistance.

About the year 1876 I constructed a recorder of the most simple kind, in which the signal coil was pivoted and to which the siphon was directly attached. The controlling springs or fibres were dispensed with by attaching a small piece of iron to one corner of the coil and bringing it under the influence of another movable piece of iron on one of the pole-pieces of the electro-magnet. It was during the construction of the instrument that I first endeavored to vibrate the siphon mechanically and also by means of magnetism, but at that time I did not succeed in getting a perfectly straight and steady line. As the mode of working before described was so satisfactory, I did not pursue my experiments any further, for inasmuch as I had eliminated the troubles incident to the use of electrified ink at the Duxbury station, I did not realize that they still existed at other stations where the methods we adopted could not be practiced, owing to the greater length of the cables. However, Mr. Dickenson, of Heart's Content, N.

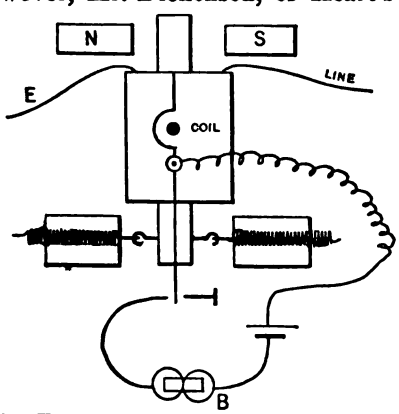

FIG. 8.—THE ALLEN AND BROWN CABLE RELAY.

F., was not idle, and during the year 1885 he invented and patented a method of vibrating the siphon mechanically. The method practiced by him was to prolong the cradle carrying the siphon. He then attached a magnet and armature at the end of the frame carrying the strained wire, and connected the prolongation of the cradle to the armature by a silk fibre. When a battery is connected to the magnet and its circuit is rapidly interrupted, the motion of the armature is communicated to the siphon by means of the connecting fibre. What success this invention has met with in practice I am unable to state.

When I became identified with the Commercial Cable Company, I found that it was decided to prolong their ocean cable, which landed at Coney Island, into the heart of the city by means of an underground cable, and to use a recording instrument upon it. The type of cable and the high rate of speed at which it was to be worked required that the instrument should be of the most sensitive class, hence electrification of the ink or some other device for preventing friction between the siphon and the paper slip must be used. Therefore, as nothing else offered, we adopted the electrified ink recorder. It was not long before the old troubles were encountered, as the office was very small, and we were obliged to keep the windows open for ventilation. Consequently it would be only a short time after a rainstorm began before I heard the old cry, "the ink has failed." This was such a constant source of trouble that I determined to try again and find some other way of vibrating the siphon. After mature thought, and with the experience gained from previous failures, I was convinced that, in order to make any device work successfully and still leave the instrument as sensitive as by the use of electrified ink, the siphon must hang perfectly free and not be retarded in its lateral movements by any extraneous fibres, and that, at the instant it touched the paper to leave its clot of ink, the point must be locked, as it were, to prevent its rebounding laterally, in case the surface of the paper should be slightly irregular. The only resource seemed to be magnetism applied as nearly as possible in the same manner as had previously been practiced with electricity. I determined therefore, that the part of the siphon under its influence must be the marking point. The question then arose in my mind as to the possibility of attaching a sufficiently large piece of iron to the end of the siphon without weighting it to a degree that would be detrimental to the clearness of the signals, by reason of its increased inertia. Another very doubtful point was, would it be possible to construct a magnet with a field of force so uniform that a siphon tipped with iron would vibrate at right angles to the plane of its polar face without any tendency to irregular lateral movements, or in other words, if it were placed near the edge of the magnet, would it not have a tendency to be drawn toward the centre? When the idea was first conceived, I must admit that I had the greatest doubts of its success. But nevertheless I determined to give it a trial, so I attached a toothed wheel to the shaft of an electro-motor, so as to act as a contact breaker for the local circuit, containing the electro-magnet with which it was desired to vibrate the siphon which had its point armed with a small piece of iron, and was attached to the usual strained wire suspension of a recorder, held firmly in a vice on the same table upon which the motor was running. The siphon was now approached by the rapidly vitalized electro-magnet, but without its showing any signs of vibration. Thinking that perhaps the battery was not strong enough to energize the electro-magnet sufficiently, more was added to the circuit, but still without effect. The electro-magnet was then removed, intending to replace it with a more powerful one, but the motor was still running; so imagine my surprise the next time I looked toward the table when I saw the siphon vibrating beautifully, describing an arc of about half an inch.

Thus without any apparent cause it was doing of itself what I had vainly endeavored to *make* it do with a powerful electro-magnet. However, the solution of the mystery was soon arrived at, as I accidentally touched the table and felt a very slight but regular vibration, then everything was clear and I saw that the motor put the table into a state of vibration, the rate of which was exactly equal to that of the natural rate of the siphon; which, therefore picked up the vibrations and showed them in a greatly magnified form. I realized plainly from this experiment that to make the siphon vibrate by magnetism all that was necessary was to vitalize the magnet at a rate equal to the natural period of the siphon. In a short time by means of a second experiment I succeeded in producing these vibrations by magnetism and found them just as regular at the edge as at the centre of the magnet, the siphon not having the slightest tendency to move laterally from any position in which it was placed.

It would be uninteresting to you to follow me through all the numerous experiments that were made before the vibrator was perfected. But I will mention one instance that shows how simple may be the cure for the unforeseen difficulties that constantly arise when one is trying to perfect an instrument. When the first vibrator was tried, in which mercury was used to alter its rate, it was noticed that the record would fail with great regularity for about an inch. The trouble was located in the glass tube, and was due to some of the mercury climbing up it under the influence of the vibration and then falling back to the

Digitized by Google

main body. This, of course, made variations in the rate, and was fatal to the instrument unless it could be remedied. I tried to put weights on the top of the mercury, but they would not work satisfactorily, and at last when almost in despair, the remedy was found in two drops of glycerine. The viscosity of the glycerine, I find, is so great that it prevents the column of mercury breaking up.

This method of vibrating the siphon by magnetism has been applied to all the Thomson recorders in use on the Commercial Cable Company's system for upwards of a year with the greatest success. Failures of the ink now are a thing almost unheard of, and the recorder, so far as ink failures are concerned, could, if necessary, be worked under a shed during a rainstorm or fog, as well as though it were in a warm room.

In all the Thomson recorders that I have seen the movements of the signal coil are controlled by the lead weights before spoken of, and the clearness of definition and shape of the signals depend almost entirely upon the adjustment of the fibres which are attached to the signal coil and support these weights. In practice more or less trouble is found in maintaining such an adjustment as will give the best shaped signal. This is owing to the dust which collects upon the weights, wedging them fast in the grooves. Consequently any change of temperature, or humidity of the air, will alter the tension on one or both of the fibres, and thus oftentimes render the signals unreadable. So much trouble was experienced from this cause at our Canso station that it led the superintendent, Mr. S. S. Dickenson (who was ably seconded by Mr. J. C. Upham, the mechanician), to devise an adjustment in which the weights were discarded and a spring used in their place. The fibres could also be spread to any desired extent, and as the strain on both of them was exactly the same, the signal coil was always in a truly central position in the magnetic field.

Since this improvement has been applied to the instruments the adjustment has rarely been changed, and, what is of still greater value, a decided increase of speed has been effected. With the exception of these recorders, it is always necessary to stop work when it is desired to make any change in the adjustment of the controlling fibres, as they are very inaccessible. This, together with their occasionally breaking, led me to try and construct an instrument in which these difficulties would be removed. The result has been the instrument now on exhibition at the American Institute Exhibition.

The siphon P is a fine glass tube about one hundredth of an inch diameter, one end of which writes upon the paper slip J, and has attached to its point a piece of No. 30 iron wire about one-eighth of an inch long, which serves as an armature and is controlled by the impulses of the magnetic table T over which the paper slip passes. The impulses of the magnetic table are controlled by the vibrator, which is placed on the large permanent magnets M M, and consists of a glass tube W which is connected by a tube of india-rubber to the mercury reservoir X. The glass tube is supported by a steel rod carrying a spring contact point V, and carries an armature, seen opposite the poles of the small electro-magnet Z. When a battery of three or four gravity cells is connected to the terminals 1 and 4, the glass commences to vibrate at a rate determined by the height of the column of mercury in the glass tube W, the height of which can be regulated by turning the milled thumbscrew at the top of the mercury reservoir which connects with a plunger within the latter.

From the terminals 2 and 3, two wires connect to the electro-magnet of the magnetic table T. Thus every time the contacts at B are closed the table is energized and the siphon is drawn down to the face of the paper by the attraction of the magnetic table for the small piece of iron which is attached to the point of the siphon. If the impulses given to the siphon are in accordance with its natural rate of vibration a succession of fine dots of ink will be left on the paper in a perfectly straight line so long as the siphon is not moved laterally by the coil R and a supply of ink is maintained in the ink pot Q. Should the impulses given to the siphon by the vibrator not be in accordance with the natural rate of vibration of the siphon, it will not vibrate and the record will fail. But by manipulating the plunger in the tube X, the height of the column of mercury W is varied, so that the rate of the impulses can be maintained anywhere between 60 and 100 per second. Hence any siphon that would be suitable for the instrument can be controlled, as its rate will lie within these limits. When the proper height of the mercury has been once determined, which is generally found in less than half a minute, the siphon will continue to vibrate until it is broken or removed for other causes.

The signal coil R, which is moved by the currents transmitted from the distant station, is pivoted at the bottom and top, B, in agate bearings, and is free to move in the annular space between the poles of the permanent magnet M. On the top of the coil there is attached an aluminum extension, E, which has a narrow slot at its upper end through which passes the regulating fibre D′, one end of which is attached to a rigid support, O, the other end being fastened to a flexible spring, F. The strain on this spring and this fibre is regulated by moving the index G′, and the strain thus produced controls the movements of the signal coil R. Close to the point E and at right angle to the fibre L′ there is another fibre, D, one end of which is attached to an exceedingly delicate spring, F, the other end is fastened to an extension from a fine brass wire contained in the tube L, to which the siphon is secured. The upper end of this strained wire is attached to the thumbscrew K, so that by turning the latter the siphon can be moved laterally over the face of the paper to any required position.

Thus it will be seen that if the siphon is moved off the paper slip toward the front of the instrument when the fibre D is strained by moving the spring F outwardly, the siphon can be pulled by it into a position over the centre of the paper; the torsion on the strained wire and the strain on the spring now balance each other, and if the two cross fibres are fastened together at a point as near as possible to the extension E, any movement of the coil will be multiplied and transmitted by means of the fibre D to the siphon. By lifting the fibres out of the slot E and turning the coil toward the front of the instrument, the coil and part of the pole-piece C can be removed from the instrument without disturbing any other part, and, when replaced, no readjustment will be necessary.

It has been suggested to me that pivoting the coil was a step backward, as it introduced friction, and would mar the definiteness of the signals. I can only say, in reply, that when the instrument is adjusted, and giving good signals at a rate of 30 words per minute, I cannot detect the slightest friction. If I deflect the siphon laterally only the width of a hair it immediately, on its release, returns accurately to zero, which it certainly would not do if there was any friction worth speaking of in the pivots.

I have received good signals on this instrument at a speed of 30 five-letter words per minute, over our New York Canso cable, which has a length of 980 miles, capacity of 231 microfarads and copper resistance of 13,680 ohms.

I do not intend to stop at this speed, but think that with the next instrument, in which some of the parts will be slightly modified, a speed of 25 or 26 code words a minute will be attained over our long sections, which have a length of 2,740 miles, capacity 874 microfarads and copper resistance 6,967 ohms.

I will not take up much more of your time this evening, but as the title of this paper is so broad I am loth to leave the subject without mentioning the great advance that has been made during the last few years in the working of the Morse system on cables.

Before the year 1879 no section of the Atlantic cables

Digitized by Google

had been worked by any other method than mirror or recorder. That the Morse *has* been successfully introduced on two sections is due to the determination and persistance of Mr. G. G. Ward, of this city, at whose request Mr. T. J. Wilmot, now superintendent at Waterville, Ireland, applied himself day and night to the task of originating a translating device by which, in the year 1879, Torbay, in Nova Scotia, was put in direct communication with New York.

This same device, in which the Allen & Brown relay is used as a receiving instrument on the cable circuit, is now worked on our Rockport and C. S. section. The difficulties that were surmounted will be better appreciated when I mention that the length of cable in circuit is 610 miles, with an inductive capacity of 168 microfarads and a copper resistance of 8,482 ohms. The total circuit, inclusive of the land line, is 942 miles.

The Allen & Brown relay consists of a coil through which passes a soft iron core. The ends of the core project into the magnetic field produced by the permanent magnets N S, and are consequently polarized by them. In the diagram, the mark in the centre of the rectangle represents the axis of the coil. If, now, we connect the coil to the cable circuit and have two fixed contact points for the local circuit, as in an ordinary relay, the first impulse, of say the letter "s," which consists of three dots, will close the local circuit; but as the cable does not lose its charge rapidly, as is the case with a land line, the coil will not return to the back-stop and be ready to close the circuit again with the second impulse of the letter, but will be held fast to the front contact, keeping the sounder closed all the time. This, of course, will prevent any more signals being received over a cable, and some means had to be found by which the armature tongue would open the circuit whenever the potential of the cable fell ever so slightly from its maximum. This was accomplished by allowing the armature tongue, which is called the "jockey," to have a movement around an axis of its own. It was therefore pivoted, as shown, slightly in advance of the axis of the coil; you will now see that if the two points which control the local circuit are adjusted very closely together, allowing the end of the jockey a play of only $\frac{1}{1000}$ of an inch, every time that the coil falls back toward its centre position (after having been deflected by the receiving current) only $\frac{1}{1000}$ of an inch, the local circuit will be opened, and *vice versa* any increase in the potential sufficient to move the coil the same amount will again close the local circuit. By this means the coil is moved sometimes considerably in one direction, and, although by watching it very closely, no backward movement can be detected, the jockey will open the circuit, sometimes two or three times, proving that there has been corresponding falls in potential. On the axis of the "jockey" is a very delicate spring which can be pressed down by a small nut so that just sufficient friction is maintained on its jockey to enable it to close the local circuit firm enough to pass the signals to the local circuit.

Some few changes have been made in the jockey of the relay by the superintendents at the terminal cable stations —Mr. Dickenson at C's and Mr. R. Hearn at Rockport— until at last such perfection has been arrived at that the signals are passed from Canso to New York in such a perfect manner, that none but an expert could tell that there was any cable in the circuit. This is, I believe, the longest section of cable on which the Morse system is worked, and although repeated efforts have been made to attain the same results on a cable only about 100 miles longer, the retardation was so severe that the speed attained was too low to allow this system to be adopted. Gentlemen, I thank you for the patience with which you have listened to me this evening, and I regret that time will not allow me to touch on several other interesting branches of investigation, such as curb sending, the duplex, automatic transmission, etc. But the object of this paper will have been attained if you realize that, although seldom heard from, there *are* many patient investigators in our remote cable stations, and that to their unflagging energy is due the fact that we are now easily able to handle a bulk of business that would have staggered us a few years ago, and do it with so little delay, that a message can be sent from New York and delivered in London in less time than you can send one from down-town to Harlem.

USES OF ELECTRICITY IN MILLS.

AN ADDENDUM.

BY C. J. H. WOODBURY.

THERE are some applications of electricity in mills which are so exceedingly common and prominent that they escaped notice, and therefore were not referred to in my previous article on the subject.

Supposing that we were to revisit the mill for the purpose of examining some applications of electricity which had escaped record on the previous visit: our entrance to the office would be stopped by the fact that the door knob would ineffectually turn round and round without catching upon the latch until someone touched an electric button which connects by wires to the latch and causes the mechanism to engage with the knob, permitting the knob to be turned just once, and requiring another pressure on the electric button to turn the latch again.

The time used in large mill corporations is distributed by synchronous electric clocks used in most of the rooms, while the most careful measures are taken in every large manufacturing city to secure the distribution of accurate time. For many years the corporations in Lowell had a contract with the Harvard Astronomical Observatory by which they received the standard time once a day; and in about all the mills in New England arrangements are made by which they obtain the exact time as it is signaled over the wires once a day. Those mills which are engaged in manufacturing standard print cloths, which are subject to fluctuations in price, are frequently provided with stock tickers showing the daily quotations of print cloths and cotton.

Electricity is not used for lighting gas jets in mills as in the method of pendant sparking apparatus used in houses, or the static electric apparatus used in theatres, unless the former kind may be applied in the office. There are two types of electric gas lighters, one being the well-known arrangement of chloride of silver battery, a primary coil contained in a single hard rubber case, and furnishing a succession of sparks over the burner and igniting the gas. Another type contains two vulcanized rubber cases, one of them holding the bichromate of potash battery, and the other containing a primary coil. As in the former case, a motion of the thumb upon a switch produces a spark and ignites the gas. There is also a portable static machine for lighting the gas, but it cannot be used in rooms where there is sufficient escaping steam to render the air humid.

Telemeters are used for transmitting by electric means any form of observation which is desirable, such as the height of water in the source of supply furnishing power to the mill, the pressure of steam, or the condition of the elevated water tanks. One of these instruments was of especial value at Holyoke in notifying the engineer in charge of the water power, of a forthcoming rise of water in the river three hours before it had reached the dam at that city.

In the allusion to the method of electric clocks for recording the work of the watchman, there was an omission of reference to the alarm which can be sounded at the house of the superintendent, or the watchman's room, or any other convenient place if the watchman is late at any

Digitized by Google

point in patrolling his course, the limit of such tardiness being usually fixed at twenty minutes, and the operation of the device is automatically produced by the mechanism of the watch clock.

Another form of thermostatic alarm for a different purpose in dry rooms, is the well-known metallic thermostat, in which a straight or coiled strip of metal, by its expansion or contraction under changes of temperature, causes an electric circuit to be closed and an alarm to be given whenever the temperature rises or falls beyond certain limits. The usual combination for such thermostats is a bar or base of vulcanized rubber and a bar or strip of steel.

The electricity used in mills for telephones and other signaling purposes is frequently obtained from large magneto machines, especially in paper mills where the continuous operation of the beating engines ensures that the electric current will be ready for use at all times, irrespective of ordinary working hours.

Magnetism serves several useful purposes in manufacturing establishments, for separating brass and iron filings and turnings in machine shops, for removing bits of metal from the paper pulp in beating engines of paper mills, and also for removing pieces of metal in grain mills; and, so far as I am aware, these devices are all dependent upon permanent steel magnets instead of upon the use of electro-magnets, which would give them a much higher magnetic attraction and would never be required except when the machinery was in operation, and therefore would allow the production of the source of electricity by a generator whenever it was needed.

The use of electric motors in mills has grown very slowly, partly, no doubt, on account of the delays in furnishing electro-motors which could be applied in conjunction with electric illuminating systems. They have, however, proved to be of great convenience and cheapness for the elevators in storehouses situated too far away from the prime mover of the mill to allow the application of power by ropes or shafting in the ordinary manner. Electric motors have also been used for driving light machinery, such as winders for spool cotton, which it is frequently desirable to place apart from the main portion of the mills and inconveniently situated in respect to the power; and this permits that they should be placed near the packing and shipping department.

Several years ago I called the attention of a prominent electrician engaged on the question of electric transmission of power to the important purposes electric motors could serve in operating the calico printing machines, where it is necessary that each machine shall be driven at periods and rates entirely independent of its neighbors and based solely upon the conditions of the fabric and pattern. This work is now done by independent steam engines, which take up valuable space and render the room so hot as to interfere, I believe, with the best work of the men. It is here that there is an opportunity for electric motors especially designed for such purposes, and there have been recent accounts in the foreign electrical papers of motors designed and applied in this specific manner in England.

There is one new use of electricity which has not yet reached a general application, but which will, no doubt, become a most valuable adjunct in every repair shop in the country, and that is the system of electric welding invented by Professor Elihu Thomson.

Some of these applications of electricity have had but limited service and are scarcely known beyond where they have been tried in almost an experimental manner; others are in general use rendering valuable service, and have rewarded their inventors in the most liberal manner.

Wherever in any process of manufacturing there is a demand for extending the capacity and use of the human senses in the perception of size or temperature, there is ample opportunity for the exercise of electrical invention in the production of mechanism to fulfill that office.

DYNAMIC ELECTRICITY.

BY CARL HERING.

(Concluded from page 434.)

CHAPTER X.—EXAMINING MACHINES.

After a dynamo is completely finished it is well to subject it to a thorough examination, not only for the purpose of being assured that it will run properly, but also to find out whether it is properly proportioned in all its parts, or whether it could have been improved in some of its proportions, and if so, what proportions are faulty, and to what extent they could have been improved. It will likewise show whether the machine is run under the most advantageous conditions, and if not, what changes would enable it to be run so. The data which may be obtained from such examinations when properly made, will often be found to be of great assistance in designing other machines of different sizes, proportions and styles.

As these tests may sometimes show faulty construction or proportioning, it is well to make some of them while the machine is wound with temporary field magnet coils, that is, before it is finally wound with its proper coils. This applies more particularly to the saturation and the heating tests, as also to the test for the effect of the counter magnetization of the armature. Some of these tests will, of course, be different according as the machine is separately excited with temporary coils and an exciter, or whether it is self-exciting, as a shunt, series or compound machine.

Among the most important of these tests is the determination of what are called the "characteristics" of the machine. These are the results of a succession of tests plotted in the form of a curve, which then shows graphically some of the more important features of the machine.

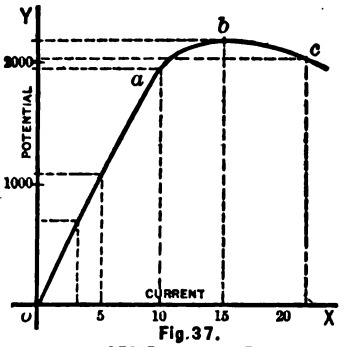

Fig. 37.
SERIES MACHINE.

Such curves will show at a glance how one quantity, say the electromotive force or current, will change, when changes are made in another quantity, say the external resistance, speed, or magnetization. For instance, let a series wound machine be run at a constant speed, and let it discharge through a succession of different resistances (which need not be measured) varying from a very large one to as small a one as the machine will stand without injury. Measure both the difference of potential at the terminals, and the current, for each resistance. On a piece of cross-section paper lay off these different currents to any convenient scale, along the horizontal line o x, figure 37, from o to the right; similarly lay off the differences of potential from o to Y on the same or on any other convenient scale. The intersections of the vertical and horizontal lines drawn through each two corresponding values of the current and difference of potential respectively, will give a series of points, the curved line *o a b c* through which will be the characteristic for the current and potential of that machine. This curve shows at a glance that when the currents are small the potential increases rapidly with an increase of current; and as the first part of the curve is a straight line it shows that the potential increases in

Digitized by Google

the same proportion as the current. When the current has been increased to a certain value, in this case ten amperes, the potential no longer increases so rapidly, and at fifteen amperes it has reached a maximum limit; for still greater currents the potential falls again. From this characteristic the following deductions can be made. Barring other considerations, this machine should not be run normally for currents or potential less than those of the point *a*, for if it is, the curve shows that it is not running to the best advantage, or in other words, the machine is larger than it need be. It should not be run much beyond the point *b*, as that is the maximum point for the potential, and it is probable that the machine heats greatly beyond this point, and therefore runs at a disadvantage and with poor efficiency. Furthermore, for values of the currents between *a* and *c* the machine will give a nearly constant potential for different loads, the variations in the potential being less the nearer this part *a c* of the curve approaches a horizontal, straight line. The curvature at *a* is due to the iron having become saturated, and shows that a greater current in the series coils than that for *a* has little effect in increasing the magnetism, and therefore, the potential; series wound machines for arc lights in series may therefore be run above the point *a*, because changes in the current due to poor regulation of the lamps, will then have less effect in causing the potential to change, in other words, the magnets are less sensitive to changes of current beyond the point *a*, and, therefore, the current will be more nearly constant.

In the same way the characteristic may be drawn between the known external resistance and the potential, showing how the latter will vary for different external resistances. Similarly, that for the resistance and current will show how the latter will vary with changes in the former, and between what values of the resistance the

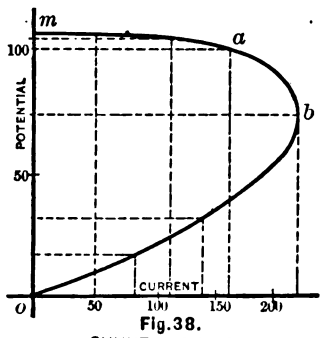

Fig. 38.
SHUNT MACHINE.

current will be nearly constant. By running the machine at different speeds and discharging through the same fixed resistance, the characteristic for the speed and current, or speed and potential may be obtained. Or if the resistance is also varied for each speed a succession of curves, like that in figure 37 will be obtained, showing the effect of changes of speed. But in general, characteristics involving changes of the speed, though interesting and instructive, are of less practical value, as it is assumed at the outset that the speed is as great as mechanical considerations will permit, as pointed out in another chapter. The speed characteristics become important when it is desired to shift the curved part *a b* of the characteristic nearer to or further from the point o.

A characteristic curve can be obtained for any two varying quantities which depend on each other, and for only two, as for instance, the current and potential; all other quantities (as for instance, the speed) should remain the same, except, of course, such quantities as the external resistance in this particular case, which must be changed to produce a change of current and potential. If it is desired to vary a third quantity, such as speed in this case, separate curves must be drawn for successive values of the speed.

Similar characteristics cannot be compared with one another, unless reduced to the same scales, for it is evident that two characteristics drawn to different scales, may be identical in appearance and size, but still represent totally different results.

The general characteristic for current and potential of a shunt machine, for different resistances, is shown in figure 38. Starting first with open circuit, that is with an infinitely large resistance, and, therefore, no current, the machine gives its maximum potential *o m*; with a gradually decreasing resistance the current increases and the potential falls slightly; it will continue to fall proportionately to the current as the resistant decreases, as far as the line *m a* is a straight line. At *a* the potential falls rapidly, and at *b* the maximum current is reached; by decreasing the resistance still more, the current and potential both fall until the resistance is zero, that is, until the machine is short circuited, when both are zero. This shows that there is a maximum current *o e*, which can be obtained from a shunt machine, and that the maximum potential *o m*, is when the machine is run on open circuit. It, furthermore, shows that if the armature can stand the maximum current *o e*, then no adjustment of the external resistance will injure the machine. This is not the case with a series machine which would soon be destroyed when run on too small a resistance, as seen from its characteristic. A shunt machine is never run in practice between the points *b* and *o*, because, as could readily be proved, the same output could be obtained from the same armature and frame with a much less expensive winding of the field magnets; it would therefore be very uneconomical, as far as first cost is concerned, to run a shunt machine at the part *b o* of the curve. The best machines are seldom run near the point *b*, being usually limited to a short part of the line *m a*. It would not be safe, therefore, to diminish the external resistance too much for fear the maximum current *o e* might be too great for the armature.

It will be noticed that the part *m a* is nearly straight, and that, therefore, the potential falls regularly but slowly even for wide ranges of the current, and that if this line could be made to be horizontal the potential would be constant for the corresponding values of the current from *o* to *o f*. The inclination of this line is due to the fact that some of the electromotive force is absorbed in the armature itself to overcome its internal resistance, and that this amount increases with the current. If, therefore, the armature resistance be practically zero, there would be no fall of potential in the armature, and, therefore, this line *m a* would be horizontal, in other words, the shunt machine would have a constant potential for greatly varying currents. This, however, would necessitate having either a very large armature or a very intense field, both of which add to the cost of a machine. Instead of avoiding this fall of potential, it may be neutralized or balanced by a simple combination of the two characteristics, figures 38 and 37, that is by a combined shunt and series winding. In figure 38 the potential at first falls in a regular proportion, while in figure 37, it rises in a regular proportion, therefore, by a proper combination of the two their total action may be made to keep the potential constant. To do this the part *o a* of the series curve should make only a small angle with the horizontal, as *o a*, figure 39, which is accomplished by using only a few series windings. This angle should be such that the increase of potential *f a*, figure 39, due to the series coils for any current, *o f*, should be equal to the fall of potential, *g a'*, due to the shunt coils, for which *m a'* is the curve. The resulting action of the two will, therefore, be a constant potential for all currents from zero to a certain limit, *o f*. The characteristic for this compound machine will therefore be *m g*. How to proportion these two sets of coils to obtain this result has already been explained in chapter viii. It will be noticed that the shunt characteristic in figure 39 curves downwards for currents greater than *o f*, and, that therefore, that for the compound machine *m g*, will also curve down-

Digitized by Google

ward beyond g. This shows that a compound machine should be used only in such parts of the two characteristics, $o\ a$ and $m\ a'$, as are nearly straight lines, for up to this limit only, can it be made to have a constant potential for different currents. It can readily be shown that the curving of the line $m\ g$ at g, is due chiefly to the magnetic parts of a machine being nearly saturated; a compound machine should therefore be run below the saturation point, as explained in chapter viii.

This leads to another and very important test which machines should be subjected to, namely, the test for

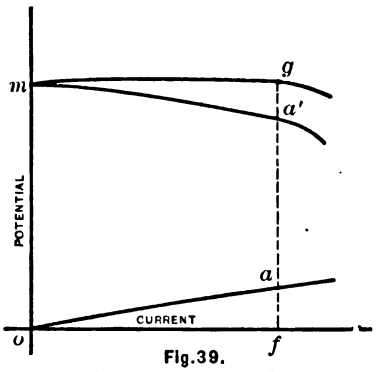

Fig.39.
COMPOUND MACHINE.

saturation. This test is best made with temporary coils on the magnets, excited by a separate exciter the current from which can be varied between wide limits. It can also be made with the finished coils of a machine if the exciter has the proper potential for these coils. It can also be made with shunt or series machines by letting them excite themselves, but this is generally less satisfactory, at least when it is desired to test the magnetic qualities independently, especially for series machines, as it is preferable and in some cases essential to have no appreciable current flowing in the armature.

To conduct this test, run the machine on open circuit at a constant speed and excite the magnets with currents varying successively from a very small current to as great a one as the magnet coils will stand. Set the brushes to the position of greatest potential and measure in each case the potential at the brushes and the exciting current. This potential will then be a correct measure of the useful magnetism of the field for each case, while the exciting current will represent the cost of generating this magnetism. Lay off these values to any convenient scale and find the characteristic curve as shown in figure 40. It will generally be found that this curve resembles somewhat that of a series machine, figure 37, being at first nearly a straight line, showing that the magnetism increases rapidly with the exciting current; it then curves, showing that it no longer increases rapidly, or in other words, that the iron has become saturated. If this curving of the line is short and decided as in $o\ a$, it shows that the iron parts, including cores, armature and yoke pieces, are all saturated about the same time, and are therefore properly proportioned as far as saturation is concerned. If, on the other hand, the curve is gradual with little or no straight part, as $o\ b$, it shows that some of the iron parts are saturated before the others. This, in some cases, as for compound machine, is objectionable, and should be remedied by increasing the iron parts of smallest cross-section, except when the machine is to be magnetized only as far as the curve is tolerably straight. Whenever the smallest cross-section of the iron parts is in the yoke piece, it should, of course, be remedied for any machine, but wherever, as is usually the case, it is in the cross-section of the magnet cores, or in Gramme ring machines, in the armature core, it is a question easily determined by trial calculations, whether the gain in the economy of magnetism obtained by increasing this cross-section, is justified by the additional expense of the increased amount of wire, the greater size, weight and resistance of the armature, etc., which this necessitates.

The end of the tolerably straight portion of this characteristic shows the limit at which magnetism is produced economically. Whether the machine (shunt or series, but not compound) should be run at a higher degree of magnetization can readily be determined by trial calculations; it evidently depends on whether the gain in the output of the machine is justified by the poorer magnetic economy (*i. e.*, lower efficiency of the machine) and the other objectionable effects of over-saturation.

Regarding the details of this saturation test, it is evident that a reliable voltmeter with a large range is required. It is not necessary to know the actual values of the readings in volts, but it is necessary to know the relative values, that is, the voltmeter should either be one whose deflections are proportional to the potential, or else one in which the relative values of the deflections are known. If the voltmeter has only a small range of readings the machine may be run at different speeds, the speed being made lower as the exciting current increases. To correct the readings for this change of speed, it is sufficiently accurate to assume that the voltage is proportional to the speed; this enables all the readings to be reduced to one speed, and applies therefor as well to the first method if the speed during that test has varied slightly. Instead of changing the speed to enable a voltmeter of small range to be used, successive resistances equal to that of the voltmeter may be used in series with it, thus reducing the readings to one half, one-third, etc.; but this is not to be recommended, as these resistances should not only be equal to that of the voltmeter, but also have the some self-induction, and unless they are carefully made it is difficult to make both the resistance and self-induction the same. If the voltmeter has no appreciable self-induction this objection does not apply. In the absence of a suitable voltmeter any indicator of small currents, as for instance a test galvanometer, may be used together with a suitable adjustable resistance, such for instance as the plug resistances box accompanying a Wheatstone bridge. Connect the resistances in series with the test galvanometer and adjust them so that any suitable deflection is obtained for the first reading. For any other potential adjust the resistances until the deflection is reduced to the same reading, then, knowing the resistance of the galvanometer, the potentials will be proportional to the total resistances, including that of the galvanometer and that in the resistance box.

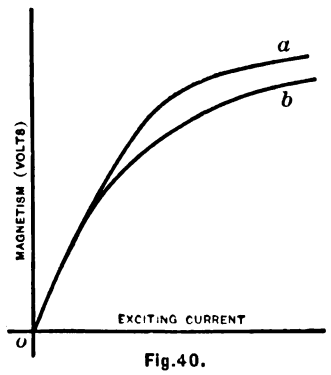

Fig.40.
SATURATION CURVE.

If this saturation test is made with a shunt machine, that is, self-exciting, the speed should be somewhat greater than the normal in order to get the characteristic curve through the saturation point. For the same reason if the machine to be tested is series wound it should be tested for a greater current than the normal, but its speed may be much less, the external resistance being made smaller. It is preferable in this case to keep the armature current constant, and therefore vary the exciting current by variably shunting the current around the magnets.

In this saturation test the exciting currents multiplied

Digitized by Google

by the number of windings in the exciting coils gives the ampere turns. This might have been laid off along the horizontal line in figure 40 in place of the exciting current, but as the number of windings is constant it would be equivalent merely to changing the scale of the diagram, but would not alter the relative proportions between different parts of the curve. If the coils used in this test are different from those to be used finally, it is necessary, of course, to reduce the exciting current to ampere turns, in order to eliminate the two unlike windings.

The numbers obtained from this saturation test will often be found to be of great assistance in designing other machines, or in correcting the proportions of a faultily constructed one. In chapter vii some of the applications of this data has been described, as for instance in correcting the proportions of an over-saturated frame. As described there, the exciting power of the coils (that is, the intensity of the field in the coil if there was no iron core) may be readily calculated approximately from the ampere turns and the cross-section of the core space. The constant thus obtained can be used as a guide in calculating the size of the cores or the ampere turns for other magnets in which the exciting power is to be of the same intensity. By calculating the total number of lines of force generated by the coils themselves (without iron cores) as described in chapter vii, and comparing this with the total number of useful lines of force in the armature field, found by calculation from a test (see chapter v and p. 423 ELECTRICIAN AND ELECTRICAL ENGINEER, November 1, 1886), constants may be obtained between the actual number of lines of force in the field, and the ampere-feet (that is, the number and

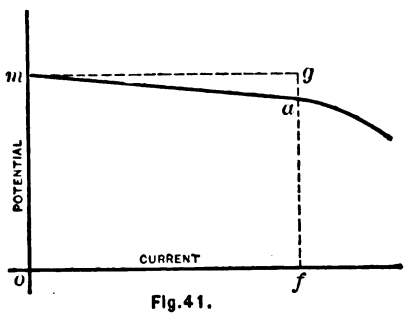

Fig. 41.
SEPERATELY EXCITED MACHINE.

length of the ampere turns) which generate the same. This constant serves as a valuable guide for determining the coil space, ampere-feet and ampere turns in designing other machines. There are, of course, other factors which enter into such calculations for new machines, for instance the quality of the iron, the magnetic resistance due to different lengths of cores, yoke pieces, etc., or to different air spaces between the field and the armature core; these will modify the calculations somewhat, and would complicate them very greatly if introduced, but as they are of secondary importance they may be neglected in approximate calculations, unless they are too widely different in the two machines. As in almost all other calculations which engineers have to make in designing any structure, a suitably chosen "factor of safety" will cover all such inaccuracies.

A careful study and analysis of the characteristic curves of a machine may often be the means of finding out faults in the proportioning of the parts, or of indicating the most favorable conditions of running, and it is therefore to be recommended. Such curves are to the electrical engineer as the curves of a steam indicator cards are to the mechanical engineer, and there is no doubt that the latter have been the means of making a much more careful study of the steam engine.

The characterists for the current and potential of the principal forms of machines, namely series, shunt and compound, have been shown in figures 37, 38 and 39, that for the less frequently used form, the separately excited machine, is shown in figure 41. The exciting current being constant the magnetism of the field magnets will be constant; the potential will therefore be a maximum on open circuit, that is for the point m, when there is no current. As the current from the machine increases (for decreasing external resistances) the potential will fall slightly, which is evidently due to the internal resistance of the armature which consumes an amount of potential proportional to the current. The first portion, $m\ a$, of this curve is therefore straight and slightly inclined to the horizontal. When the armature current becomes very great, and especially when there are many armature windings, the counter magnetism of the armature will become great as compared to the magnetism of the field; this will, by diminishing the useful magnetism, cause the potential to fall more rapidly, and the curve will then no longer approximate to a straight line, as shown beyond the point a. As this counter magnetism generally necessitates shifting the brushes, well built machines are usually run with currents less than that for the point a where this rapid fall of potential begins. The fall of potential in the armature due to its internal resistance, as for instance $a\ g$, divided by the total electromotive sorce $g\ f$ and multiplied by 100 will evidently give the percentage of energy lost in the armature. The continuation of curve $m\ a$, if it were possible to determine it, would ultimately meet the line $o\ f$, at a point which represents the greatest current which the machine gives on being short circuited, that is, when the potential at the poles is zero and the total electromotive force of the armature is absorbed in overcoming the internal resistance. This portion of the curve, although of interest theoretically, is of no use in practice.

Besides determining and examining the characteristics and the saturation curve of a machine, tests may also be made to determine other qualities, such as the counter magnetization of the armature, the shifting of the brushes, the exploration of the field, the magnetic leakage, the resistance of the armature, heating of armature and field, etc., some of the results of which tests may be of use also for determining co-efficients which may serve as guides in designing other machines.

The effect of the counter magnetization of the armature may be ascertained by exciting the field with a constant current from some outside source and finding, with the aid of a voltmeter attached to the brushes, the position which the brushes must have to give the greatest potential first on open circuit and then for the greatest armature current; the amount of the change of the position of the brushes indicates the effect of the counter magnetization of the armature.

The effect of shifting the brushes may be determined by separately exciting the magnets and moving the brushes to successive positions to the right or left of the neutral line, measuring the potential in each case. This may be done for open circuit, for various current strengths, or various degrees of saturation; the same test may also be made with self-exciting machines.

To explore the field surrounding the armature, the following simple method may be used. Wind a single coil of one or more turns of fine wire around one part of the armature, over or next to one of the regular coils; connect one end of this coil to the shaft and the other to a little insulated metallic block fastened on to a wooden ring secured around the commutator, so that it acts as a single commutator bar for this little coil. Connect the terminals of a sensitive voltmeter or galvanometer to two brushes, and apply these to the two ends of this coil, one on the shaft and one on the wooden ring containing the metallic block. When the machine is running normally this little coil will generate an electromotive force, and therefore a current, which is proportional to the strength of that portion of the field through which it is passing when the brush is in contact with the block. The reading of the voltmeter or galvanometer will therefore indicate the strength of the field. By moving that brush which is resting on the wooden ring

Digitized by Google

around to successive positions on the circumference of the ring, the relative strengths of different parts of the field may be determined, showing whether it is unbalanced, and if so where and how much, also where the neutral line is, how wide the neutral space is, how great the magnetic lag is, etc. This test may be made first, when there is no current in the armature, and second, when the normal current is flowing, and it will then also show the effect of the counter magnetization of the armature. The results may be plotted in the form or characteristic.

The magnetic leakage may be found by simply exploring the space surrounding the machine and armature by means of a compass needle, the direction of which will indicate the direction and position of the lost lines of force.[1] To determine this leakage quantitatively, make a small, thin loop of one or more turns of fine wire, connect its terminals to a sensitive galvanometer having a moderately heavy needle so as to act as a ballistic galvanometer. When the machine is excited normally from an external source, the armature being at rest, place this little coil or loop to its full length in the space between the armature and the pole-piece, and withdraw it very rapidly; it will cut the lines of force and develop an electromotive force which will be proportional to the current or deflection of the galvanometer. By similarly moving this same coil through the lines of force of the leakage, its plane being always perpendicular to these lines of force, the deflections of the galvanometer will indicate the intensities of the leakage at different places, as compared to the intensity of the useful field, and will therefore give the percentage of leakage. If the actual useful number of lines of force per square inch of the armature field has been calculated as described from the induction in the armature, the actual number of lines of force per square inch of the leakage is readily determined.

The armature resistance may be measured by any convenient method of measuring small resistances, one of the best of which is to measure the fall of potential by the potentiometer method,[2] when a known current is sent through the armature, or to compare its resistance with a known resistance in series with it, by the fall of potential in each.[3] When a reliable volt and ampere meter are at hand, a very simple way of measuring it is to measure the potential first on open circuit while running, and separately excited, and then on closed circuit with a current which is not great enough to distort the field; the difference of the two potentials divided by the current will then be the resistance of the armature. If the exact length and diameter of the armature wire is known the resistance may be calculated, remembering that it is one-fourth of that of the whole wire.

The heating coefficients may be ascertained by placing the bulb of a thermometer on the magnet coils after the machine has been running normally for at least three or four hours, and placing a little cotton around the bulb. Measure the radiating surface of the coils and the number of watts dissipated in them, from which the coefficient may then be calculated as described in chapter viii. To measure the same for the armature it will be sufficiently accurate for all practical purposes to hold the thermometer in the air currents from the armature, between the pole-pieces, or else to place it on the armature immediately after stopping, and surround the bulb as before with cotton.

The efficiency of a machine is obtained from the horse-power applied at the pulley, and the electrical power developed. There are several ways of stating this efficiency, the real or true commercial efficiency being the useful energy delivered in the external circuit divided by that applied to the pulley. This in the best machines varies from 80 per cent. to 91 or 92 per cent., and evidently takes into account all losses in the machine. The other efficiency, and the one often given by the makers, and called the total efficiency or efficiency of conversion, is the total electrical energy divided by that applied to the pulley, the total electrical energy being that in the external circuit, that lost in the armature and that lost in the field. It is evidently higher than the other, being sometimes as high as 97 per cent. The "economic coefficient" is the first efficiency divided by the second. In measuring the efficiency as well as in all cases in which it is necessary to measure the actual potential accurately, care should be taken in selecting the voltmeter, for if the voltmeter is in the form of a coil having considerable self-induction, the readings for the same potential will be quite different (as much as 25 per cent. it is claimed) according to whether the machine gives a steady current (as a unipolar machine or battery), or whether its current pulsates as in any machine with a commutator. The value of a reading therefore depends on the number of commutator bars and the speed. The most reliable method is to use a sensitive reflecting galvanometer with coils of few windings, calibrate it with a standard cell, and when using it with the high potentials of a dynamo add high resistances in the galvanometer circuit sufficient to get proper deflections. The constants of the instrument in volts per degree of deflection, will then be proportional to the resistances in the galvanometer circuit in the two cases.

THE WESTINGHOUSE SYSTEM OF ELECTRIC LIGHTING.[1]

BY G. L. ADDENBROOKE.

THE electrical and scientific world is certainly indebted to Mr. Pope for his clear and able exposition of the system pursued by the Westinghouse company,[2] and the principles which have guided them in working out the eminently simple method of using alternating current dynamos and transformers, which they have adopted in America with such striking success for electric lighting.

Mr. Pope has now done for the Westinghouse system what Messrs. Zipernowsky, Deri and Blathy have done for theirs. While they, however, had to devote a great deal of space to showing that their system was practical, and could only draw experience from a few installations, Mr. Pope has no need to demonstrate the feasibility of the thing that is already a thoroughly accomplished fact, and he has the experience to draw from which the knowledge gained in the manufacture and installation of nearly 100,000 lights has given.

In nothing more than in electricity, or, at all events, in electrical engineering, is the maxim true that mathematics are an excellent servant but a bad master. For some time past now we have had many learned disquisitions on the action of alternating currents under many different aspects; but while these treatises have had their value from a theoretical point of view, they have not been marked by that practical familiarity with the subjects with which they dealt, which daily experience on a commercial scale gives.

Literature of this sort suffers from what may, in default of a better term, be called "want of balance." In it complicated subsidiary effects, which in practice only come in as small percentage factors, are often treated with much minuteness and at great length.

The main points, then, being of a simple nature and easily explained, as most great truths are, occupy so small a share of the letter-press and mathematics that the student or general reader, unguided by experience, will often quite lose all sense of proportion in the subject he is pursuing. He is thus led to foresee difficulties and uncertainties where such do not really exist; while, on the other hand, the real difficulties which occur in practice are often so obscurely stated, if mentioned at all, that there is danger of being thrown off the track in endeavoring to reduce the problem to a commercial shape.

For these reasons this contribution of Mr. Pope's is welcome as

1. From the *Telegraphic Journal and Electrical Review* (London).

returning once more directly to the subject; and, further, because at the same time his article gives an exposition of the principles involved in this system of lighting, which is capable of being grasped by engineers generally and the more intelligent portion of the non-technical public.

Passing now from the system itself as described by Mr. Pope to the apparatus by which it is carried out as manufactured by the Westinghouse company, the first point deserving attention is the dynamo. In this the Siemens type, as usually employed with various modifications in Europe, is considerably departed from. Instead of the alternate poles of the field magnets being set opposite each other, as in the Siemens type, with a narrow space between for the armature coils to revolve in, the magnets are set side by side with their faces pointing inwards around the outside of the armature, which is of the drum type. As far as the field magnets are concerned, the chief objection which can be urged against this arrangement is a certain tendency to magnetic short circuit. That is each N pole having a S pole on either side of it, and the poles having some inclination towards each other, there will be a strong tendency for a large number of the lines of force to pass through the intervening air space direct instead of cutting the wire of the armature, magnetizing the iron beneath it, and then out again, so to speak, to the neighboring pole on either side. The diagrams given by Mr. Pope and his explanations, admirable as they are on most points, are somewhat incomplete on this, and in the absence of measurements and fuller particulars it is not possible to say what loss may take place on this account. As, however, the watts taken for the exciting current do not exceed two per cent. of the watts the machine gives at its full load, waste from this magnetic short circuiting may occur without seriously detracting from the efficiency of the machine.

Further, owing to the small size of the armature its periphery velocity is low, and consequently the speed has to be high to give the requisite E. M. F., 1,000 volts. The armature itself seems to be a very solid piece of work, and if it keeps fairly cool should wear well. I should imagine such a construction would hardly bear a higher number of volts permanently than that for which it is actually made. The reports of burnt armatures in the American electrical papers, which have once or twice rather inadvertently come to light, bear out this supposition, though no doubt manufacturing improvements will soon reduce this risk. Next to altogether avoiding the chance of burning a coil in an armature, the best thing is to be able to quickly replace one which has been burnt. It would be interesting to know how this is done and how long it takes in the Stanley machine. Apparently it could only be done in a machine shop with proper appliances. Otherwise there is no doubt that the machine is very open and favorably constructed for inspecting the working parts while in motion, a very important point, often less thought of by dynamo makers than it should be. To be able to get a clear view in a moment of all working parts, is the best preventative of accidents which can be devised.

In the drawing of the machine 16 field magnets are shown, and it is stated that with the 650 and 1,300-light machines the number of revolutions is 1,650 per minute. This gives the large number of 20,400 alternative, 40,800 reversals, per minute, or 680 per second, which strikes one as being a very high, an unnecessarily high number.

As regards the transformer, it is obviously a much more workmanlike and practical piece of apparatus than the Gaulard & Gibbs pattern, under the patents for which it is constructed. No doubt it works perfectly well; indeed, transformers are so simple an arrangement of iron and wire that, now the principles which regulate their construction are well known and clearly defined, it seems as if it would be difficult to make anything which would not work. It is with transformers as with dynamos.

The principles which govern their action once understood, dynamos can be constructed with different arrangements of armature and field magnets, which, supposing the workmanship in each case equal, will all give in practice almost precisely equal results.

The points which need attention in a commercially successful transformer, besides the satisfaction of the electrical conditions, are:

1. Protection of the coils from damp or wet. If damp or wet gets to the primary coils, short circuiting and consequent cutting of the transformer out of the circuit is sure to be the result. If the current is always passing through the transformer, protection is not of such material importance, as the expenditure of energy in the transformer is always sufficient to keep it pleasantly warm and consequently dry.

2. Proper insulation of the primary and secondary coils from each other and the arrangement of the primary so that points of too high potential are not brought electrically near each other. As the teaching of the Law and the Prophets was summed up in a short sentence, so the maxims regarding transformers may be summed up in the apostrophe:—Beware of damp and short circuits, keep points of greatly differing potential separate, and avoid contact between primary and secondary.

Anything approaching short circuit of a coil is instantly fatal, because the short circuited portion acts as a closed secondary to the other coils, which leads to almost instant fusion somewhere. Respecting contact between the primary and secondary, this is the point to guard against in working a transformer system on a large scale. As I pointed out a few weeks ago, the actual insulation of an extended series of mains cannot be very high in damp weather) although the specific insulation may be so. There will consequently always be a strong tendency in the mains for the current to go to earth. Now, the style of work usual in installations, however ample it may be to stand the voltage it is intended for, is hardly ever calculated to endure the tension of the mains in a transformer system, therefore if there is any weakness between the primary and secondary coils in the transformer, the main current is not unlikely to go to earth through the secondary somewhere or other in an installation. Of course this happening would soon cause the cut-outs to fuse, but still some one in the meantime may get a pretty severe shock, or something else may happen of an unpleasant nature.

I do not wish to say anything of an alarmist character—there is no need for it; but as every accident which now happens is so much against the system generally, it is important that inventors should not neglect to take proper precautions under this heading, seeing that they are sufficiently simple, so as to obviate any chance of an accident of this kind.

3. The third point is good ventilation. No special arrangements seems to be made for this in the Westinghouse type of transformer. As apparantly, so far, only comparatively small transformers seem to have been made of this pattern, the question no doubt has not particularly needed to be dealt with, but with larger sizes they will probably have to make some arrangements by which cooling can take place more rapidly than it could do through the sides of a completely closed iron box. It is obviously most important that the temperature should never reach the point when carbonization of the insulating material commences, as then all insulation is soon at an end.

The little connecting and cut-out boxes fitted in the transformer case are particularly neat and compact. Apparently from the construction there is no separate switch used for disconnecting the mains when the transformer is not in use. It would be interesting to learn how the cut-outs act in these boxes, whether the glass front is blown out when they go, or what occurs. There are some curious points about the action of cut-outs when currents of high tension are used which need elucidating, and which, if properly investigated, would not improbably lead to conclusions of considerable theoretical, if not practical, importance. Placing transformers on poles is a happy idea; and evidently, from the photographic illustrations given with Mr. Pope's article, when thus placed, they are not so unsightly as one would at first imagine. Although such a method is hardly applicable to a large town, yet for small ones and villages it appears eminently practical. How many small communities in our own hilly districts could easily and cheaply obtain all the advantages of electric illumination in such a manner, the power being supplied from some neighboring mill stream.

It is not a very complimentary reflection for European electricians and capitalists that although all the ideas and experimental work needed for the development of the transformer system of electric light have come from Europe, and although Messrs. Zipernowski, Deri and Blathy demonstrated commercially the perfect practicability of working transformers in parallel two years ago, it should be reserved for an American firm to take up the system and make it the commercial and practical success which the Westinghouse company is now doing.

WESTINGHOUSE BRAKE TESTS.

ANOTHER of the series of trials of the Westinghouse freight brake took place at Ridgefield Park, on the West Shore road, near Weehawken, on the 21st inst. The usual tests were made, with very satisfactory results. The novel performance of running a train of 20 freight cars fitted with the freight brake, but with increased leverage, against an ordinary passenger train, proved especially interesting. The passenger train was composed of ten West Shore passenger cars, which, as our readers are generally aware, are all of the most modern description, and built in the best possible style. Notwithstanding this fact, at a speed of 45 miles an hour, the improved brake stopped the train of 20 cars in 495 feet, while the passenger train with the ordinary brake ran 709 feet further. It is hardly necessary to point out the great importance of this difference, which would in many cases of emergency mean all the difference between perfect safety and a frightful disaster. As on previous test of this description, the trains ran on parallel tracks at the same speed, the engines keeping abreast of one another. At a given signal the brakes were applied simultaneously on both trains, with the result that the passenger train shot ahead with its whole length clear of the freight train. A more forcible proof of the great improvement that Mr. Westinghouse has effected in the operation of his brake could hardly be given.

Digitized by Google

The results obtained were as follows:

TRAINS OF 50 EMPTY FREIGHT CARS, 60,000 POUNDS CAPACITY.

	Speed. Miles per hour.	Distance. Ft.	Time. Secs.
1. Emergency stop.	23	203	12½
2. " "	41	674	20
4. " "	41	672½	20
6. Hand-brake stop.....	21	2.137	85

7. Break-away test. The portions of train when stopped were 43 feet apart.

The following tests were made with a train of 20 empty freight cars of 60,000 pounds capacity fitted with the freight brake, but with increased leverage for passenger service.

8. Emergency stop...	22	91	6
9. Omitted..... ..	....	....	....

The following test was made with the above train and a train of West Shore passenger cars run side by side, the brake being applied simultaneously to both trains when the engines were abreast and running at the same speed:

10 { Freight.....	45	495	13½
{ Passenger.....	45	1,204	27

Among those present at the test were: Messrs. J. D. Layng, general manager; C. W. Bradley, superintendent; Theodore Houston, late receiver, and W. G. Wattson, West Shore; Joseph Crawford, superintendent N. Y. Division, Pennsylvania; S. M. Felton, Jr., first vice-president; R. H. Soule, general manager, New York, Lake Erie and Western; H. J. Hayden, second vice-president; Walter Katte, engineer; Theodore Voorhees, assistant general superintendent; C. M. Bissell, division superintendent, and J. H. Franklin, New York Central.

The trials with the Westinghouse train will be repeated on the 26th inst. at Winnewood, situated on the Pennsylvania, near Philadelphia. The train will then proceed to Washington, where some further trials will be given, and thence to Pittsburgh, where the series of trials will be concluded.—*The Railroad Gazette.*

BRITISH ASSOCIATION NOTES.

THE following note from Professor Lodge in correction of his sketch of electrical papers at the British Association Meeting (see ELECTRICIAN AND ELECTRICAL ENGINEER for November, 1887) appears in the London *Electrical Review.*

"IN my sketch of electrical papers read at Section A (see *Review*, September 23d) there were one or two slips which you will allow me to correct.

"The mercury standards which Mr. Glazebrook had found to vary were not those of M. Mascart, but were made by Strecker and Himstedt (see his paper in the October number of the *Philosophical Magazine.*) Mr. Glazebrook tells me that Mascart's standards agree consistently with his own.

"All mention of Mr. Preece's paper on "The coefficient of self-induction in telegraph wires" was inadvertently omitted. This, and one or two other communications which I failed to hear read, will shortly appear, or have already appeared, in full in these columns.

"Sir William Thomson publishes his paper "On the vortex theory of the lumiferous ether" in the October number of the *Philosophical Magazine* under the title "On propagation of laminar motion through a turbulently moving inviscid liquid," and an abstract in *Nature* for October 6th, page 550.

"It there appears that the subject has occupied his thoughts at intervals for the last 20 years, and that I must have been wrong in judging from his manner at Manchester that it had been to him a fairly easy problem only lately attacked. This is a personal matter of no concern to anybody except, perhaps, a future biographer; all that I wish to call attention to is the official publication of the discovery, so far as it is as yet made by the author. The one definite point in the proof, still incomplete, is that a dissipation of wave-energy by rearrangement of the vortices has not yet been shown to be impossible, or, if possible, so slow as to be negligible. In other words, an assemblage of vortex filaments has been proved capable of transmitting waves of distortion like an elastic solid, but it has not yet been proved to be thoroughly *transparent.* It is hardly likely that the ether itself is absolutely transparent, else would the midnight sky be one blaze from an infinitude of stars foreshortened together. Either the universe of worlds is limited, or the ether has a trace of opacity. The latter is the more probable hypothesis: and, accordingly, the amount of transparency possessed by an assemblage of vortices of any required degree of smallness has still to be worked out. Let us hope that by the time the British Association meets in Bath the illustrious author will have this step also ready to communicate."

OLIVER J. LODGE

University College, Liverpool,
9th October, 1887.

CORRESPONDENCE.

NEW YORK AND VICINITY.

The Investigation of the Telephone Companies.—The Telegraph Companies seeking better terms from the Stock Exchange on their Quotation Business.—Telegraph Lines Prostrated by an early Snow Storm.—Subway Workmen dissatisfied with the proposed Cessation of Work, December 1.—A House-Mover Chops down some Wires and Cables in his way at Orange, N. J.—The new Factory of the United States Electric Lighting Co., at Newark.—A remarkable Electro-Magnet.—Trouble at Kiernan's News Agency.—Mr. Chas. W. Price, formerly of the Baltimore and Ohio Telegraph Co., engages in Electric Railroading.

THE investigation of the various telephone companies doing business in this state, by a legislative committee, does not appear to awaken the interest of the public. The usual testimony has been elicited regarding the royalties exacted by the parent company, and the dividends paid to stockholders. According to the testimony of Mr. Hovey, there are about 175,000 telephone subscribers in the United States, and it is to be presumed that there are ten times as many more who would like to use telephones if they could afford the expense. Mr. Storke would not admit that the telephone had become a necessity, and it is difficult to believe that any person would consider it a luxury. Perhaps the committee will define its exact status in their final report.

One of the results of the recent change in the telegraphic situation is an attempt by the managers of the various telegraph companies to secure a reduction in the heavy rentals exacted from them by the Stock Exchange for office privileges on the floor. Unless some concession is made the companies threaten to withdraw from the exchange. At a recent meeting with the committee of arrangements, the following telegraph and cable representatives were present:—Charles A. Tinker, general superintendent Western Union Telegraph Co.; A. S. Brown, general superintendent of the Mutual Union; Albert B. Chandler, president and general manager of the Postal, and George G. Ward, general manager of the Commercial Cable Co. In addition to a large fixed rental the companies pay tolls on each message received or sent which amounts to a large sum. The matter was discussed very fully, but no decision was reached, beyond referring it to the governing committe of the exchange for consideration at their next meeting.

It appears to be rather early in the season for damage to telegraph lines by snow storms, but there was a fall of about five inches of snow on November 16th, up the Harlem railroad which stuck to the wires and broke them down to a very considerable extent in the vicinity of Millerton, Copake and Boston Corners.

There is much dissatisfaction among the workmen employed by contractor Crimmins on the subways, because the city authorities will not allow the work to proceed after December 1st, by reason of the probability of the weather preventing the proper restoration of the streets. It is said that the Phenix Construction Co. is willing to proceed with the work if the necessary permission can be obtained. There is a large number of men engaged in this work, but it will doubtless be suspended if cold weather sets in.

The foundation of a law suit was laid at Orange, N. J., a few days ago, when Peter Dexheimer, a contractor, was engaged in moving a house. The wires of the New York and New Jersey Telephone Co. were in the way, but the superintendent offered to remove them temporarily for $25. The contractor thought he could do the work cheaper himself which he proceeded to do, cutting down the wires, and a 50-conductor cable. Over a hundred telephone subscribers were thus cut off, and it is supposed the company will bring suit for damages.

The United States Electric Lighting Co. has erected a handsome building on the site of the factory on Orange street, Newark, which was burned last summer. They have not been able as yet to resume the manufacture of incandescent lamps on a large scale because of the scarcity of expert glass blowers capable of making the vacuum pumps. They require one hundred of these pumps to exhaust the number of lamps necessary to keep up with their orders. They are now purchasing a portion of their lamps from the Sawyer-Man company.

The following curious yarn which bears the ear-marks of the newspaper scientist is going the rounds of the press, dated from Bridgeport, Conn., Nov. 14.

One of our leading army engineers has brought before the engineer classes of late, an experiment of so startling a nature in its inception as to promise wonderful results. It is a monster magnet made of two Rodman guns, which are connected at the breech. Around the magnet thus formed is wound about 20 miles of submarine cable. The cable is some that has been used in the torpedo service. It is wound and fastened in a substantial manner, making a permanent magnet. When electricity is applied some strange results take place. For instance, a bar of railroad iron 30 feet long, if placed in the open cannon's mouth, cannot be drawn out by as many men as can grasp it.

Another instance of the strength of this big magnet was illustrated Saturday with a 350 pound cannon ball. The shot was placed in the mouth of the cannon on the negative side. On reversing the electrical current it fell from its position, but was attracted to the opposite cannon and clung to its side. The positive cur-

Digitized by Google

rent was then reversed alternately with the negative, and the heavy cannon ball played between the two cannon like a tack between the poles of a toy magnet. Before many days there will be a public exhibition of this remarkable attractive magnet.

An apparent disruption of the firm of John J. Kiernan & Co. made a sensation in Wall street, last week, by reason of a proclamation from his partner which was sent out over the financial news "tickers" leased by Kiernan & Co., cautioning all persons against negotiating any form of paper purporting to emanate from the said firm. Senator John Kiernan was the founder of that special branch of the telegraph business which has certainly been very lucrative; sufficiently so to encourage competition. He has been an exceedingly liberal man, but has not given that attention to the symmetry of his bank account which modern business methods require, and his partner claims to have been annoyed by the alleged attenuation of his balance. Senator Kiernan on the other hand asserts that he is tired of partners and believes he can do better alone, and proposes to start a new system, having his headquarters on the ground floor of the Mortimer Building, at No. 11 Wall street.

Mr. Charles W. Price, formerly superintendent of the Metropolitan District of the Baltimore and Ohio Telegraph Co., has made an engagement with the Daft company, and has gone on a western trip in their interest. He is very much impressed with the future of the motor business, having examined the matter thoroughly before taking it up.

NEW YORK, November 21, 1887.

PHILADELPHIA.

The Alleged Forfeiture to the State of Baltimore and Ohio Telegraph Property.—The Proposed City Electric Light Plants.—The Thomson-Houston Co. Suing Alleged Infringers in this State.—Telephone Lines to go Underground.—The New Eight-Wheel Electric Car Equipped by Mr. Reckenzaun for Mr. Wharton.—Annual Meeting of the Society of Mechanical Engineers.

COUNCIL'S sub-committee on law, to which was referred the question of suing upon the forfeited $50,000 bond of the Baltimore and Ohio Telegraph Company, has prepared a report. It recommends that the city solicitor enter suit as soon as possible, and leave the legal questions and points raised by the corporation to be settled in the courts. The report has been submitted to the full committee.

It is claimed that, on account of the violation of a state law perpetrated in the absorption by the Western Union Telegraph Company of the Baltimore and Ohio Telegraph Company, the lines of the latter and all the property used in operating them within the borders of the state, in addition to the franchises by virtue of which they are operated, can be confiscated by the state of Pennsylvania.

The Baltimore and Ohio Railroad, from which the telegraph company derives its name and being, has along its tracks the wires of the company, and they do a large business. The railroad strikes north from Maryland and enters Pennsylvania at a point near Hyndeman, going to Pittsburgh, and leaving the state at West Alexander, W. Va.. The distance traversed is 191 miles.

The act to which reference is made was passed at the legislative session in 1883, and approved by Governor Pattison on June 5th of that year. The first section is as follows:

"SECTION 1. *Be it enacted, etc.*, that when any telegraph corporation, telegraph association, or telegraph company, chartered for telegraph purposes and owning and controlling a telegraph line in this state, shall consolidate with any other telegraph corporation, telegraph association, or telegraph company, chartered for telegraph purposes and owning and controlling a competing telegraph line, the said competing telegraph lines and all franchises and property connected therewith for the operation of the same within the state shall be forfeited to and become the property of this Commonwealth."

Some readers of this section claim that it tends to confiscate not only the belongings of the Baltimore and Ohio Telegraph Company within the Commonwealth, but also those of the Western Union, inasmuch as the act uses the plural in declaring that "the said competing telegraph lines" shall be forfeited. It is held by others that this was not the intention of the framers of the law, although the only expression from them that can be taken in a court is what they said in their statute.

The first section provides against a "consolidation," perhaps meaning a deliberate pooling of plants and effects by two corporations. The second section prevents the holding of a controlling interest in a telegraph company by a competitor, or the acquiring by purchase of a controlling interest, in which case provision is made for taking the possessions of the controlled company only. The section reads:

"SECTION 2. Whenever any such corporation, association or company, owning and controlling a line of telegraph, shall hold a controlling interest in the stock or bonds of any such other telegraph corporation, association or company owning a competing line of telegraph, or shall acquire, by purchase or otherwise, any other competing line of telegraph, the stock or bonds so held and the telegraph line, together with all franchises so purchased or otherwise acquired, shall be forfeited to and become the property of the Commonwealth."

The act further provides that the issue of confiscation may be raised by *quo warranto* proceedings in any court of common pleas in the state. Stock or bondholders who were opposed to a consolidation subsequently effected by two lines are considered innocent holders of their securities, and are protected by the court. After a final decree establishing the forfeiture, the property seized is to be exposed to public auction at the state capitol, and sold to the highest and best bidder for cash. The competing company cannot buy at that sale.

The act merely enforces the provisions of the Constitution prohibiting the consolidation of rival telegraph corporations.

Chief Walker, of the electrical bureau, will ask the finance committee of city councils at its next meeting for an appropriation of from $350,000 to $400,000 to construct two electric light plants to furnish the streets, public buildings, wharves and bridges with electric lights. The chief has prepared plans for this work, which have been approved by mayor Fitler and directors Stakley and Wagner. He intends that the stations shall be constructed on the banks of the Delaware and Schuylkill rivers. The building now used by the Kensington pumping station, at Otis street wharf, will be vacated by the first of the year, and the chief purposes that this structure shall be transferred to the electrical department to be used as the Delaware river electric light station.

The plans for this station provide for 12 dynamos, or sufficient to supply 600 arc lights. In case of necessity 16 dynamos can be put in, with a capacity of 800 lights. The station will have two condensing engines, of from 300 to 500 horse-power. These will consume 650,000 gallons of water a day. The location of the plant on the Schuylkill river has not been decided upon. The plans, however, are prepared, and provide for a larger building than that at Otis street wharf. Three 500 h. p. engines will be put in, with 24 dynamos of 1,200 arc light capacity.

"The city now pays for 537 lights at an average of 55 cents each per night," said chief Walker. "It will probably cost $130,000 for lighting the streets with electricity during 1888, and it will take a year to construct the proposed plant, after which the city will save 50 per cent. on its electric light bills, or enough to pay for the outlay in seven years. The location of the stations on the banks of the two rivers will be an immense saving in supplying water and coal for the engines and in removing the ashes."

The Thomson-Houston Electric Light Company of Connecticut, on the 11th of the present month began proceedings in the United States Circuit Court to have the Allentown Electric Light and Power Company, the Edison Electric Light Company of York, and Jacob Reed's Sons of this city, enjoined from the making of alleged infringements on improvements in current regulators for dynamo-electric machines, to which the complainant, under a patent, claims the exclusive right.

The Bell Telephone company have about completed arrangements for placing their wires underground, and a sub committee of the electrical committee of councils met recently for the purpose of considering an ordinance granting permission to the telephone company to construct man-holes and lay and maintain underground conduits, cables and wires for electrical purposes throughout the city. The streets named in the ordinance include nearly all the principal thoroughfares in the city. The ordinance, as approved, prohibits the erection of wires over or across any main street, or the stretching of the same from one pole to another. It also requires that the work of laying the conduits shall be done in the night time.

Mr. W. Wharton, Jr., says that the new eight-wheel storage battery car, recently completed by his company, ran a few days since 45 miles with one charging of the batteries, 12 miles of which distance was run in one hour without the least heating of the machinery, or any trouble whatever. This distance was accomplished around the track in their yard, consisting of sharp curves and grades for at least one-half of the distance. Two Reckenzaun motors of 8 h. p. each are used on this car, capable, however, of developing when required up to 15 h. p. each upon the driving axles of the cars. These motors weigh about 500 pounds each, and are exceedingly light for the power developed by them. One hundred and sixteen cells of the Electrical Accumulator Company's make, of the 23 — C pattern, weighing 40 pounds each, filled ready for use, are used on the car. Mr. Wharton said that the 4-wheel car had given great satisfaction, and proved reliable at all times, but that the new 8-wheel car with the Reckenzaun motors is a great advance upon it.

The eighth annual meeting of the American Society of Mechanical Engineers will be held in parlor C in the Continental Hotel, beginning on Monday evening, the 28th, and ending on Friday, December 2d. This society is composed of over 700 mechanical engineers in all parts of the Union, and this time was chosen so as to admit of persons visiting their eastern homes on Thanksgiving day and attending the meeting during the same trip. The committee of Philadelphians who are arranging for their reception comprises some of the best known engineers in this city, and is headed by Mr. Horace See, C. E. The programme includes visits to the representative mechanical institutions in the city, and a reception will be held at the Academy of the Fine Arts at the close of the session.

PHILADELPHIA, November 17, 1887.

BOSTON.

The Telephone Patent Suits.—Rise in American Bell Shares.—Infringing Telephones in the West.—Improved Methods of the New England Telephone Co; their Quarterly Report.—New Police-Signal System.—Auxiliary Fire Alarm Telegraph Companies.—The Woonsocket Electric Railway.—The Electric Car of the West End Railroad Co.—The Boston Electric Club.—A Treasury Decision that Electricity is not Dutiable.—Business Undertaken in Mechanial Telephones.

"WAITING for the verdict" is still the position of the American Bell Telephone Co., in respect to the Supreme Court of the United States; at the same time, there does not seem to be an oppressive anxiety in the Bell company's offices concerning the matter. The Bell stock has been very firm in price, and at every suggestion that the decision is to be rendered "to-day," it jumps up 10 or more points.

One reason of its firmness is found in the fact that the system of long-distance telephone lines, which are to be practically owned and controlled by the company, is rapidly nearing completion. The income from such lines, when established, as they will be in the near future, will add immensely to the company's revenue, which, of course, means larger dividends, and a consequent further enhancement of the value of the stock.

Meanwhile, the telephone business continually increases; and in the west the infringer flourishes like a green bay tree—exchanges are in operation and single telephones are freely circulated. The Bell people are, however, kept in complete knowledge of the operations of the agile infringers, as each local telephone company, wherever the infringer is operating, keeps the main company informed; and when the proper information has been obtained, the ever ubiquitous Mr. Tompkins makes a Sheridan like ride through the infested territory, and files papers of warning, injunction, and admonition upon the offending parties, striking terror and consternation to their guilty souls, and causes them to surrender and discontinue the use of the coveted telephones and apparatus.

The following circular has been issued to telephone subscribers by the New England Telephone Co.:—

Owing to the great inconvenience of the present system of numbers in our exchanges, as well as delays caused by operators being obliged to look over the list to find the line on which a subscriber is located before calling, it is thought best, in order to insure quicker service at all the offices, to make a complete change in all the numbers of suburban subscribers, to be published in the catalogue to be issued January 1st.

With the increased number of subscribers in all the exchanges the service is not what it should be. To make it so several very radical changes will be made, the most important of which is the above.

Also better apparatus in offices; fewer subscribers on a line where it is possible; a thorough inspection of instruments, and old bells replaced by new when necessary; and other minor things of less importance, all of which it is the intention of this company to do at once. The best apparatus will be used for the offices, and everything done on the part of the company to insure good service in all the suburban exchanges.

The New England company, have had recently, a complete overhauling of their suburban lines (near Boston), to see how many grounds are made in cisterns, etc., how many microphonic joints there are in the lines, and what occasions large resistances in short lines.

The directors of the New England Telephone and Telegraph Co. declared the usual quarterly dividend of 75 cents per share. The comparative statement for the quarter ended Sept. 30, is herewith given.

Quarter ended Sept. 30—	1887.	1886.	Increase.
Gross receipts	$255,856	$232,585	$23,271
Gross expenses	174,737	162,774	11,963
Net earnings	$181,119	$69,811	$11,308
Construction	1,149	778	371
Surplus	$79,970	$69,033	$10,937
January 1 to September 30—	1887.	1886.	Increase.
Gross receipts	$717,546	$681,372	$66,174
Gross expenses	518,786	488,469	30,317
Net earnings	$228,760	$192,903	$35,857
Construction	4,699	2,847	1,852
Surplus	$224,061	$190,056	$34,005

Compared with the previous quarter ended June 30, the showing is quite favorable, gross receipts increasing $4,074; net earnings $7,925; and the surplus is $6,776 larger.

A special telephone cable is being manufactured for the New England Telephone and Telegraph Co. of Boston, and is to be used to connect Long Island with Deer Island, so that there may be telephonic communication between the new city almshouse on the former island with the office of the Board of Directors of Public Institutions in Boston.

Edward Davis, of Cambridge, has invented a police-signal system, which has been exhibited at 109 Court street. The main advantages claimed for this system is its simplicity of construction and the large number of different signals of which it is capable. It has, for the use of the officer, a number of pulls, each of which is recorded at the central office with the number of the box from which it is sent. These signals are for fire, ambulance, patrol wagon, etc., and a telephone can be used if desired. If keys should be furnished to citizens, any person who uses one and sends a call from any box will be known at once by the number registered at the office, both the box number and the citizen's number being registered, also the exact time the call is sent.

Mr. Davis was the inventor of an individual bell, a few years since, for telephone lines, and is a very successful electrical mechanician.

The auxiliary fire alarm telegraph companies are coming to the fore, in this vicinity, at the present time. The company operating under the Rogers patent, have quite a hold in New England; their system operated to perfection at a recent small fire in the Parker House.

Then there is the Gamewell Fire Alarm Auxiliary Co., who are associated with the Gamewell Fire Alarm Co.; the latter company inform their patrons that they will not be responsible for any auxiliary system, other than the one they recommend, that may be attached to the Gamewell Fire Alarm System, The last candidate for public favor in this line, is a company organized under the inventions of Mr. W. J. Dudley, which seems to possess merits of advantage.

Representatives of the Thomson-Houston Electric Light Co., capitalists and members of the press from Boston and other points, visited Woonsocket, on the afternoon of Oct. 19th, there to witness the work of the electric street car in operation there the past few weeks. The system is the Bentley-Knight, and its power is supplied by an overhead wire from a regular Thomson-Houston dynamo. The car worked satisfactory, ascending and descending steep grades, running at as high a speed as 10 miles an hour at times, and being under perfect control. This is the first car run in New England by this system.

The West End railroad people seem to be highly pleased with the results obtained last month by their motor for street cars. Whether correct or not, there seems to be a prevailing impression, that if electric motors are to be used for street cars, the cars themselves should be larger—capable of carrying more passengers.

The Boston Electric Club continues to flourish and expand itself. Professor Cross, of the Institute of Technology is to give before the Boston Electric Club, on the 17th inst., an illustrated talk on "Acoustic Principles of Telephony."

The United States Customs Department have tackled the invisible force, and Secretary Fairchild has informed the collector of customs at Eastport, Me., in reply to his inquiry on the subject, that electricity, being an invisible subtle agent for power, possessing no substance as a merchantable commodity, would not be liable to duty when brought into Calais by wire for purposes of illumination.

A new mechanical telephone company called the "American Acoustic Co." has appeared and advertised itself quite extensively. Its managers have obtained control of all the early fundamental patents relating to mechanical telephones and apparatus, some 16 or more in number, and announces that it proposes to stop infringements, and occupy the field. If there is anything in mechanical telephones—and it would seem there should be for properly constructed and erected apparatus for short distances—this undertaking, if rightly managed, ought to lead to success.

At a meeting of the Board of Aldermen on the 14th inst., a petition from the Franklin Electric Light Co., of Maine, for leave to lay underground subways and conduits for the storage of electric light, telephone and telegraph wires, was referred to the committee on electric wires. The petitioners state that their system of underground construction will obviate practically the tearing up of the streets frequently, as is now the case, as the construction will be of a brick arch of sufficient size to permit a person to walk through the subway. These subways will only be constructed in such streets as will not interfere with business.

Concessions by the American Bell to Licensee Companies.—Improved Condition of some Western Telephone Companies; Accumulating Surplus for Underground Construction.—The Chicago Gas Trust Contention.—The City Electric Light Scheme.—An Ordinance Requiring Telegraph and Telephone Wires to be Run in the Alleys of the City.—The Municipal Telephone Tax not yet Approved by the Mayor.—The Telephone Company's Franchise Attacked.—The Fat Cattle Show Lighted by Ninety Western Electric Company's Arc Lamps; New Contracts of that Company.—The New Single Cord Multiple Switch-Board.—Mr. W. A. Ford to have a Multiple Switch-Board of his invention made by the Standard Electrical Works for the Denver Exchange.—The Westinghouse Incandescent Light Plant of the Denver Light, Heat and Power Co. to be the largest Incandescent Plant yet installed anywhere.—The Denver Illuminating Company to operate the Thomson-Houston Arc Light.—The Western Electric Company to be represented in Denver by Mr. J. G. Kaelber.—The American Bell Company Pursuing Western Infringers.—The Chicago Electric Club.—Notable Success of Electric Fire Alarms in Hotels and Public Buildings.

THE American Bell Telephone Company has made concessions in several instances to its licensees where the over capitalization of the sub-company, or the falling off of business has appeared to

Digitized by Google

demand some sort of relief. These concessions vary in form and amount, but the result is that telephone companies in the west are most of them getting on a dividend paying basis, albeit the dividends are small in most cases.

The Great Southern Telephone and Telegraph Company, after for three years devoting its earnings to the payment of debts, now has the balance on the right side, and has declared a dividend of two and a half per cent.

Some of the telephone companies, especially in the large cities, are laying by a surplus for the construction of underground circuits when the time comes that wires must go underground. In two western cities particularly, the underground question has been discussed lately with much seriousness. In Minneapolis the indefatigable Dorsett is at work, and several large fires in Kansas City have set the newspapers at work there.

The Gas Trust continues to be an object of attack for the City Council. On one side it is asserted that the franchises granted two of the companies composing the Trust, cannot be revoked without an appeal to the courts, and the preponderance of legal opinion seems to incline to that view. But on the side of the Council it is urged that the case can be brought before the courts best by the action of the Council in revoking the franchises and cutting the pipes, thus giving the Trust the opportunity of making the city the defendant in the case. A conference between representatives of the various companies composing the Trust and a committee of the City Council resulted in a report to the Council, by the committee, recommending the revoking of the franchise of the Equitable Gas Company.

Keeping pace with the agitation against the Gas Trust is the scheme for the city to erect an electric light plant of its own. The main difficulty in the way of accomplishing this on a large plan, is the fact that the city has reached the legal limit of its bonded indebtedness and is now living up to the maximum legal rate of taxation, so that there seems to be no way of securing the funds for the purchase and erection of a large plant.

The Gas Trust and the companies composing it are involved in much litigation, brought by dissatisfied stockholders, and with the large Edison central station and the city arc light plant for lighting the bridges and viaducts nearing completion, the gas monopoly is not having everything its own way.

An ordinance has been introduced in the City Council requiring that all telegraph and other wires be laid through alleys, where practicable, and that permits for the same be issued only on condition that the work be done at night.

The ordinance aiming to tax the telephone company $10 00 on each set of instruments, is still without the Mayor's approval, and in the meantime the City Council has discovered that the franchise granted to the Bell Telephone company was not assignable, not having been made to said company and its successors or assigns. It is therefore claimed that the Chicago Telephone Company, which is a successor of the Bell Telephone company, is carrying on its business without a franchise. As the Chicago Telephone Company has complied with all the conditions of the franchise, and has paid into the City Treasury the amount required under this franchise, receiving the receipts of the city for this account, it is claimed on the part of the company, that any defect in the title to the franchise is cured, or at least, that the city is effectually barred from questioning it.

The fat stock show, which has became one of the regular autumnal features of Chicago, has been lighted during its recent very successful meeting by 90 Western electric arc lights. This company has recently closed contracts for lighting the cities of Valparaiso, Ind., and Champaign, Ill., and is putting a 40-light plant into the large building to be occupied by Kuh, Nathan & Fisher, clothing manufacturers. Mr. Patterson reports that cable work is rushing. He is turning out large orders, principally of telephone cable for Boston, New York and Chicago.

The new single cord multiple switch-board is giving good service in the branch exchange, at Eighth and Freeman streets, Cincinnati. This board and the one at Columbus, Ohio, are watched with much interest by telephone men, as they are novel in many respects and relieve the operator of six out of thirteen motions in making a connection and disconnection.

Another new telephone switch-board is that invented by Mr. W. A. Ford, manager of the Colorado Telephone Company. Mr. Ford spent a day in Chicago early this month, on his way from Cincinnati, where he had been to place an order with the Standard Electrical Works, for one of his boards for Denver. This board is a multiple, but very different in form and operation from the regular multiple, and opinions differ as to whether it will be a success or not.

The Denver Light, Heat and Power Company is progressing satisfactorily with the work of installing the largest alternating incandescent electric light plant in the world. When this plant is completed, there will be in operation 9,000 Westinghouse lamps in addition to the Edison municipal plant of 800 twenty-candle power lamps, and the commercial plant of nearly 500 Brush arc lights, all operated from the same station.

Competition in the business of commercial lighting at least, is promised by the Denver Illuminating Company, which has secured a franchise, and proposes to operate the Thomson-Houston arc light system.

The Western Electric Company has established an agency at Denver, in charge of Mr. J. G. Kaelber, formerly of Rochester, N. Y.

Mr. Frank Knight, special agent of the American Bell Telephone Company, has been successfully engaged for some weeks in weeding out infringing telephones, which lately have been springing up rapidly throughout Kansas. The despatches stated that the suit brought by the American Bell Telephone Company against infringers in Little Rock, Ark., was based on the Edison patents. This was an error. The suit is on the same Bell patents which have been involved so often before, and always triumphantly. The date for the hearing of this suit is the 17th of this month.

The Chicago Electric Club has opened its restaurant, and it is extensively patronized, especially at noon. During the month two interesting meetings have been held. At the first Mr. Sunny, superintendent of the Chicago Telephone Company, read a paper on the effect of electric light induction on telephone wires; at the second Mr. Van Depoele was to have read a paper on electric railroads, but owing to pressure of business, he was unable to get his paper ready, and Mr. C. C. Haskins kindly took his place and read an interesting paper on "Coupling Dynamo Machines Together."

Three notable instances have occurred here during this month, showing the success of electrical appliances for guarding against loss of life and property by fire. The Mercurial Fire Alarm saved the Chicago Globe building, and one week later, the Union League Club building, from destruction by fire, and the guests in the Saratoga Hotel, which was burned recently, were aroused by the bells in their rooms, rung by the fire alarm apparatus in the office, and all escaped without injury.

CHICAGO, November 22, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICIAN AND ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

THE REIS TELEPHONE CONTROVERSY.

[82].—The letters published in THE ELECTRICIAN AND ELECTRICAL ENGINEER, by Stein, Houston and Kintner, have induced me to present a phase of the controversy as to Reis's invention which is not developed in them but which seems to me to be of importance if one would come to an abiding conclusion. 1st. There is the distinction between actual history and legally constructed history. As applied to the present case the matter stands thus, saying nothing of Bourseal and his description of apparatus for the transmission of speech. Reis did in 1861 and 1862, make something which he called a telephone. It consisted of (*a*) A transmitter which was in all respects the mechanical equivalent of the transmitter of to-day. The only important difference being that he used platinum terminals where we to-day use carbon. (*b*) A receiver for transforming the electrical waves into sound waves similar to the original ones. These were connected to a galvanic battery circuit several hundred feet long, and sounds of many sorts were made at the transmitter and head by one at the receiver, and among these various sounds so transmitted and heard were vocal sounds of many kinds and articulated words. So much is a part of printed history. It has been disputed however, that he even transmitted speech, and here it is where the hedging begins, and it is evident that those interested have each a definition of the term "transmission of speech," that suits his view of the case. One party argues that speech was not transmitted unless all of the consecutive vibrations in a sentence of several words were heard so as to be understood by one who had no experience in listening to telephonic sounds. The other party thinks that if single words were transmitted and heard with the apparatus, no matter how it operated, that the speaking telephone was invented, and needed but improvement to perfect it. As Reis nowhere says that he could transmit anything but single words of speech, it is by some taken to mean that the transmission of single words is not the transmission of speech, and therefore Reis did not invent a speaking telephone. So much for Reis. It is asserted, and so far as I know, has never been contradicted by any one, that Yates, of Dublin, did transmit speech in the sense of consecutive words in 1866, with Reis's apparatus. The credibility of this is precisely the same as that of the relation of any events that happened years ago, say of the stories of the late war now being published for the first

Digitized by Google

time. Therefore if Reis did not invent the speaking telephone, Yates did. This is simply actual history and needs not the slightest defense.

2d. For the protection of inventors it is supposed to be necessary to subject history to a legal construction, so that if events which really happened were not published in certain ways, they are to be treated as if they had never happened. It is not argued here that such a course is always unwarrantable, but a *historian of events* who should construe history on such a basis would be contemptible. It is absurd to say that a given event did not happen in Europe, because it was incompatible with the laws of the United States that it should happen. One who did not go beyond the records of the courts in order to determine who invented say the electric telegraph or who discovered America, would be a very vealy historian.

3d. When the appeal was made from the original description of Ries's apparatus and its working, to the apparatus itself and what it can do now, the first objection that faced every one who attempted to work it was this. It is impossible for Reis's telephone to transmit speech because it works by makes and breaks in the current—a condition that may enable one to transmit pitch but not quality, which latter necessitates an unbroken circuit. Attention was therefore directed to the actual operation of the transmitter, to determine whether it did as a matter of fact work in the supposed way. When a magneto receiver is used with the Reis transmitter for the sake of observing the mode of action in the latter, it is found that the latter does in reality transmit all the peculiarities of speech, the current is the so-called undulatory one, but the speech is not loud enough for much service, and often breaks. Still one can hear a great deal that is said. When one has satisfied himself that Reis's transmitter can and does produce the proper undulatory current, he is directly informed that he is not using the transmitter as Reis instructed him to use it, and that he is not using Reis receiver at all. It is implied by the first statement that the transmitter *must work* in such a way as to break the current for every vibration; but such objectors need constant reminding that Reis's transmitter and every body else's transmitter, works *automatically* from necessity. Neither Reis nor anybody else did or can make it work in the way it is asserted Reis "intended" it to work. Reis did *intend* that it should so respond to every vibration of the membrane that every characteristic of sound should be reproduced by the current, and he made a device that would do it. Let me repeat for the benefit of every one interested in this matter that the transmitter is *an automatic device and is not subject to the intention of anybody while it is in operation.* As to the second statement that the receiver is not a Reis receiver. It is true enough that a Reis knitting needle receiver is not a very good receiver, it transforms into sound waves only a small proportion of the electric energy spent in it, but it is equally true and beyond dispute that precisely the same order of transformations takes place with it as with the magneto telephone, and that the knitting needle receiver is capable of receiving well, I know, for I have heard talking plainly from it ten feet away. Of course I had an improved transmitter that could handle a strong current. But the second transmitter of Reis, namely the electro-magnet with armature, is precisely the same kind of a thing and works as a receiver in precisely the same way as does Bell's 1876 receiver. I never have heard that disputed. Therefore when one utilizes such principles in his receiver as those of an electro-magnet he does use a Reis receiver and nothing else. I would ask, if any one really believes that by mounting an electro-magnet in a box for convenience of handling and to prevent the scattering of the sound waves produced by it, he is using different electrical or mechanical principles in his so-mounted instrument? Yet precisely that is implied when one says that by listening to a magneto telephone connected to a Reis transmitter, one is not using Reis's principles.

4th. Mr. Kintner says in his letter that there is no conclusive proof that any one has been able to transmit intelligible speech between two distant points with Reis's apparatus as a whole, such as would be acceptable in a court of equity in this country. As I have had not a little experience of that kind, I have somewhat to say as to the proposition. I once made some tests of the sort for a court trial, and in the tests some 50 words were transmitted with Reis's cubical box transmitter and his knitting needle receiver. The words were not consecutive, but at the time I was not aware that that was essential. I started with the expectation of showing that "words could be transmitted." The other side expected me to show that "speech could be transmitted" meaning by speech—sentences such as the readings from a newspaper, etc. The number of words spoken at the transmitter were counted and the number of words said to have been heard, and the ratio was supposed to show that no words were heard and that those which were thought to have been heard were only guessed at and not heard at all. As I said before some 50 words were heard at that trial, yet the court did pronounce it an "utter failure." Again, I once had three gentlemen call to see if I could make the "Reis telephone as a whole" talk so that they could hear it and understand it. Of course I was very desirous of making them hear it especially as one of them was a reporter for an important paper. Two of them had but little difficulty in hearing words and some short sentences, but the reporter could not hear a word, nothing but inarticulate sounds. I worked an hour or more with him and only succeeded in making him hear three or four words at the end of the time. I remember that he said he distinctly heard the word *transmitter* when he was not expecting it or any other word. Now if that word was spoken and heard with Reis telephone by an inexperienced person and at an unexpected moment, was speech transmitted or was it not? If he had left at the end of half an hour's trial he might fairly have said that he could not hear a word with it, but he would have no right to say that others could not hear, for as I have said both the others were able to hear not a little. I conclude that whether one hears or not depends quite often upon the delicacy of his hearing and his ability to separate articulate sounds from other sounds.

I also conclude that historically, either Reis or Yates invented the speaking telephone, and that legally, whether Reis invented it or not depends upon the definition given to what we call "speech."

A. E. DOLBEAR.

College Hill, Mass., Nov. 18th, 1887.

ELECTRICAL NEWS AND NOTES.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS AND THE NEW YORK ELECTRICAL SOCIETY.

JOINT MEETING OF NOV. 15, 1887.

THE meeting originally appointed for November 9th, having been adjourned on account of the sudden death of Mr. Sidney F. Shelbourne, the societies assembled November 15th.

The meeting was called to order at 8 P.M. by the president, Mr. T. Commerford Martin, in the rooms of the Society of Civil Engineers, 127 E. 23d street, New York.

The proceedings were as follows:—

The President—You are all, no doubt, aware of the sad circumstances which attended our last meeting, of which the present is the adjournment. Before we proceed, therefore, to the regular business of the meeting, I will ask the secretary, Mr. Pope, to present the resolutions which have been adopted by the Council of the Institute with regard to Mr. Shelbourne's death. It may be within the recollection of most of you that Mr. Shelbourne was from the earliest time associated with the Institute, and that during the last two or three years he had taken an active part in its work as a manager, giving his time and attention and legal ability freely to the service of the Institute. We miss him very greatly, and as a member of the council myself, I can only say that I have very often been greatly encouraged in the work that I would myself do for the Institute by seeing that which he was at all times willing to undertake in its behalf.

If the secretary is here, I will ask him to read the resolutions adopted by the council this evening.

The secretary then read the following resolutions:

Whereas, in the death, by accident, of Sidney F. Shelbourne, the American Institute of Electrical Engineers has sustained a severe loss,

Resolved, That we, the members of the Council of the Institute hereby record our deepest pain and grief at the sudden blow which has deprived the Institute of an active and unwearying manager, and ourselves of an associate ever prompt to render assistance in the regular work of the Institute, and to assume new duties and responsibilities in its behalf.

Resolved, That we specially recognize the value of Mr. Shelbourne's services in his revision, as a member of a committee, of the Institute's rules and regulations, a work performed with the utmost care, discrimination and success.

Resolved, That we express hereby our sense of the many estimable characteristics of our friend and associate, exhibited in his work as a manager of the Institute, his energy, his courtesy, and his persistence in what he deemed for the best interests of the body, and most likely to promote, through it, the welfare of the electrical profession.

Resolved, That these resolutions be spread on the minutes of the Council, and be printed in the Transactions of the Institute.

The President—At the joint meeting at the electrical exhibition, November 9th, a committee was appointed by Mr. Pendleton, the president of the New York Electrical Society and the chairman of the meeting, to draw up resolutions in connection with the untimely death of Mr. Shelbourne. The committee will now please report.

Mr. Hamblett read the following resolutions and moved their adoption:

Whereas, the members, in joint meeting, of the New York Electrical Society and the American Institute of Electrical Engineers, learning of the sudden death of their associate and comrade, Sidney F. Shelbourne, at the moment of their assembling, which, being communicated by the chairman, brought a resolution for immediate adjournment, in view of the calamity, and the appointment of a committee to draft resolutions appropriate as an expression of their grief at this loss, as well as a means of conveying a tribute to the memory of the deceased,

Digitized by Google

Resolved, That in recording the death of our valued associate, Sidney F. Shelbourne, we desire to pay a tribute to his personal worth and good qualities, as seen both in his friendly relationship with the society, and in his services as a member and officer of the Institute. We deeply regret and deplore the calamity of his untimely and accidental death, depriving us and the electrical profession of an earnest worker, always willing, upright, genial and considerate in his connection with us.

The resolutions were unanimously adopted.

The President—The resolutions will accordingly be entered in the Transactions of the Institute, and a copy will, as requested, be forwarded to the Electrical Society.

The subject before us this evening is one of the greatest interest, and will be presented to us by a gentleman whom we all recognize as foremost in his profession in this country. It deals in recent improvements in apparatus for ocean telegraphy, and I have great pleasure in requesting Mr. Cuttriss to proceed with the reading of his paper.

Mr. Cuttriss then read his paper on "Recent Improvements in Apparatus for Ocean Cabling." (See page 482.)

Mr. J. M. Pendleton here took the chair, and stated that Mr. Martin would read a paper contributed to the discussion by Mr. Thomas D. Lockwood.

Mr. Martin then read the following paper:

NOTE ON THE SIPHON RECORDER AND OCEAN TELEPHONY.

BY T. D. LOCKWOOD.

As some of you are aware, I was present at the time and place appointed for our meeting, to hear Mr Cuttriss explain and describe the improvements he has effected in the siphon recorder.

Although the unfortunate accident which we all deplore deprived us of the pleasure of hearing Mr. Cuttriss at that time, and myself perhaps for all time, still I congratulate myself that my visit to New York has at least given me a personal knowledge which I had never before possessed of that beautiful instrument, the siphon recorder. I have obtained a new illustration of the impossibility of obtaining an accurate knowledge of the construction and operation of a delicate piece of electrical apparatus from text-books. I had studied the siphon recorder in books, but found myself ignorant of it when the opportunity of examination at length presented itself.

It was especially gratifying to me to learn that we were to hear about an important branch of telegraphy, for I think that telegraphy has been of late neglected.

Though I yield to no man in my admiration for the immense recent amplification of the work of electricity, or in my appreciation of motors, lighting apparatus and heavy currents, I love variety, and have found it somewhat palling to read and hear as much about them as I have had to of late; for just as the human stomach quails at the idea of eating quail more than 40 meals in succession, so the human mind revolts at the notion of considering electrical currents due to an E. M. F. of 600 to 1,000 volts perpetually, and longs to demi-volt once in a while. Therefore I hailed with joy the announcement that we were to hear about the siphon recorder.

I learned that Mr. Cuttriss' recorder was operated by a permanent magnet instead of an electro-magnet. That is an advance which appeals strongly to me; and it means, as I look at it, a considerable diminution in the amount of attendance required. When I consider the number of telephones in use now, and reflect what a number of cells of battery would have been required had it not been discovered that permanent magnets could be utilized, and that the use of the battery was chiefly to make the magnetism, I cannot but appreciate that this is a material advance step.

Then let us look a little further; I understand from the text-books that on long cables it was found that if the siphon end were allowed to touch the paper, the freedom of its movements was interferred with, and that it was therefore found necessary to oppositely electrify the ink and the paper, the former being thus caused to issue and to mark the paper in a succession of fine dots.

If I understand the instrument of Mr. Cuttriss, it dispenses with this feature, which must have often marred the usefulness of the recorder, since on our eastern coast the atmosphere is usually rather "hygroscopic." I can well imagine occasions when all the ability of the operators and electricians must have been called into play to get the electrifying machine—the "mouse-mill," I believe, to work—in places and at times when the air was surcharged with moisture, and the "relative humidity," as the signal service calls it, was up in the nineties per cent.

It is interesting to note with Prescott, that while the telegraph of the United States, the Morse, which made its proud boast that it was a recorder, and by the way the first recorder has now almost totally been transformed into an acoustic or aural transient signal, the Cook and Wheatstone telegraphic idea, the visual semaphore, has evolved into the wonderfully delicate recorder before us.

I am also desirous of calling the attention of the Institute to the fact recorded in a letter of Mr. John Gott, dated St. Pierre, Miquelon, March 24th, 1887, to the Society of Telegraph Engineers, that the siphon recorder was capable of transmitting and reproducing speech telephonically, and that Mr. Gott had actually used it as a telephone. As I think this circumstance deserves a wider recognition, I will quote certain portions of the communication.

Mr. Gott says: "With the object of stimulating inquiry into the means of improving the telephone of Mr. Bell, which is the most beautiful adaptation of telegraphy ever made, I desire to draw attention to a few simple methods by which any one may satisfy himself of its practicability, for no one having witnessed its performance can fail to see a great future before it. The recorder of Sir William Thomson affords a ready means of speaking, and gives out such clear tones as to make the listener at first involuntarily look for the speaker behind the instrument (who may be miles away). It suffices to take a tube two inches in diameter, and stretch over one end a membrane of parchment or thin gutta-percha (the latter is less affected by the breath, the former becoming somewhat flaccid after a time). To the centre of the membrane cement a straw, and fix the tube in front of the instrument; about six inches from the movable coil, cement the other end of the straw to the coil at the point where the silk fibre is usually fixed; this is all that is necessary for both speaking and receiving. Six or eight cells on the electro-magnets suffice.

"A pair of these tubes may also be connected in a similar manner with the tongues of the two polarized relays. The tube is to be fixed in a convenient position at right angles to the tongue, taking care that the latter is free from its ordinary contact points. No battery is required for speaking with this arrangement. Or a pair of these speaking tubes may be connected with the ordinary armatures of any instrument or relay, and a current kept on the line.

"By these simple means may be demonstrated the possibility of speaking over many miles of telegraph line. The sound in the tube is not that of a whisper but of a voice at a distance; I have spoken through four knots of buried cable without sensible diminution of effect."

Since writing the foregoing it has been suggested to me that I might say a few words on the possibility, or possible practicability, of telephonic transmission over long submarine cables.

There is, I think, little to say on this head. You are all aware that in telegraphy it has been found possible to clear cables of charge by sending after each impulse of definite direction a clearing impulse of opposite direction, by which the static charge of the conductor was neutralized and the line cleared for the transmission of a second signal.

The first idea regarding the transmission of telephonic or voice currents over submarine cables is in favor of its practicability; for it may be argued, since the foregoing practice aids the transmission of telegraphic signals, and since telephonic currents, as usually transmitted, consist of a series of rapid alternations, why have we not here just the conditions of success.

The truth is, we have not. For in telephony the changes occurring are infinitely *too* rapid. They cannot serve the purpose of clearing the line; they rather serve the purpose of blocking the line, for the successive and consecutive impulses of opposing direction succeed one another so swiftly that they practically neutralize one another.

Take, for example, the magneto telephone. It is well known that the currents generated by this instrument when used as a transmitter are alternating, and follow one another with extreme rapidity; so that for a long time it was thought that they were so infinitesimal as to be immeasurable.

Suppose we have a fine galvanometer, and telephone through it. We see no deflection, but not because the current is so small, but because the plus currents succeed the minus currents of like potential and strength so fast that the needle cannot respond, and therefore does the next best thing and stays at zero.

Let us now consider the battery transmitter and induction coil. A moment's consideration will show us that we have a close analogue to the operation of the magneto telephone.

For though it is true that in the battery transmitter the action of the diaphragm merely varies the resistance of the circuit, and consequently the ratio, yet it is none the less true that the use of the induction coil develops currents in the secondary circuit and line which are alternating, because caused by the successive rise and fall of current in the primary circuit.

Consequently these currents are subject for long circuits of high capacity to the same drawbacks as those of the magneto telephone. We have then at present only one other alternative method, namely, the plan of including the battery and transmitter in the main line, and allowing the transmitter to vary a permanent current flowing in the main line, thus dispensing altogether with the coil. But this also is impracticable, because the very small proportion of variation in the total resistance of such a circuit cannot develop fluctuations of sufficient strength to satisfactorily influence a receiving instrument.

I am, therefore, convinced that electric telephony—that is, the transmission and reproduction of the human voice—will not, at least in the near future, be possible over long cables.

Digitized by Google

Electro-static induction and the retardation and prolongation resulting therefrom is the reason.

When I say *long* cables, I mean, for example, those over 100 miles long; and it would be difficult and not commercially successful over much shorter distances.

My conviction is that those who advertise the operation of telephones over Atlantic cables, either do not know what they are talking about, or, knowing, wilfully make misstatements for personal prospective gain. I am very sorry that I cannot be present to hear Mr. Cuttriss, and the discussion of the subject, but will certainly enjoy reading it afterwards.

The President—Gentlemen, you have heard the paper of Mr. Cuttriss, and Mr. Lockwood's somewhat informal comments thereon, and it is now open for discussion. I will take the opportunity of saying that should there be any gentlemen present who are not members of the Institute, we should be very glad to hear from them in case they wish to elicit any points or in case they may be able to give us information with regard to the subject now before us.

DISCUSSION.

Mr. Jos. Wetzler—I would be pleased to learn from Mr. Cuttriss what his experience has been in telephoning over cables.

Mr. Cuttriss—My experience in trying to telephone over cables commenced, I think, the same year, or at any rate the year after the telephone was brought out by Professor Bell. I was then at Duxbury. The late Mr. Gower, whom I presume most of you know of, came down there with the best telephones made up to that date, in order to try to speak over the Duxbury cable. He also brought down with him his electric harp, as he termed it, which was a series of reeds which could be struck by hammers the same as in a pianoforte. This would vibrate the contact points underneath the reeds, and send the same number of vibrations into the line to which the reed was tuned; and it was his desire to put that on the cable and have the superintendent, Mr. Gott, at St. Pierre, listen at the telephone for any sounds. He evidently, at that early time, appreciated the fact that it would be easier to get an intermittent current over a cable than it would be to get speech over it. We listened, and Mr. Gott reported nothing. He tried varying the power of the currents to the limits to which we allowed him to go, but still Mr. Gott reported that there was nothing. We then asked Mr. Gott at his end to send currents into the cable through condensers and also without condensers—intermittent currents. These were from a key. Nothing was heard; it was absolute death in the telephone. Mr. Gower would not believe, nor could we convince him, that the telephone was properly connected with the cable; so to prove it, I connected his telephone in circuit with the recorder, and got the party at the other end to send regular telegraphic signals into the cable. By this means they must come through the telephone, and on their way to earth also pass through the recorder. If the signals came we must see them. The consequence was that every signal came out written perfectly on the recorder, which we all read; but still it was death in the telephone—not a symptom of a sound. Still Mr. Gower was doubtful, and I did not know what to do. He did not like to doubt us, and yet we could see that he was doubtful. At last it struck me that I would put a rapid rheotome in the circuit with the telephone. Now, if there is any current coming over the cable at all, although it is infinitely weak when it arrives at the receiving station, this rapid make and break would vary it so much as to certainly make it audible in a telephone. The next time the signals were transmitted over the cable, the make and break being started, the room was filled with the sound of the pitch of the note that the make and break took, showing that the cable current was all the time passing through the telephone; but its wave was so slow and so even that although the diaphragm responded to everyone, it was totally beneath the capacity of any human ear to take the waves up and hear them as sound. Of course you will all readily understand that not sending more than probably one hundred signals in the circuit at the time, the vibrations coming in waves of that period would not be audible, because no ear can take up sound at that rate. That has been my experience. We have tried it over our cables here in New York for several parties, and we have also conducted experiments for Professor Moses G. Farmer, within the last year, over our Rockport cable, to see if we could get any sounds in that way, But in every case it is absolute death. The greatest distance through which I have heard signals on a telephone has been through about 75 miles of artificial cable.

The President—This cable subject is one that is not comparatively new to most of us in America, but somewhat unfamiliar. In America we have made so much progress in all the other departments of electrical application that we seem to have left that of cabling to our European—more particularly our British—brethren as a sort of consolation cup. (Laughter.) And they have certainly made remarkable progress in that field, and can in that respect and in that department set us an example. We have with us this evening one or two gentlemen who are quite prominently identified with some of these departments of work, and there is here one gentleman that, if I could induce him, I would like very much to address the meeting. He is not altogether a stranger in this city, and is certainly very well known to every one who has had anything to do with cabling. I refer to Captain Trott, of the cable repairing steamer "Minia," which happens to be in port at the present time. (Applause.) Captain Trott is a very reticent man, but if we could once get him started he would give us such a wealth of information that it would take a good deal of time to digest it.

Captain Trott—The president has intimated that Captain Trott is rather reticent. That is not altogether Captain Trott's fault. We belong to an old telegraph company, the oldest Atlantic company. We represent the first Atlantic cable company—that is, the Anglo-American. I am its representative here with you, and as such it is hardly open to me to say all that I know on submarine telegraphy. The branch of it before you here to-night is not a part of my subject. It belongs to the electrical part of it. My special duty is to lay and repair. I was connected first with the direct cable. I was in command of the ship on the laying of that cable, and also the French cable; but those gentlemen who were with us then are in opposition to us now. We are friends just the same, but I hardly think it right that we should give them all that we still have when they are fighting us. (Laughter.) As you will have inferred from the description of the recorder here to-night, submarine telegraphy is rather a dry subject, except our branch of it, which is very wet sometimes. It would take too long to go into all the details of our work. They are very difficult at times, and at other times we consider them tolerably easy. Of course, as you know, we have to do the fishing for these things at the bottom of the ocean, and we have played our part at that, and no matter what the gentlemen present may think of that branch of electricity, I am quite sure you will all admit they cannot do without it. If we stopped the Atlantic cables, why some considerable business would stop. Therefore you are to some extent depending on the telegraph cables. I thank you for the kind notice you have taken of me, and I beg you will excuse me from going into the matter of the operations, because it would take too long. I could not deal with it in such a manner, in the short time before us, as to make it anything like interesting. If any of you choose to come on board my ship, which is in the dry dock at the Erie Basin, we can show you some things there that perhaps you would be interested in. We have no secrets in that. We are prepared to show anything that we have there. There has been a great mystery made sometimes of submarine telegraphy, I think a little too much so, that only certain individuals should know anything about it. We look upon it as a thing that is pretty well known to-day, and therefore we have nothing, so far as we are concerned, either as a ship or a company, but what we are quite willing the world should look at there. (Applause.)

I, perhaps, might say one word on the question of telephoning on submarine cables. We did once put a telephone to the cable, I think, 83 miles from shore, and spoke through it and got conversation back. I think that is the utmost which was done. We have had singing through the cable at much greater distance, and they could tell on shore the songs that were sung on the ship, but there was nothing in the shape of conversation, I think, beyond that distance, to my knowledge.

Mr. S. S. Wheeler—How deep can you grapple a cable?

Captain Trott—2,600 fathoms is the deepest water that I have worked in.

Mr. R. W. Pope—We understood from Mr. Cuttriss that we were indebted to Mr. Ward for the progress made in introducing Morse on the cables. A great proportion of American electricians know something about Morse, and, of course, they are interested in knowing just what there has been done and what more there is a prospect of doing, and I presume that that point will be welcome if Mr. Ward could give us any further information upon it. I should, for one, be very glad to hear from him.

Mr. G. C. Ward—Mr. Cuttriss has told you as far as we have gone. We are working Morse on the Rockport cable. It was tried on the cable between St. Pierre and Cape Cod, but we found we could get no good results from it and it was abandoned. Since then nothing has been done on it, and the best results that have been obtained are, I believe, on this Rockport cable of ours between Canso and Rockport.

A Member—Would not Mr. Cuttriss kindly tell us something of the vibrator invented by Mr. Pescod, that has been in use for several years past?

Mr. Cuttriss—In reply to that I would say that I cannot say anything about that vibrator. I have never seen it, nor have I seen any drawing of the method. I have heard that he does it by vibrating the whole coil and siphon of a small Thomson recorder, in which the siphon is attached directly to the coil. He vibrates the whole thing so that he lifts the siphon a small distance off the surface of the paper. That, I believe, is what his invention is. Whether he has made any other improvement since I heard of it I do not know. I know that there is a counter claim between him and Mr. Dickenson, of Heart's Content. As to who is right in the matter I have no knowledge, and consequently I should not want to take ground one way or the other.

Digitized by Google

The method is the same as Mr. Dickenson's, practically, with the exception that Mr. Pescod vibrates the whole coil and siphon and Dickenson merely vibrates the siphon by pulling it with a silk fibre.

Mr. Ward—With regard to the Morse I should like to say that the relay is the invention of an American gentleman. You said that the Britishers were taking the steam out of the Americans in the matter of cables; but this Allen & Brown relay was invented by a Mr. Brown, formally associated with Mr. Edison in his automatic system. Mr. Allen is the financial part of the invention, sir. (Laughter.) So the Britishers will not take credit for that.

Mr. Wheeler—I think this question of telephoning through cables is so important that it ought not be passed over lightly, and I would like to ask Mr. Cuttriss to tell us something about what can be done to overcome the induction. I mean, has the effect of a complete metallic circuit been tried, and have there been any induction devices used?

Mr. Cuttriss—Until you can change the nature of a cable I don't think there is much hope of doing anything. Of course, metallic circuits have been tried. I do not know that you gain anything by them. In fact, if the two circuits are parallel for any distance I think that you would probably lose by them, for you are getting this whole reaction between the two parallel wires; that would act the same as a condenser, and there I must say that once, in talking over this matter with Mr. Edison, he told me that he did not believe it would be possible for us to speak from the corner of Wall street down to the Coney Island hut through our underground cable for that very reason. He said he thought all the current would be neutralized, so to speak, or short-circuited probably would be the better term, before it got down to Water street. In that he was wrong. I have spoken from Wall street down to Coney Island very recently, and in one case, where we had to open our cables to search for some trouble, at Flatbush (not half way to Coney Island), I spoke from the office to Flatbush direct quite easily; but found (after concluding my test through that part) that when we went over to the other end of the circuit which was looped through our Coney Island hut back to New York, so that we spoke through three times the circuit, part of which was laid double and parallel, it was as much as I could do to hear the voices. Whether that arose from any action between the two cores, or to what it was due, I have not been able to determine, nor have I had any opportunity for pursuing experiments in that line. I do not think that with long cables a metallic circuit is going to be of any help. Of course, a great deal depends upon where your circuit is. If you are in a straightaway country road, then I should say, as I before stated, that I think the straight line is the better; but if you are coming over the Brooklyn Bridge, then I should say you will do better to use a metallic circuit. Otherwise you get no speech at all on account of the induction from the other wires passing over the bridge.

Mr. Wheeler—Are we to understand from that, that a double wire would overcome the difficulty caused by the static capacity of the cable, but would bring up a greater difficulty, namely, self-induction between the two limbs of the circuit?

Mr. Cuttriss—I cannot say that I think the double circuit is going to overcome the static capacity at all. It cannot do it. The static capacity is still there. You would reduce your static capacity by using the two to about one-half. But at the same time you are doubling the resistance. Of course, with a telephone that would not amount to much, because it would go through the resistance very easily, but I think it would bring somewhat into play this effect of short circuiting across—the same as trying to talk through two parallel plates of a condenser. Of course this is all conjecture on my part, not having had a chance to try it. I think, if you were working over a good road, clear of outside induction, you would gain nothing by working in metallic circuit.

Mr. Pope—If I understand the gentleman correctly the capacity of the recorders as now operated is such that it does not appear to me that anything is to be gained by telephoning over a cable, excepting as a matter of experiment; that is, unless the telephone system was a great deal better than our local service I would much prefer a siphon recorder for accuracy in the transmission business. (Laughter.)

Mr. Cuttriss—On that point probably I could give a little light. The same day that Mr. Gower came down to Duxbury to try his electric harp, he stated what a wonderfully beautiful thing this was going to be to speak across the ocean. Well, having that trouble with the mirror between "M" and "N," "P" and "B," and other letters, we rather doubted it, but we thought we would put the thing to a trial. So he went up stairs with one telephone and we had the smartest of our clerks with a telephone down at the other end of the circuit. We took up with us what was then one of the most beautiful of cable messages, a "stoker." If a man could make anything out of the words of a "stoker" message he could understand almost anything. We told him to speak that message through his telephone, letter by letter, to the clerk down stairs, who should write it down, and then the clerk should repeat it back to Mr. Gower, who should also correct it from the copy. I think, if my memory serves me right, the message was something like a 40-word message. The clerk down stairs got over 80 errors. It was repeated back to Mr. Gower. There were two telephones in the circuit. Mr Gower was listening at one and another gentleman at the other, and Mr. Gower corrected, as he supposed, 40 of the errors: but there immediately arose a dispute between Mr. Gower and the other gentleman as to what certain letters were that were being sent. Now there were two people listening in the same circuit, and yet they could not agree as to what one letter was. So long as a telephone will not speak more clearly than that, through a room, you can imagine what it will be through cable service on a long cable.

Mr. Pope—That coincides with the early experience I had with the telephone. I was connected with the Western Union supply department, and I had occasion to inquire of that department about the shipment of three or four carboys of acid to Charleston, South Carolina. I got along with the whole business until the man at the other end attempted to tell me the name of the schooner by which it was shipped. It was a simple name—Mary Jane, or something of that kind. But of course there was no context to give me a clue as to what the words were. In other words, to telephone successfully you must have an inkling of the business that is to be transacted and who the person is who is sending it. I have had occasion once in a while to answer the inquiry, who is at the telephone, and before I could succeed in making the person understand that my name was Pope I would get disgusted and give it up. I presume that is one of the names that does not go through a telephone very well. That is one of the difficulties that I have always apprehended in connection with this proposition of telephoning commercial messages, and those who were most ardent in their advocacy of telephoning for commercial purposes were those who were not familiar with the facility with which a Morse operator can receive either proper nouns or cipher messages, or anything of that kind—and the same would apply to cable messages. Of course, most of us understand that the bulk of the business transmitted over the cables is in cipher, and I doubt whether it would be possible to carry on the cable business as it is to-day with the best working telephone line there is in existence. That is my opinion of it.

Mr. F. Bennett—I understand Mr. Cuttriss to say that the diaphragm of the telephone responded to the undulations of the current but not in rapid enough succession to be audible. Now, supposing this diaphragm had a needle on it such as there is on the phonograph, and that the cylinder, like that of the phonograph, was to be rotated at a given speed, and the undulations of the diaphragm repeated on the tinfoil of the phonograph, and after the message was sent let the cylinder be rotated at a more rapid pace. Would it not cause the undulations of speech to be reproduced so rapidly as to be audible to the human ear?

Mr. Cuttriss—In reply to this, I would say that it certainly would not be heard at the other end. There is no reason why the current controlled by the phonograph should be any stronger than one from any other source. The electrical harp that I speak of Mr. Gower's using was merely a rapidly interrupted circuit, according to any note that he struck. The harp contained about two octaves, and of course we had any range within those two octaves in which to try it, but no sound was got from it at all, and in that he used, I think, four cells of Leclanché and a powerful induction coil, the current from which was strong enough to give you a very disagreeable shock. So you can see if that would not go there would be no reason why anything from a phonograph would. It is exactly as Mr. Lockwood said in his paper: the currents are small, and go with such infinite rapidity that they are neutralized before they get to the other end. They are actually swamped, and that is the reason that you cannot get anything through. The receiving currents of course came through his instrument, because they came slowly, and were powerful enough to deflect his diaphragm. If we had a make and break on there it is possible we could have opened and broken the circuit from the diaphragm. Still, you can see why we could get no audible effect; for, the moment we began to increase our speed sufficiently to bring it up to that point we were sending the currents into the cable so rapidly that they were beginning to neutralize one another, and before we could get to the audible rate they were neutralized, probably, before they got twenty miles from the station.

Mr. Bennett—I think Mr. Cuttriss did not fully understand my meaning. We will take for illustration the old register that makes the dots and dashes on the paper. Of course we understand that that rotates at a given velocity, the same as it does in the phonograph. Now, supposing the cylinder on the phonograph were revolving the same as it does in the siphon recorder, it would cause the undulations, or the dots and dashes for instance, to make indentations on the tinfoil, and then by revolving the cylinder faster it would cause sharper vibrations in the diaphragm and therefore cause it to be more audible.

Mr. Cuttriss—Certainly, that would be so. But what advantage would you have from getting a sound in that way if it took you probably half an hour to get sufficient signals over the cable to move the diaphragm? That is, if it took you half an hour to get sufficient signals over the cable to be made audible through

Digitized by Google

the diaphragm, by rotating the cylinder afterwards rapidly, I do not see what gain you would derive, because your signals would have to come very slow to indent the tinfoil at all, and they would have to be reverse currents. You cannot send the same number of words over a cable per minute by reversals as you can by using what we term a mixed signal. The reversal has to be a change to one polarity from another; but in a mixed signal, as we term it, the same as in the letter "S" where it goes up with the wave, all you need is that wave and the length of the wave to show that three signals have gone. Therefore, the continuous sending of reversals through the cable does not increase the speed.

Mr. Pope—I would say before we close that these questions that have come up in regard to what can and what cannot be done over a cable can be looked at, I presume, from two different points, from the experimental point and from the commercial point. As matters of experiment they may be very interesting, but commercially we must remember that the cable is a very expensive affair; its service is expensive and it is necessary to utilize every moment of time. Consequently any system that is introduced must be an improvement in speed or an improvement by reason of doing away with these detentions and faults in apparatus which Mr. Cuttriss has brought to our attention in describing the older forms of instruments. As I understand it, the improvement has been in the continuity of the service rather than the speed; that is doing away with detentions caused by repeating back signals and also by failures of the apparatus.

PRIMARY BATTERIES.

The use of primary batteries for electric lighting purposes cannot be said to have met with success, and it is somewhat surprising that so many inventors are found applying their energies to this branch of electricity when there is better prospect of success in other directions. The number of primary batteries which have already been put before the public is legion, and a portion of these were dealt with recently, by Mr P. F. Nursey, before the Society of Engineers. On that occasion he described the batteries of Holmes & Burke, Ross, Coad, Lalande, Skrivanow, Upward, Pollak, Newton, D'Humy and Friedländer, and the "Regent," the "Union," and the "Eclipse" batteries. Mr. Nursey did not enter into any critical comparison of the merits or demerits of the batteries which he described, but impartially stated the claims of the various makers, leaving his audience to draw their own deductions, which proved, in the case of one speaker, to be that all were equally bad. The course adopted by Mr. Nursey, in view of the fact that the inventors or representatives of many of the systems described were present in the room, was an instance that discretion is the better part of valor, for when Mr. W. H. Preece, with his customary frankness, declared, during the discussion, that the batteries were nearly all equally unsuitable for ordinary domestic lighting, the dissent of many among the audience showed that this honest criticism, to which every practical electrician will readily agree, was but little relished by those interested in pushing particular batteries. But the hardest blow dealt against primary batteries was a speech by the representative of Lord Onslow. When this gentleman began his remarks the spirits of the battery owners rose with the expectation that something more favorable would be said about them, but they were doomed to disappointment. This speaker announced that Lord Onslow had adopted primary batteries for lighting his house, and that the makers had been very careful to point out how valuable the by-products were, and they also undertook to collect the same and keep the installation in order. At the present time the lights had gone out, and no one had come to collect the by-products. This account of the practice of primary batteries as contrasted with the grand theories contained in circulars and trade puffs, was not at all calculated to cheer those who had already been depressed by the utterances of Mr. Preece. Neither will the suggestion thrown out by Mr. Nursey, in his paper, bring relief. Mr. Nursey proposed that a committee should be organized, consisting of electricians, chemists, engineers, and commercial men, who would make it their business to test primary batteries to destruction, so that, as the author quaintly put it, the fittest may survive. We suspect that Mr. Nursey was quietly poking fun at the knights of the primary battery, or does he really think that there will be even one, among the whole number of batteries in the market, which will stand the ordeal of a practical test in the hands of an unbiased committee? The promoters of primary batteries have certainly up to the present not been without the means which should insure success to a really good invention. They have had command of sufficient funds to carry out experiments on the largest possible scale, and they have generally managed either to get a favorable opinion from some scientific man of high standing, or to construe an indifferent opinion into one of commendation, by a judicious selection from the reports of scientific men and journals. If, with these advantages, private enterprise is unable to develop a really practical battery, this aim will certainly not be attained by the committee suggested by Mr. Nursey. The reason why primary batteries fail, when applied to ordinary domestic lighting, is obvious. In the first place, they are less clean than a gas, hot air, or steam engine and dynamo; in the second place, they are more difficult to manage; and in the third place, the working expenses are incomparably higher. As long as we must burn zinc, iron, or any other metal in a battery to produce the current, competition against a dynamo driven by a heat engine is utterly hopeless. Where cost is not a consideration, such as for instance in miners' lamps and in the electric light installation of amateurs, batteries might with advantage be employed; but in the general domain of domestic electric lighting they have no chance whatever.—*Industries* (London).

THE COLOGNE ELECTRIC TRAMWAY.

The first trial trip which was recently made in Cologne with the new electric car of Messrs. Huber & Herebrand, of Ehrenfeld, was perfectly successful. The car is, in general principles, identical with those used in Hamburg, but certain details had to be altered in order to enable the machinery to develop greater power and overcome the difficulty of snow and ice on the road. Current is supplied by E. P. S. accumulators, which the firm manufacture under license from the English company. At the first trial trip everything went well, with the exception of the chain brake, which was found to be very unreliable. This circumstance did not, however, prevent the car from being operated in a most satisfactory manner, provision having been made for applying electricity as the brake power. The ordinary brushes on the motor are replaced by contact blocks pressed against the commutator by long springs, and to reverse the motion the position of these blocks need not be altered; it suffices to reverse the direction of the current through the armature. The controlling switch is so arranged that upon interrupting the current from the accumulators, the armature of the motor can be short circuited, by which means the motor begins to act as a generator, and to absorb power, thus bringing the car quickly to rest. If it is desired to stop in a still shorter time, the current from the accumulators is not interrupted on reversal, and the brake action of the motor becomes still more efficient. Even when used in this way, the sparking at the commutator was very trifling.—*Industries.*

PERSONAL MENTION.

Mr. Carl Hering.

It is a pleasure to record the appointment of Mr. Carl Hering, to the entire charge of the instruction in electrical engineering at the University of Pennsylvania. The instruction in this branch at present forms part of the course in mechanical engineering, but it will probably soon be made a separate and distinct department, in which the graduates will receive the degree of Electrical Engineer. The instruction at present embraces a general course in electrotechnics including the general principles, the principal applications, electrical computations, and practical work in the laboratory; the latter being limited chiefly to such work as would be required of a graduate in actual practice as an engineer.

The laboratory at present includes a small steam engine, several dynamos, storage batteries, and tangent and mirror galvanometers. Students are required to design, calculate and construct apparatus, to wire the laboratory, make specifications, and to calibrate instruments.

The rapid growth of this course at the university is due to the work of Professor Wm. D. Marks, of the department of mechanical engineering, who has, during the last few years, given special attention to instruction in electricity, and to the equipment of the laboratory.

Mr. Hering has achieved a well merited reputation among electricians. His services as assistant to Professor Houston in the arrangement and charge of the electrical exhibition at Philadelphia, in 1884, were signally successful. His various publications on electrical topics, well known to readers of this journal, evince talent and acquirements that ensure Mr. Hering's success in his new field of work.

OBITUARY.

Sidney F. Shelbourne.

Mr. Sidney Fortescue Shelbourne, whose sudden and apalling death by accident at the Electrical Exhibition on the evening of the 9th of November, has been fully noticed in the daily and weekly press, was widely known as a man of character and attainments. To those of our readers who may not have seen an account of the manner of his death, it may be well to state that while inspecting the Mather Electric Light plant at the Exhibition, Mr. Shelbourne fell against the fly-wheel of an engine driving the incandescent light dynamo—and was instantly killed.

Mr. Shelbourne was 51 years old. A graduate of Yale College, he was ordained as a clergyman in early life, and served some time as a chaplain in the army during the war of the rebellion. He

Digitized by Google

afterwards spent a period abroad, engaged in scientific studies. He also pursued a course of legal studies and became a member of the bar. During the few years just passed he had been chiefly engaged in projects for underground electric line construction. At the time of his death he was president of the New York Electric Lines Co., of which he was the originator and promoter. In the prosecution of this enterprise, though unsuccessful, Mr. Shelbourne exhibited remarkable persistence, pluck and courage.

As a member of the Council of the Institute of Electrical Engineers, Mr. Shelbourne was known to many of its members, and particularly to his colleagues of the council, as an earnest and faithful worker in all directions looking to the welfare of the Institute or the interests of electrical engineering. Reserved, but courteous in manner, and apparently seeking little personal intimacy, Mr. Shelbourne leaves upon those who knew him an impression of sturdy uprightness, fearless expression of honest conviction, and a strength of character that gave him courage and hope under many and great disappointments.

GAS AND ELECTRICITY IN EUROPE.

The chairman of the Imperial Continental Gas Association, being questioned at its half-yearly meeting as to the reasons the company had for undertaking the lighting by electricity of the Burg Theatre at Vienna, replied that there were special circumstances which rendered that course desirable. He did not state precisely what those circumstances were; but he furnished one reason, which he seems to have thought good enough to satisfy the dissentient English shareholders. This was that "if we can show our (electric lighting) competitors what the cost of an electric lighting station is, and what return it is likely to give, they will not be so ready to enter the field as they otherwise would be." A shrewd suspicion that this might be the ingenious motive of certain gas companies nearer home in seeking powers to supply the electric light, may have induced the board of trade some time ago to refuse their applications. We entertain no doubt that the gas companies will one day be glad to take up their competitor's business, not for the purpose of discrediting it but of working it for profit. Meanwhile, nobody will attach much value to their estimate of what an electric station ought to cost or what the profits are likely to be.—*The Electrician* (London).

ELECTRIC LIGHT AND POWER.

Anthony, Kan., has closed a contract with the Archer Electric Light Co., of Wichita, for a plant consisting of 300 incandescent and 10 arc lights to be put in immediately.

An American arc light plant is to be erected at Sydney, New South Wales, and 100 tons of appliances were shipped last week by steamer from New York.

The Heisler Electric Light Co. are now building all sizes of machines. Heretofore they only built the 150 dynamo; now the sizes are 150, 200, 300 and 400, 30 c. p. light.

The Westinghouse Electric Co. has been awarded the contract for lighting the senate chamber of the Capitol at Washington. This contract calls for 1,300 electric lights, which will include all candle-power from 9 to 16, 25, 50, 75, 100 and 150. The entire plant will be placed in the building, including the power, machinery and other essentials.

The Brush Electric Light Co., Louisville, Ky., will make extensive improvements to its plant.

E. M. Roberts will establish an electric light plant at Ashland, Ky.

The Knoxville Car Wheel Co., Knoxville, Tenn., will erect an electric light plant at its works.

The Norristown Electric Light and Power Co. will make improvements to its plant at Norristown, Pa.

The Fremont Electric Light and Power Co. will erect a plant at Fremont, Ohio.

W. G. Allen is interested in an electric light plant to be established at Dayton, Tenn.

The Westinghouse Electric Co. will install an electric light plant at Palmer, Mass.

The council of Kansas City, has granted a franchise to A. L. Ellis to construct electric light works.

The electric light plant and gas works of Arkansas City, Kas., are about completed. The dynamo for the electric light plant is set, the necessary building completed, and J. R. Strignell, an expert electrician, is superintending the work of getting the wires and machinery into good operating condition. There will be two sets of lights, one for all night and one for use until midnight. The mains and pipes of the gas works are laid and nearly everything at the gas works is ready for operation. It is the intention to turn on the electricity and gas at the same moment.

J. M. Shockley, representing the Western Electric Co., of Chicago, is in Concordia, Kas., overseeing the putting in of a new dynamo there in the electric light works, and making arrangements for running incandescent lights.

Lawrence, Kas., is now enjoying electric light, it having been turned on for the first time, last week. A score of electric lights are employed by the business men already, and the remaining 20 which the plant of the company enables it to furnish will soon be taken up.

The stockholders in the gas and electric light companies of Jefferson City, Mo., have organized into a new company, purchased both the gas and electric light plants, placed the capital at $100,000 and propose to expend $25,000 in the enlargement of the plants. The name of the new company is the Jefferson City Light, Heat and Power Co. The directors are as follows: Charles E. Hass, W. W. Wagner, H. C. Giesberg, J. C. Fisher, and Louis Schmidt.

An incandescent light system will be in operation in Lincoln, Neb., by Dec. 1st. The new machinery and fixtures are already being placed in position.

The Brush Electric Light Co., of Topeka, Kas., proposes to erect eight towers, furnish each with four 2,000 c. p. lights for the sum of $9,000 annually for five years.

Foreign.

England.—TRAIN LIGHTING.—There are three electrically lighted trains now running on the Great Northern Railway, and a fourth is almost completed, and will be at work before the end of the year. The South Eastern Railway Co. also has electrically lighted trains running as well as the Brighton company. The Great Northern trains so far fitted up are used on the suburban and underground service, where superior lighting is of the greatest importance. The carriages of these trains are not required to be separated, no matter what kind of light is used. The company, however, is prepared to electrically light trains from which carriages have to be detached, and to maintain the light in the separated carriages, which of course will carry their own storage batteries underneath. A large extension of train lighting by electricity is now being arranged for by this company.

Germany.—ELECTRIC LIGHT STATISTICS.—According to Dr. Schilling, the number of electric light installations in the 13 principal towns of Germany has increased during the last two years from 131 to 604; the number of arc lamps has increased from 591 to 3,280, and the number of incandescents from 10,403 to 50,469. The number of gas lamps in these 13 towns is 1,221,882, and therefore, lamp for lamp, electricity furnishes about four per cent. of the total illumination. In Munich this proportion is as high as eight per cent. According to another authority there are in Hamburg at the present time 78 installations of electric light; 325 arc lamps and 5,300 incandescents. About 1,000 h. p. is employed for these installations, of which one-fifth is furnished by gas engines.—*The Electrician* (London).

Switzerland.—The Winterthur correspondent of *Industries* states that the electric light is making great strides in Switzerland. Hotel-keepers and others interested in the prosperity of watering places have discovered that the electric light is almost a necessity if they would attract visitors, and as they are not wanting in enterprise, electrical engineers are kept well employed. The electric light was installed at the beginning of June in the large hotels in Engelberg, in various places in the Berner-Oberland on the lake of Lucerne, and also at Schaffhausen, where the fall of the Rhine is every night brilliantly illuminated with arc lights. In this case, the power is supplied from a turbine driven by the stream. In most places in Switzerland water-power is obtainable at a small initial expenditure, and this circumstance naturally facilitates the introduction of the electric light very considerably.

New Incorporations.

The Sturgis Gas and Electric Light Co., Sturgis, Mich. F. B. Ainger, and others, incorporators.

The American Illuminating and Power Co., Gouverneur, N. Y. Capital stock, $20,000. J. E. McMaster, and others, incorporators.

The Olean Electric Light & Power Co., Olean, N. Y. Capital stock, $25,000. W. M. Irish, and others, incorporators.

The Cauterskill Electric Light Co., Catskill, N. Y. Capital stock, $20,000. John H. Posson, and others, incorporators.

The Edwardsville Light and Power Co., Edwardsville, Ill. Capital stock, $10,000. Cyrus L. Cook, and others, incorporators.

The Gaynor Electric Light Co., Louisville, Ky. Capital stock, $20,000. T. T. Gaynor, and others, incorporators.

The Standard Electric Co., Louisville, Ky. Capital stock, $200,000. W. W. Hite, and others, incorporators.

The United States of America Arc and Incandescent Electric Light Co., Camden, N. J. Capital stock, $100,000. William Cohlman, Philadelphia, and others, incorporators.

The Sandusky Edison Electric Light and Power Co., Sandusky, O. Capital stock, $40,000. Henry Grafe, and others, incorporators.

The Oakland, Cal., Electric Light and Motor Co., has been incorporated. The directors or trustees are as follows: James Gamble, H. H. Watson, W. W. Blow, Thomas W. Cordor and Andrew Baird. The amount of capital stock authorized is $200,000. It is stated that the new corporation has taken steps toward securing the plant of the Pacific Coast Electrical Construction Co,

Digitized by Google

The Herrington Electric Light and Water Works Co., of Dickinson county, Kas., has been incorporated. The amount of the capital stock is given at $12,000. The list of directors is as follows: J. W. Creich, M. D. Herrington, E. T. Patton, T. J. Nair, C. N. Hull, F. Hartman, C. B. Kinney, S. G. Cooke and J. H. Bedson, all of Herrington.

The Salina Electric Light and Power Co., of Salina, Kas., has been incorporated. The amount of the authorized capital stock is $25,000. The following is the list of directors for the first year: William E. Geis, Joseph Suebert, George Kreuger, W. G. Gilbert, John Buchi, and J. F. Burrows, of Salina, and Henry Lehman, of Wichita.

TELEPHONE NOTES.

A telephone line is being established between Stockton and Tracey, San Joaquin county, Kas.

The St. Joseph (Mo.) Telephone Co. has added a new 50 number switch-board to its exchange, which gives the exchange a capacity of 650 subscribers. Enough applications are already on file at the superintendent's office to take every number of the new board and more. The company is now having a 1,200 drop multiple switch-board constructed by the Western Electric Co., in Chicago, which is expected to be position and in working order by the first of March next.

The Topeka Belt Railway Co., of Topeka, Kas., recently incorporated, proposes to run telegraph and telephone wires to nine suburban points from Topeka, and then to run one in a circle around Topeka, connecting these nine points directly.

South America.—THE TELEPHONE.—A new telephone company at Buenos Ayres has ordered from the Paris General Telephone Society the necessary material for a system comprising 2,000 subscribers, about to be established in that town. The same company have in hand a scheme for connecting the town with the outer harbor, by means of a telephone line. It is proposed to erect a small iron tower in the middle of the river to serve as a maritime station.

Austria.—A project of long standing concerning the management of telephone exchanges by the state has at last been carried out. The government offer to connect subscribers to central telephone exchanges in various towns and with the telegraph offices, in order to facilitate telephonic business, and also the transmission and receipt of telegrams by telephone. The charges are moderate, and in the majority of cases will not exceed 100 florins ($40 per annum). This change in the administration of telephones has been received very favorably by the present subscribers to the private telephone exchanges, who are all anxious to be connected with the state exchanges. As a consequence there has been a drop in the value of the shares of the private telephone companies.

ELECTRIC RAILWAYS IN AMERICA.

Now in Operation.

APPLETON, WIS.—Appleton Electric Street Railway; overhead conductor, 4½ miles, 5 motor cars. Van Depoele system.
ASBURY PARK, N. J.—Sea Shore Electric Railway; overhead conductors, 4 miles. Daft system.
BALTIMORE, MD.—Union Passenger Railway Co.; overhead conductor. Daft system.
BELLEVUE, PA.—½ mile.
BINGHAMTON, N. Y.—Washington Street and State Asylum Electric R. R.; overhead conductor, 5⅛ miles. Van Depoele system.
DENVER, COL.—Denver Tramway Co.; conduit, 4 miles. Short-Nesmith series system.
DETROIT, MICH.—Detroit Electric Railway Co.; overhead conductor, 2 miles, 4 motor cars. Van Depoele system. Highland Park Railway Co.; overhead conductors, 3 miles, 2 motor cars.
GRATIOT, MICH.—Gratiot Electric Railway Co.; overhead conductor, 1 motor car. Van Depoele system.
ITHACA, N. Y.—Ithaca Street Railway Co.; overhead conductor. Daft system.
KANSAS CITY, MO.—Kansas City Electric Railway Co. Henry system.
LIMA, O.—Lima Street Railway Motor and Power Co.; overhead conductor, 6½ miles, 7 motor cars. Van Depoele system.
LOS ANGELES, CAL.—Los Angeles Electric Railway Co.; overhead conductor, 5 miles, 4 motor cars. Daft system.
MANSFIELD, O.—Overhead conductors. Daft system.
MONTGOMERY, ALA.—Capital City Electric Street Railway Co.; overhead conductor, 11 miles, 20 motor cars. Van Depoele system.
PORT HURON, MICH.—Port Huron Electric Railway Co.; overhead conductors, 2¾ miles, 3 motor cars. Van Depoele system.
RICHMOND, VA.—Richmond Union Passenger Railway; overhead conductor. Sprague motors.
ST. CATHERINES, ONT.—Overhead Conductor, 6 miles. Van Depoele system.
SCRANTON, PA.—Scranton Suburban Railway Co.; overhead conductor, 2¾ miles, 3 motor cars. Van Depoele system.
WICHITA, KAN.—Wichita, Riverside and Suburban R. R. Co.; overhead conductor, 4 miles, 6 motor cars.
WINDSOR, CAN.—Windsor and Walkerville Electric Railway Co.; overhead conductor, 1¼ miles, 1 motor car. Van Depoele system.
WOONSOCKET, R. I.—Woonsocket St. Railway Co.; overhead conductors.

A trial trip has been made over the San Diego (Cal.) electric road, and it has proved a complete success. The road is 11 miles long and extends from the centre of the city to Pacific Beach.

THE WESTINGHOUSE, THOMSON-HOUSTON, SAWYER-MAN COMBINATION.

AN IMPORTANT ANNOUNCEMENT.

The union of interests effected by the Westinghouse and Thomson-Houston Electric Companies, noticed in THE ELECTRICIAN AND ELECTRICAL ENGINEER of October, has led to a further combination with the Consolidated and Sawyer-Man companies, which is announced in the following circular:—

NEW YORK, November 15th, 1887.

To the stockholders of the Consolidated Electric Light Co., and to the patrons of the Sawyer-Man Electric Co.:

GENTLEMEN:

The Consolidated Electric Light Co., owner of the Sawyer-Man patents, has, from time to time, received numerous applications for licenses to manufacture and sell the incandescent lamps, and other electrical apparatus covered by its patents, which applications it has been constrained to decline.

With the view, however, of utilizing the inventions of others who have achieved success in the electric lighting field, and at the same time of concentrating and enlarging its business to meet the constantly increasing demand for its apparatus, the Consolidated Electric Light Co. has recently completed the following important transactions, which are of interest to its stockholders and patrons.

First:—It has granted to the Thomson-Houston Electric Co. a license to manufacture and use incandescent electric lamps and attachments, in plants and stations established by that company in combination with its extensive and popular arc lighting system, upon an agreed royalty: and has also entered into a contract with that company, whereby the interests of both companies, in the manufacture and sale of electrical apparatus other than that covered by the Sawyer-Man patents, are mutually promoted.

Second:—It has purchased from the Westinghouse Electric Co. its valuable electric lamp factory and equipment at Pittsburgh, Pa., with a guaranteed capacity of 5,000 incandescent lamps per day; and has entered into an agreement with the Westinghouse company whereby the purchasers from that company of its alternating apparatus (the most economical and efficient for central station lighting), shall also purchase from the Consolidated Electric Light Co., the Sawyer-Man lamps and attachments, for use with such apparatus, and shall have the protection of the Sawyer-Man patents.

Third:—It has purchased the stock and assumed the control of the Sawyer-Man Electric Co., which has heretofore been its sole exclusive licensee, and will conduct its commercial department through the agency of the Sawyer-Man Electric Co.

Fourth:—It has purchased that valuable and extensive manufacturing and business property, Nos. 510 to 534 West 23d street, in the City of New York, having a front of 325 feet on said street with floor space of 117,000 square feet ready for use, and with a capacity for an increase to 200,000 square feet; being sufficient for the establishment, at that point, of its general offices, and of its principal legal, technical, manufacturing and commercial departments.

To meet the increasing business demands of the Westinghouse company, the Thomson-Houston company, the Sawyer-Man company and the general public, the Consolidated Electric Light Co. will, within a short time, manufacture at its combined factories, at least 10,000 electric lamps, with the necessary electrical attachments, per day; and this demand, based upon the reputation for excellence which these companies have attained, in their respective fields of usefulness, will greatly enhance the value of its property, and will promote the interests of incandescent electric lighting to an extent hitherto unknown.

Digitized by Google

This recognition of the Sawyer-Man patents, and consequent concentration of power in the Consolidated Electric Light Co., is attended with a corresponding ability, on the part of this company, to protect itself from infringement of its patents; and steps have recently been taken, in the institution of new suits against infringers, and in the vigorous prosecution of those heretofore instituted, which, it is believed, will speedily and effectually secure to the company the additional profits from that source to which it is justly entitled.

Very respectfully,
HUGH R. GARDEN,
Vice-President and Counsel.

MANUFACTURING AND TRADE NOTES.

THE WESTERN ELECTRIC CO., of Chicago and New York, have for some time been supplying a very effective fire alarm and guest call for hotels. At the recent fire in the Saratoga Hotel, which was supplied with their apparatus, the alarm was given from the office to the guests in their rooms "and many lives were saved thereby" the architect of the building says. Mr. J. L. Griswold, who has the same alarm system in his hotel at St. Louis, says: "Permit me to say that the system is working with admirable success, and is giving excellent satisfaction. I am much pleased with its introduction into my hotel."

THE SPRAGUE ELECTRIC RAILWAY AND MOTOR CO. is giving great attention to the transfer of power to considerable distance in the mining regions. In many instances abundant water power can be had at some miles distance which can not be directly transferred by aqueducts without enormous expense. The Sprague company is now prepared to install electric power plants in such places.

MR. JOHN J. HOGAN, Mechanical Engineer, 37 Centre street, New York, has prepared, copyrighted, and published a series of "Formulas for Steam and Water Heating Apparatus," which must prove extremely useful to all interested in the introduction of steam or water heating, and to owners of buildings, architects, and contractors.

These formulas supply an uniform method of specification which has been for a long time much needed. They are plain, simple and of practical utility. They facilitate the means of informing intending purchasers of warming apparatus as to the requirements of such systems, and save much time and trouble now incurred by the contractor in explanations. The formulas of Mr. Hogan are the first ever published for this class of work.

THE "C. & C." ELECTRIC MOTOR CO. have transferred their department of sales from the treasurer's office, No. 2 Wall street, to their factory, No. 90 South 5th avenue. This change has been made to facilitate the filling of orders, and that all correspondence may have prompt attention.

The company are now delivering automatic constant speed motors for incandescent circuits, and *safety* (shunt wound) motors for arc circuits, with the Wheeler regulator. This regulator is arranged to be operated by treadle or handle, and dispenses entirely with shunts or resistance boxes.

MESSRS. THOS. H. DALLETT & CO., Mechanical and Electrical Engineers of Philadelphia, have, we learn, devised and constructed a dynamo, which they intend to manufacture and put upon the market at an early day.

THE HARFORD ELECTRICAL CO., East Saginaw, Mich., are manufacturing and supplying a "Combined Clock and Automatic Guest Call" for use in hotels, apartment houses, etc. The company claim several points of superiority with simplicity of construction for their apparatus, and invite direct enquiries for information and estimates.

THE CALLENDER INSULATING AND WATER-PROOFING CO. are meeting with success in offering to electric light companies their Trinidad line-wire. The "Underwriters'" wire, to the defects and dangers of which general attention has now been drawn, has obviously had its day, and there is a demand on the part of prudent managers of electric lighting companies for a really insulated and safe line-wire. The Callender wire seems likely to take a prominent place among competitors. We are informed that the Thomson-Houston company have contracted with the Callender company for over 250 miles of Nos. 4 and 6 Trinidad line-wire for use in connection with their New York stations.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICIAN AND ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions, 11 Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Oct. 18th to Nov. 15th., 1887 (inclusive).

Alarms and Signals:—*Electric Alarm and Recorder for Oil-Presses*, E. W. Thompson, 371,640. *Electric Alarm Clock*, S. P. Meads, 371,696. *Electric Call or Signal Apparatus*, G. W. Foster, 371,752. *Fire Alarm Telegraph*, C. Burgher, 371,876, October 18. *Electrical Repeating Bell*, H. B. Cox, 372,057, November 8. *Alarm*, W. G. Joerke, 373,073. *Electric Bell*, G. M. Sternberg, 373,102, November 15.

Clocks:—*Clock-Synchronizing Apparatus*, C. J. Hexamer, 373,138, Nov. 15.

Conductors, Insulators, Supports and Systems:—*Conductor for Electric Wires*, J. Grant, 371,681. *Joint for Lead-Covered Cables*, R. S. Waring, 371,808, October 13. *Hauling-Through Conduit System*, J. F. Munsie, 371,-965. *Underground Electric Conductor*, H. Metzger, 372,078. *Railroad-Rail and Conduit for Electric Wires*, J. T. Nulty, 372,373, October 25. *Apparatus for Covering Insulated Electrical Conductors*, E. McKnight, 372,550, November 1. *Insulating Joint*, F. H. Soden and H. Goebst, 372,910, November 8. *Sectional Draw-Rod for Placing Electric Wires in Underground Conduits*, W. R. Hart, 373,289. *Electric Cable*, A. E. Dolbear, 373,394, November 15.

Distribution:—*Electrical Distribution and Charge of Secondary Batteries*, F. King, 371,893, October 18. *System of Electrical Distribution*, E. W. Rice, Jr., 372,330. *System of Electric Distribution for Alternating Currents*, E. Thomson, 372,501, November 1. *Electrical Distribution*, J. W. Howell, 372,797, 372,798, and 372,799. *Method of and Apparatus for Connecting Alternate Current Generators*, O. B. Shallenberger, 372,934. *Apparatus for Connecting Alternate Current Electric Generators*, same, 372,935. *Pressure-Indicating Apparatus and Circuit for a System of Electric Distribution*, same, 372,936. *System of Electrical Regulation*, W. Stanley, Jr., 372,-942. *System of Electrical Distribution and Conversion*, same, 372,943. *Method of Electrical Distribution and Conversion*, same, 372,944. *System of Electrical Distribution*, H. M. Byllesby, 373,009; G. Westinghouse, Jr., 373,035 and 373,037. *Automatic Circuit-Controlling Apparatus for Systems of Electrical Distribution*, same, 373,036. *Converter-Box*, Westinghouse, Byllesby, Shallenberger & Schmid, 373,038. *Electric Converter*, O. B. Shallenberger, 373,029, November 8.

Dynamos and Motors:—*Brush-Shifter for Dynamo-Electric Machines and Motors*, E. H. Amet, 371,536, October 18. *Regulator for Dynamo-Electric Machines*, C. E. L. Brown, 372,201. *Regulator for Electric Motors*, A. W. Meston, 372,231, October 25. *Dynamo-Electric Machine*, C. Batchelor, 372,-447, November 1; F. J. Sprague, 372,822. *Electric Motor*, same, 372,823; D. Higham, 372,910. *Dynamo-Electric Machine*, W. Stanley, Jr., 372,945. *Dynamo-Electric Machinery*, H. E. Walter, 373,034, November 8. *Electric Motor*, E. Thomson, 373,108. *Dynamo-Electric Machine and Electromotor*, W. Main, 373,145. *Electromotor and Dynamo-Electric Machine*, same, 373,-146. *Automatic Regulator for Dynamo-Electric Machines*, C. D. Jenney, 373,369, November 15.

Galvanic Batteries:—*Galvanic Battery*, J. T. Armstrong, 372,193, October 25; H. B. Cox, 372,658. *Carbon Battery*, C. H. Wilder, 372,734. *Galvanic Battery*, J. W. Howell, 373,021, November 8; C. Gassner, Jr., 373,064. *Battery-Jar*, C. A. Brown, 373,334, November 15.

Lamps and Appurtenances:—*Socket and Key for Incandescent Lamps*, J. J. Fisher, 371,570, October 18. *Governor for Incandescent Lights on Arc Circuits*, C. D. Baker, 371,915, October 25. *Incandescent Electric Light Bulb*, R. Haines, 372,313. *Lamp-Post and Lamp*, F. A. Sawyer, 372,334, November 1. *Regulator for Electric Lamps*, S. Mathias, 372,986, Nov. 8.

Measurement:—*Electric Meter*, R. N. Dyer, 371,559, October 18; H. M. Byllesby, 373,010, November 8. *Electric Dynamometer*, J. Cauderay, 372,358, November 1.

Medical and Surgical:—*Device for Indicating Life in Buried Persons*, C. Redl, 371,626. *Electric Forceps*, J. Brannan and W. E. Stone, 371,664, October 18. *Electro-Therapeutic Apparatus*, F. J. Kneuper, 372,808, November 8. *Electric Belt*, J. Williams, 372,647, November 1; G. S. Bennett, 373,044. *Therapeutic Battery*, M. A. Morehouse, 373,088. *Electrode for Forming Clots in Varicose Veins*, J. R. Hamilton, 373,399, November 15.

Metallurgical:—*Magnetic Separator*, J. Wenstrom, 373,211, November 15.

Miscellaneous:—*Anti-Induction Device*, J. Curran, 371,555. *Means for Preventing Induction on Electrical Conductors*, S. C. Drew, 371,557. *Electrical Registering Device*, A. S. Hobby, 371,583. *Electrical Indicator*, M. Waddell, 371,720. *Vibrating Rheotome*, J. R. Hard, 371,755. *Electric Circuit Connection*, S. Heffner and J. H. Phillips, 371,840. *Coin-Operated Electrical Weighing Scale*, E. R. Whitney, 371,869, October 18. *Rheostat*, J. Hartman, Jr., 371,937. *Electrical Communicating System*, A. G. Holcombe, 371,940. *Electric Current Indicator*, W. H. Markland, 371,958. *Electrical Resistance Board*, I. W. Colburn, 372,012. *Electrical Safe-Lock*, C. J. Kintner, 372,026, and 372,028. *Electro-Magnetic Safe-Lock*, same, 372,027. *Electrical Combination Lock*, same, 372,029. *Electrical Primer*, G. Stuart, 372,046. *Coin-Operated Induction Coil*, W. Oliver, 372,168. *Electric Valve Controller*, S. W. and W. V. Dermitt, 372,208, October 25. *Electric Regulator for Hydraulic Elevator Systems*, L. Daft, 372,361. *Apparatus for Transmitting and Receiving Electrical Signals*, M. Deprez and B. Abdank-Abakanowicz, 372,404. *Machine for the Manufacture of Wire Spirals*, F. Mallet-Guy, 372,423. *Coin-Operated Induction Coil*, P. G. Williams and A. W. Roovers, 372,441. *Sewerage System for Buildings*, C. H. Shepherd, 372,494. *Coupling for Wires and Bands*, C. E. Tafflinger, 372,579. *Coupling for Electric or other Wires*, F. S. Pond, 372,637, November 1. *Process of Making Electric Gold Pictures*, A. W. and E. M. Tucker, 372,720. *Electrical Pumping Apparatus*, F. J. Sprague, 372,824. *Electrical Current Indicator*, J. F. Kelly, 372,851. *Resistance Regulator for Electric Currents*, G. Montanus, 372,860. *Electric Firing Mechanism, for Guns and Shells*, W. W. Bradley and J. R. Holroyd, 372,958, November 8. *Electric Temperature Regulator*, L. F. Easton, 373,061. *Electric Valve Controller*, G. M. Sternberg, 373,103 and 373,104. *Mail-Box Indicator*, J. F. Tirrell, 373,207, November 15.

Railways and Appliances:—*Electro-Magnetic Brake Apparatus*, G. T. Woods, 371,655. *Railway Signal*, E. M. Chase, 371,670, October 18. *Electric Railway*, J. Hartman, Jr., 371,936, October 25. *Circuit System for Electric Brakes*, G. F. Card, 372,598. *Coupling for Electric Brakes*, same, 372,599, November 1. *Railway Signal*, F. Pearce, 372,865, November 8. *Electrical Railway*, B. Bidwell, 373,046. *Electric Train Signal Apparatus*, J. C. Tiffany and J. R. DeMier, 373,160, November 15.

Storage Batteries:—*Secondary Battery*, C. Hering, 372,468, November 1.

Telegraphs:—*Automatic and Autographic Telegraphy*, C. Selden, 371,980. *Telegraph Key and Sounder*, G. M. Lane, 372,155. *Autographic Telegraphy*, J. E.
